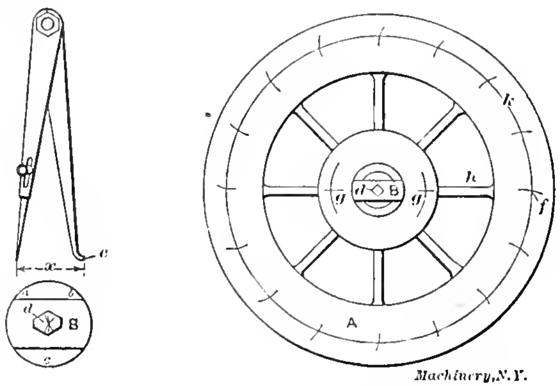
Supplement to MACHINERY, September, 1909

Operations for the Article in this number entitled "Machine Shop Practice—Laying out Work—II"

SHOP OPERATION SHEET NO. 109.

Oscar E. Perrigo. MACHINERY, September, 1909.



To Lay Out a Cylinder Head for Drilling

NOTE.—The crank-end head is taken as an example, and the holes are to be laid out for the studs by which it is secured to the cylinder, the studs by which the stuffing-box gland is adjusted and secured, and the holes for the set-screws for use in removing the head. The laying out is to be done entirely by hand.

1. Across the central hole of the cylinder head *A*, fit the brass piece *B* tightly. Force it down until its top is level with the surface of the stuffing-box boss.

2. With a pair of hermaphrodite calipers set to a distance *x* equal to about half the diameter of the hole, and with one leg located successively at the points *a*, *b*, *c* at the sides of the hole, scribe arcs cutting each other near the center. At the intersection of these arcs make a light center-punch mark. Set the pointed leg of the calipers in the center *d* and test its accuracy by swinging the leg *e* around to different points in the bore. If the center is correct the calipers will touch the bore (near the top) at all points.

3. With dividers set to one-half the diameter of the circle *k*, for the stud-hole centers, scribe this circle lightly on the surface. In the same manner scribe the circle for the gland studs *g*, *g*.

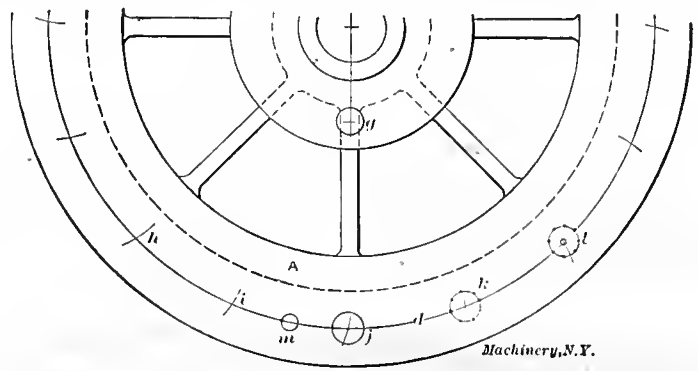
4. With a center square and scriber locate the hole *f*, opposite the center of one of the ribs *h*. As there are to be sixteen cylinder stud holes in the head, set a pair of dividers to about one-sixteenth the circumference of the circle *k*, and then "walk" the dividers around the circle to ascertain if they are correctly set. When they divide the circle into sixteen equal divisions scribe arcs as shown.

5. With a scale and scriber locate the holes *g*, *g*, exactly opposite the center *d* and at such points that when the cylinder head is in place they will be in a horizontal line.

NOTE.—To divide a circle into a given number of equal parts, particularly when the required number of divisions is large, is often a tedious and time-consuming operation. By the use of a table such as the one found in MACHINERY'S Data Sheet for February, 1903, the dividers may be set to the correct distance without any preliminary trials.

SHOP OPERATION SHEET NO. 110.

Oscar E. Perrigo. MACHINERY, September, 1909.



To Lay Out a Cylinder Head for Drilling

NOTE.—The centers of the holes to be drilled have been located in the previous operation by short lines scribed by dividers across the stud-circle at the proper points as determined by the spacing of the cylinder studs, as at *h*.

1. With a well-ground prick-punch having a point with an angle of somewhat less than 60 degrees, prick-punch each of these intersections.

2. Set the dividers carefully to half the diameter of the holes to be drilled. At each prick-punch mark scribe circles plainly, as at *j*.

NOTE.—In order that lines which are scribed on metal surfaces will be plainly visible, the surfaces are first coated with some suitable preparation. Chalk or a mixture of whiting and alcohol are often used for rough surfaces, while finished parts can be prepared either by rubbing them with a piece of moistened sulphate of copper (blue stone) or by applying a solution of the same substance. When sulphate of copper is used, all oil should first be removed from the surface to which it is to be applied. The thin film of copper which is then deposited will make all lines show plainly because of the difference in color between the copper and the iron or steel.

3. At nearly equal intervals, lightly prick-punch eight points on the circle for each hole, as at *k*.

4. Enlarge the center prick-punch mark by a heavy blow of the hammer, so as to furnish a better starting point for the drill, as at *l*. After each hole in the circle has been finished, as at *l*, mark the holes *g* in the same manner.

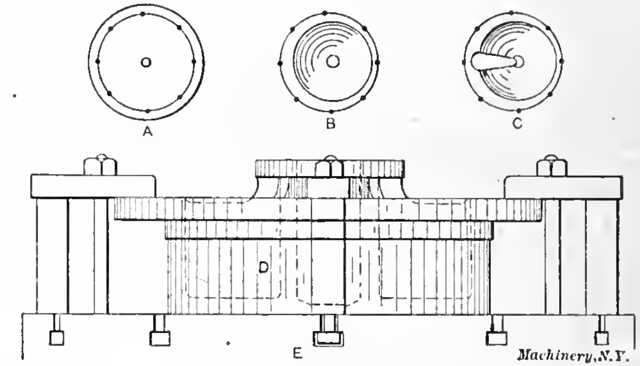
5. On opposite sides of the center of the cylinder head and equidistant between the stud holes of the outer circle, lay out two holes *m*.

NOTE.—The holes on the outer circle are for the fixed studs which secure the head to the cylinder. The holes *g* are for the stuffing-box gland studs. The holes *m* are for set-screws which are used to start the head when it is to be removed.

Where it is necessary to lay out the holes in a cylinder head or other part quite frequently, a thin metal templet is sometimes made with the holes properly located in it so that when it is laid upon the work the holes can easily and quickly be transferred by the use of a scriber.

SHOP OPERATION SHEET NO. 111.

Oscar E. Perrigo. MACHINERY, September, 1909.



To Drill the Holes in a Cylinder Head.

NOTE.—The centers of the holes to be drilled should have been laid out as described in the previous sheet, and circles equal in diameter to the holes scribed, each of these circles being marked by eight prick-punch marks. The center prick-punch mark should also have been made deeper and larger for conveniently starting the drill.

1. Upon the table *E* of an upright drill-press, place the cylinder head casting *D*, and clamp it firmly with the straps and bolts as shown. Locate the straps between the holes to be drilled so as not to interfere with the drilling operations.

2. Place in the drill-holder a twist drill of the diameter of the holes given on the drawing.

3. Adjust the work until one of the circles indicating the position of a hole is in position under the drill and start the hole. When the drill has cut nearly to its full diameter, raise it and note if it has cut concentric with the prick-punched circle. Usually the drill will "run" to one side, as indicated at *B*. It will then be necessary to chip a slight radial slot with a round-pointed chisel on the side where the prick-punched circle is furtherest from the drilled spotting, as shown at *C*. Start the drill again and note the effect. Repeat this operation until the drill cuts exactly to the circle. Throw in the power feed and continue the drilling until the hole is entirely through the piece.

NOTE.—It is the practice in some shops, when laying out work, to scribe, in addition to the lines indicating the location of a hole or finished surface, other lines concentric with or parallel to the first, as the case may be, as shown at *A*. These are known as "witness" lines and act as a check upon the accuracy of the finished work.

4. Change the position of the work by swinging the arm supporting the drill table, and by rotating the table as may be necessary, and successively drill all the holes of the outer circle as described in Step 3.

5. Replace the drill by one of suitable diameter, and drill the set-screw holes *m*, as described in Step 3.

6. Again replace the drill by one of suitable diameter and drill the stuffing-box stud holes *g*.

I.—CAPACITIES OF HOT WATER MAINS

Capacities of Hot Water Mains.

The curves in diagrams I, II, and III give the size of mains for hot water gravity circulation and forced circulation when the gallons of water per minute and the head in feet are known. To find the gallons per minute use equation: $G_1 = \frac{E \times H}{8.3 \times (T-T_1) \times 60}$ *in which* G_1 *= gallons per minute, E = efficiency of radiating surface (170 for direct, 400 for indirect, and 1000 for hot blast heating), H = square feet of heating surface, T = initial temperature of water (commonly 180 degrees F.),* T_1 *= final temperature of water (commonly 160 degrees F.), The head to produce flow is found from the equation: H = D x h x 0.000365 in which H = head, in feet producing flow, D = difference in temperature between supply and return, h = height or elevation of the heating surface above the boiler.*

Capacities of Pipes at Different Velocities of Flow.

Velocity, feet per second	Gallons discharged per minute						
	2" pipe	3" pipe	4" pipe	5" pipe	6" pipe	7" pipe	8" pipe
3	29	66	117	184	264	360	470
4	39	88	157	245	352	480	627
5	49	110	196	306	440	600	783
6	59	132	236	367	528	719	940
7	68	154	275	428	616	839	1097
8	78	176	314	490	706	959	1253
9	88	198	352	551	794	1079	1410
10	98	220	391	612	882	1199	1567

When the radiation is all on the same floor h equals vertical distance between center of radiators and center of boiler. If radiation is equally distributed on several floors it may be taken as though located on the central floor. If unequally distributed, the average elevation is found by the equation: $h = \frac{A \times h_A + B \times h_B + C \times h_C}{A+B+C}$ *in which A, B, and C equal square feet of radiation on the several floors,* h_A, h_B, *and* h_C *equal corresponding elevations of radiators on the several floors.*

In all cases the capacities are for pipe lengths of 100 feet. If the run of pipe is 200 feet, for instance, the available head for this length will be divided by 2 before the size of pipe can be found from the diagrams.

September, 1909

CHAPTERS IN THE EARLY HISTORY OF MACHINE TOOLS*—1

JOSEPH HORNER†

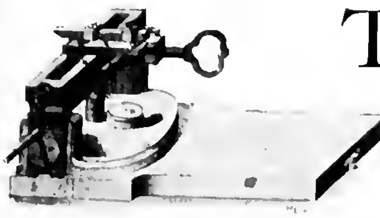

Fig. 1. French Lathe Slide-rest, 1772

THE first machine tools were the drills and the lathes, the first named being the descendants of the ancient fire drills of the archaeologists, and the second derived from the reciprocating cord-driven lathes. The drill dates from neolithic times, and the crude lathe in the form of the potter's wheel is as old, but the origin of the horizontal lathe is unknown, though its home appears to have been in Asia. The drill and the lathe were merely hand operated tools until the latter part of the eighteenth century, at which period two events occurred that were fraught with immense results. One was the placing of the steam engine on a practical basis by James Watt, the second the development of the slide-rest by Henry Maudslay. The first supplied a source of power, and the second embodied the mechanical guide principle in place of that of the human hand, which being rendered self-acting, and operated by power, has become the most essential element in all the later machine tools besides the lathes in which it had its origin.

Before the invention of the planing machine, the lathe was the only engineer's machine tool in existence, unless we except rude drill presses, and trip and helve hammers. All machine operations performed then were of necessity done in the lathe, just as they might have been done to-day but for the subsequent invention of the machines derived from the lathe and planing machine. The lathe has been the parent of the boring mill, of the bolt cutter, and of dozens of special lathes large and small. From the planing machine have been developed the slotter and the shaper, and reciprocating tool arms in their numerous forms, so that the lathe, the drill and the planer are the cardinal types of modern machine tools.

Somewhat over 100 years ago (1791) there was but one English slide-rest in existence. It was in Joseph Bramah's shop, and was invented by Henry Maudslay. That plain tool carriage, "Maudslay's go-cart," has influenced the world's history far more than the great French revolution, then in its most terrible throes. That slide-rest was like no other made before or since, and it could only have been suitable for the very shortest, lightest pieces of work. It formed a part of the back poppet, on the base of which it was mounted. A frame carried a long tool bar, sliding horizontally in ways at the front of the poppet mandrel, operated by a long screw and handle, and of course overhanging a good deal to reach the work. It was provided with cross traverse, and a swivel base. But it marked an advance over the hand work, and was a link in the history of progress, though inferior to the French slide-rests of 1772 and earlier, with which apparently neither Maudslay nor Bramah were acquainted. Maudslay commenced business in 1797 on his own account, and made a slide-rest for his own shop which was in use at the beginning of the nineteenth century. He separated the rest from the poppet, retaining the three movements, but clamping the base to the triangular bar bed. One of the first great works in which its utility was demonstrated was in the manufacture of Brunel's block making machinery, begun in 1808. His works at Lambeth became a training school for engineers, and it is significant that some of the greatest mechanicians of the first half of the nineteenth century received their training there under Maudslay. In that school, and under such a master, Nasmyth, Whitworth, Roberts, and Muir learned their craft, and these with others improved and extended the applications of the sliding tool holder. Previous to the application by these men of the slide-rest principle to other classes of machines, nearly all work that is now done in these machines was performed either in the lathe or by hand.

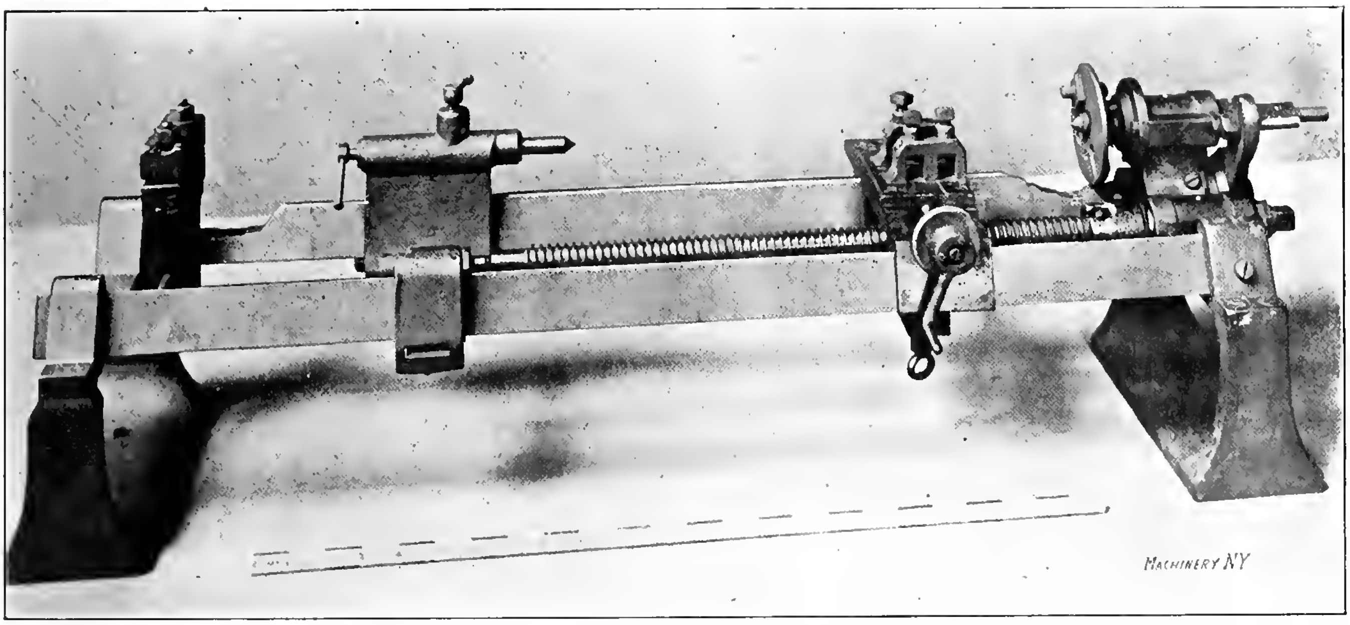

Fig. 2. Maudslay Screw-cutting Lathe, Latter Part of Eighteenth Century, South Kensington Museum

But the mechanical guide, though invented and developed by Maudslay, had been in use by French opticians more than a hundred years previously, and slide-rests had been illustrated in French works. Very curious they appear to us now. In the tenth volume of plates of the French Encyclopedia (1772) several slide-rests are shown. In these, as in Maudslay's, the saddle was clamped upon the lathe bed. The tool could be operated within the limit of range of the sli[illegible] only,

* For previous articles on early machine shops and development of machine tools, see "Chronology of the Nineteenth Century," December, 1900; "Early Machine Shops and Mechanics," October, 1902; "Talk on Lathe Spindles," by F. Emerson, May, 1904.

† Address: 15 Sydney Building, Bath, England.

and also, to a limited extent, for surfacing. Provision was made for elevating the tool point, by means of a screw, which on being turned, lifted the horizontal slide which carried the tool holder. It was capable of a swiveling movement. The construction was much simpler than that of Maudslay's. The bed or saddle, being flat, was bolted to the lathe. The swiveling plate was clamped to this by means of a single screw. The plate carried two uprights or horns recessed to receive legs from the horizontal slide. The slide carried the tool holder. The swiveling plate carried the elevating screw, and the horizontal slide the traversing screw, and the tool holder was moved by the surfacing screw. This must have been an unsteady structure. One of these slide-rests is shown in Fig. 1. The broad base has a T-groove, seen in the end, to receive the bolt which holds it to the bed. Upon this base a swiveling plate is mounted, which has two grooved horns on which the slide is carried by its horns, thus making of it an elevating rest. It is raised and lowered by a screw which has tommy-holes by which it is turned. Screws are provided for locking the slide after adjustment. The tool rest is traversed along the slide by a plain block fitting therein, by means of the screw and handle shown. The cross feed screw, which fits in a nut at the front of the slide, is capable of drawing the tool slide backwards as well as forwards.

Maudslay made a lathe previous to 1800 which was wholly self-acting for screw cutting and sliding, Fig. 2, now in South Kensington Museum. He put the change wheels at the rear of the headstock (not mounted in the illustration), and thence traversed the slide-rest through the medium of a lead-screw and split clasp nut on the under side of the saddle, the screw being carried down the center of the bed. The screw could be used also for sliding. The bed, instead of being a single bar of triangular section, comprised two such bars, secured at their ends in brackets bolted to standards. The headstock and poppet fitted on one bar only, but the slide-rest spanned both of them. The slide-rest was of gun-metal, the remainder of iron.

Another lathe of the same date, about 1800, also at South Kensington, was of a special character for cutting the fine threads for optical work. It may be mentioned that much of Maudslay's work was done in collaboration with the leading optical instrument makers of the time, who anticipated the engineers in screw cutting and gear cutting. The lathe bed, Fig. 3, is made of three bars, two of which carry the headstock and poppet, while the carriage of the rest is supported on all three. The screw to be cut is carried between centers, as seen. The lead-screw is just visible, being situated low down in the bed, and the sliding carriage is connected with it by a split nut adjustable from below. A stay at the back of the carriage steadies the work. A handwheel at the front has its edge graduated for the exact adjustment of the depth of cut. The lead-screw has 30 threads to the inch. It carries a wheel of 24 teeth which gears through an intermediate with one of 45 teeth on the lathe axis. Twenty-eight change gears are provided, ranging from 15 to 50 teeth. The intermediate wheel, as seen, has a wide face and is carried on a swinging adjustable arm to connect gears of various diameters with those on the fixed centers. A collection of threading tools is seen in a tray in front of the lathe, both single pointed ones and chasers being represented. Some samples of screws are seen in the rack in front. There is also a wide jawed caliper, looking like pincers, for measuring the diameters of screws. The long legs of the calipers are proportioned to increase the reading in the proportion of four to one.

Later, Maudslay made lathes for other firms, which save for their rather skeleton-like appearance were much like many which have been in operation until within the present generation—beds with flat ways, the hand slide-rest with three movements, the hand T-rests, the boring plate steady, and the back gear. The latter was not like that at present used, but was driven independently from a three-stepped cone on the back gear spindle, this being independent of the stepped cones on the mandrel. The back gear was put into engagement by a sliding pinion which then engaged with a wheel on the mandrel cones. It was therefore a single back gear only. There were several developments in back gears before they assumed the present form.

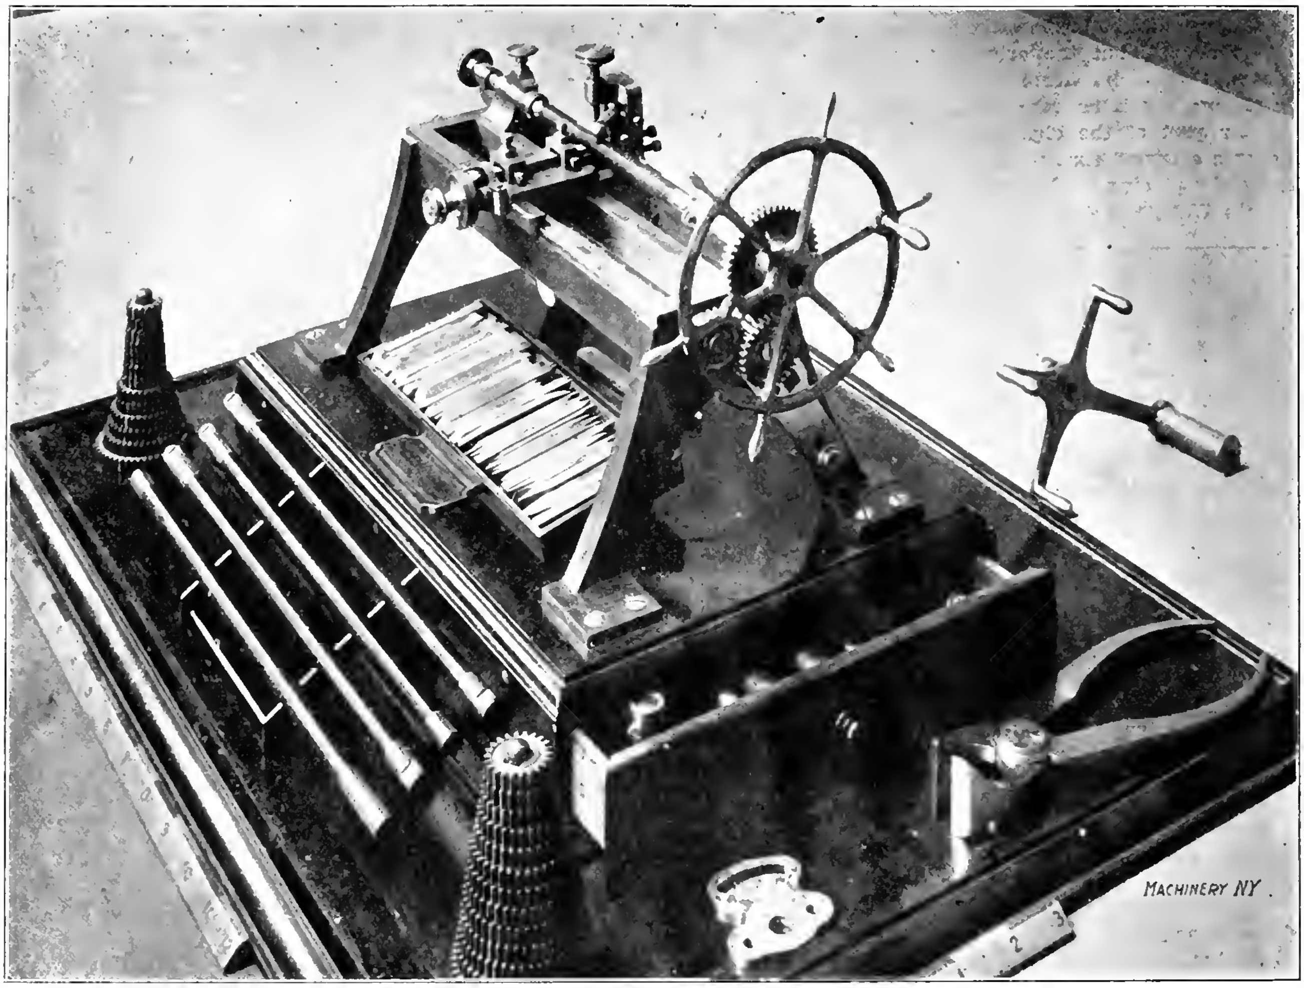

Fig. 3. Maudslay Screw-cutting Lathe, about 1800, South Kensington Museum

Nasmyth has illustrated an early method of screw cutting in the lathe, in which change wheels were placed, one on the work, the other on the end of the longitudinal feed screw of the slide-rest.

The earliest lathes were of dead center type, a principle which survives in watchmaker's turns, axle turning lathes, and in cylindrical grinding machines. The rotation of the work was at first effected by a cord, which survived in the fiddle drill, followed by a spring pole and cord operated from a treadle. The bow can be traced in works published in 1568-1569. Moxon shows it in 1703, and Bergeron in 1792. It is also illustrated in the French Encyclopedia under date 1772. The movement was necessarily one of reciprocation. But the wheel driven lathe was also in existence, and illustrated in 1624, 1677, 1701; and in the French Encyclopedia, combination lathes were in use, employing either bow or wheel.

The development of the running mandrel was slow. The first occurs in 1568. The earliest were of wood, followed by those of iron running in wooden collars, whence the traversing mandrel for cutting screws was developed, with divided bearings of lead or tin cast in dovetailed recesses in the head. The crude lathe heads passed through many stages of development, as did also the loose poppets. The beds, originally of wood, their faces protected later with iron plates, came to be made as triangular bars of wrought iron, or as separate bearers of cast iron. To this period, about the beginning of the nineteenth century, is traceable the veed edges which survive to-day. Afterwards these were cast together with ends. The writer well remembers as an apprentice some old lathes of this kind still at work, driven with ropes on veed pulleys, though of 8-inch or 10-inch centers, and old men of between 70 and 80 operating them, often using heel tools, though slide-rests were fitted.

The modern machine shop owes its existence to the development of the steam engine by Watt. The second Soho Foundry, started in 1795, was probably the first shop in which machine tools other than the lathe were constructed, and employed on an extensive scale. Many of these tools were recently still in existence—venerable relics, more than a century old. At that early period a notable feature was the massiveness of the machines which were designed and constructed, necessarily capable of dealing with the large pumping and marine engines of the later years of the eighteenth century and the early years of the nineteenth century. One of the old double geared face lathes at Soho would take a diameter of 26 feet and a width of 12 feet from the faceplate. It had back gears, the driving taking place on an internal spur ring bolted to the back of the faceplate. It had also five slide-rests, rendered self-acting by means of chain and ratchet feed actuated from the mandrel through an overhead. Some of the old lathes at Soho were like the modern break lathes, having a transverse bed on longitudinal bases.

A heavy faceplate at Soho was driven by worm gear, double threaded, the wheel being a mortise with cogs of 2 inches pitch and 6 inches length of face. The worm was driven by a four-stepped cone. A pit in front of the faceplate took large work, and a massive slide rest opposite it was power-driven from a shaft overhead, belted from the lathe mandrel. At that time square threaded screws were cut with chisel and file by hand, and specimens of these, 2 inches diameter and 10 feet long, were recently in existence.

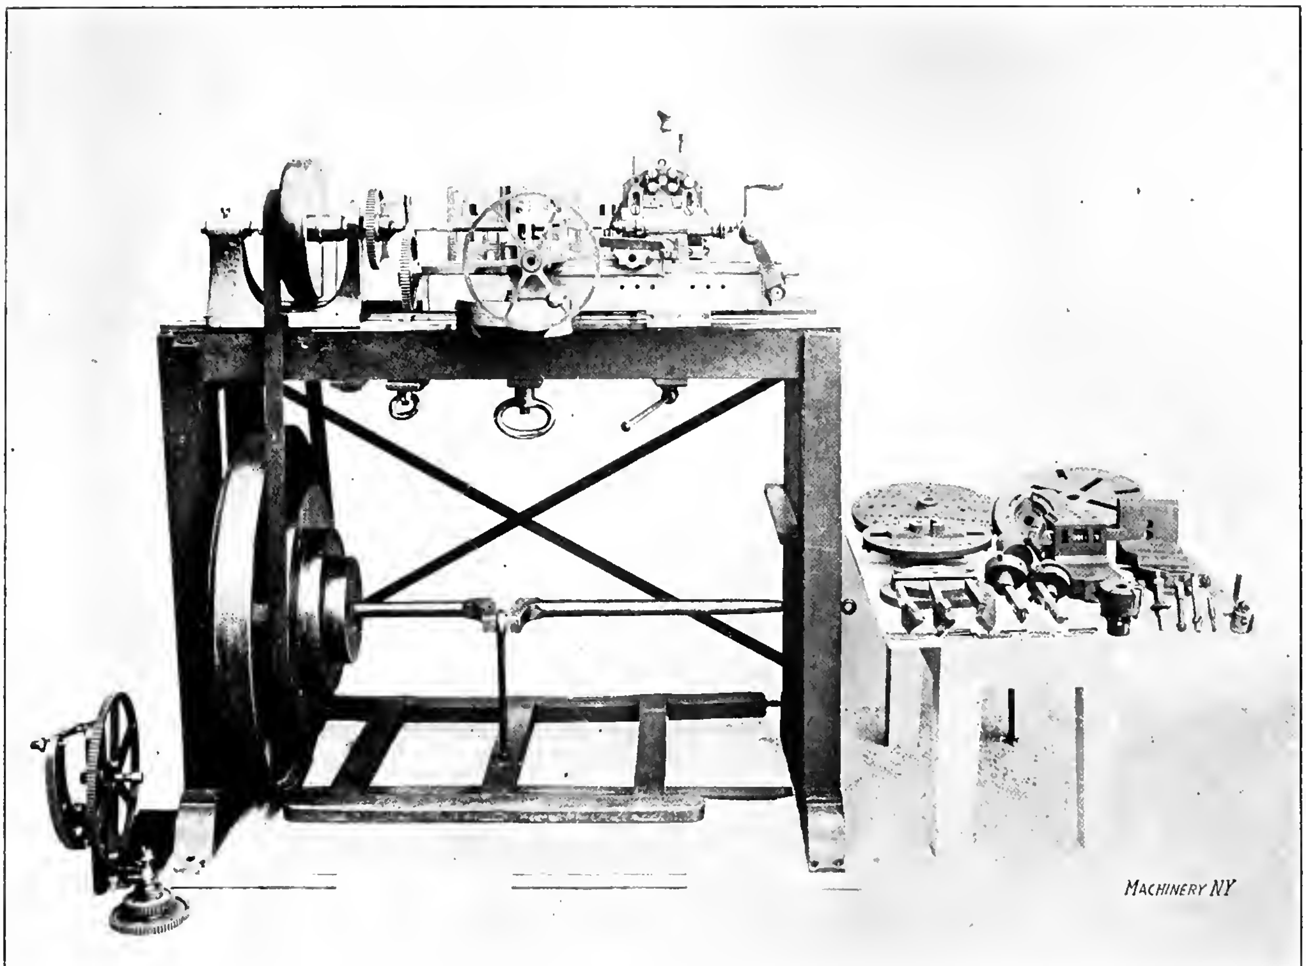

Fig. 4. Lathe used by Babbage in Experimental Work, South Kensington Museum

A very large face lathe constructed by Henry Maudslay was until a few years ago in existence at the Lambeth works, now dismantled. It was capable of facing up to 40 feet diameter, and had been used to turn the rims of flywheels. It had been employed also as a boring lathe by the substitution of a boring bar, and had bored cylinders up to 10 feet in diameter. The mandrel was $9\frac{1}{2}$ inches diameter in the larger bearing.

An interesting old lathe in the South Kensington Museum is shown in Fig. 4—interesting for three reasons; it was the one on which Babbage performed his experimental work, it contains the second compound slide-rest made by Clement, and it is an example of a machine tool in which all operations were performed that could be performed, in accordance with the practice of that period.

The bed is of cast iron carried on wooden supports. A

single pulley is driven from a three-stepped driving wheel, and the headstock was shifted along when the pulley had to be brought into line with either step. A division plate on the pulley has circles of holes of 200, 180, 112, and 12 holes each. The slide-rest has three slides, the lowest being shallow to be clamped in any position transversely to the bed. On this is bolted a long slide with a lead-screw of nine threads to the inch, the threads being of vee section, and the slide being capable of rotary adjustment through an angle of about 45 degrees. The screw operates the uppermost slide which has alternative positions for the tool holder. Babbage, it will be remembered, designed the first tool holder, which was a model not essentially different from several that are in use now. One of these is seen lying on the slide-rest. The slotted bracket seen behind the rest, and which is fixed on the lowest slide, is used for the attachment of work which has to be planed, shaped,

wide ranges in diameter beyond the capacity of the comparatively short traverse slide, the socket was carried on a sole plate movable across the saddle, to which it could be tightened with bolts. With the disuse of hand turning, the socket has been discarded in favor of the more substantial and more accurate arrangement which is embodied in the modern lathes. The tool "post" survived long as a post, because it was so conveniently used alternatively for receiving a tee rest for hand turning, and a slide-rest. It can be traced from the French Encyclopedia, 1772, down to the period of the writer's apprenticeship. In a

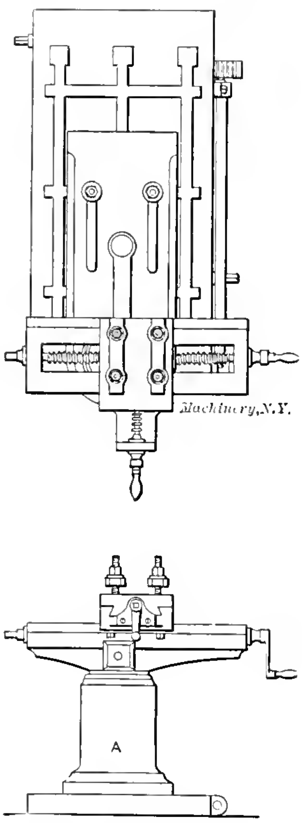

Fig. 5. Slide-rest of Boring and Turning Machine

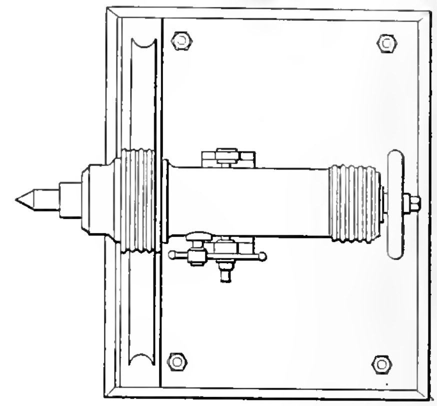

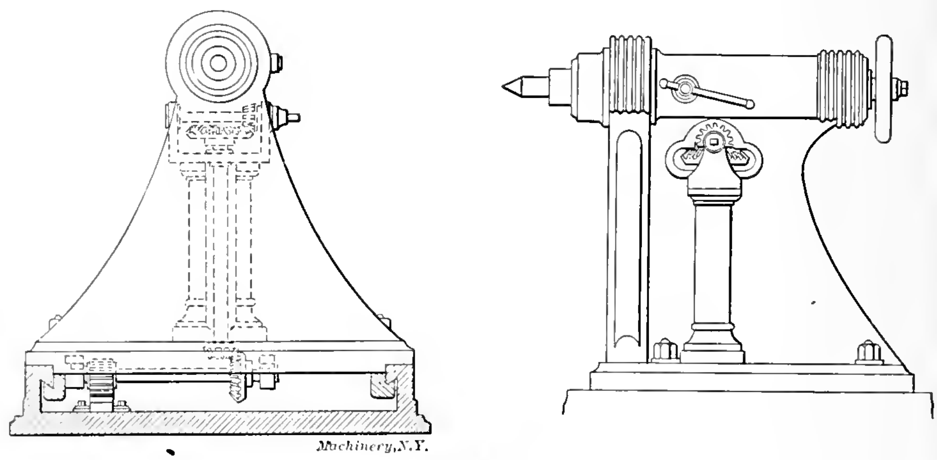

Fig. 6. Poppets of Boring and Turning Mill, Kinmonds, Hutton & Steel, Dundee, Scotland. About 1847

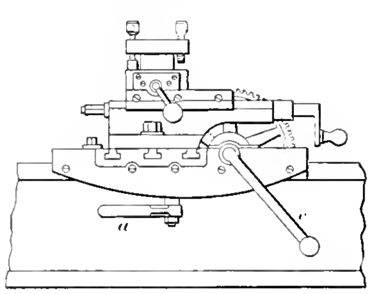
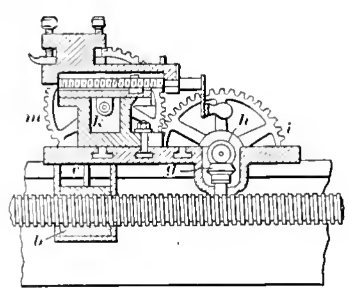
or slotted. The lathe is also rigged up for screw cutting. A chuck with the first change wheel is put on the mandrel, and a suitable train of gears, held by a quadrant bolted to the lathe bed, terminates in a wheel keyed on the end of the lead-screw of the slide-rest. Several appliances were added between 1824 to 1830, including various faceplates and chucks.

rather disguised form the same design exists in the present wheel lathes in which the post is fixed and the sliding given through a ratchet feed.

The slide-rest in its present essential design was due to Whitworth. An early form is illustrated in Fig. 7. There is no provision as yet for angular turning, and no separation





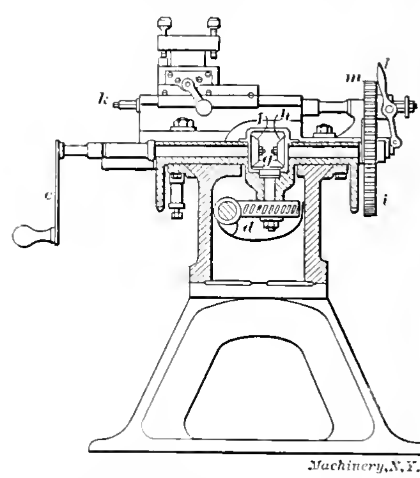


Fig. 7. Early Whitworth-Slide-rest

A two-jaw self-centering chuck is one of these, centered by means of a right- and left-hand screw. There is an adjustable face milling cutter, a large facing cutter, and a machine vise. Wood turning tools are points, gripped in holders by means of a strap, seen on the table to the right.

Many of the slide-rests in use sixty or seventy years ago, Fig. 5, were evidently variations or modifications of the older tee rests employed for hand turning; that is the sliding arrangement involved the use of a socketed pillar *A* such as was used for the tee rests. The two slides for longitudinal and cross traverse were mounted upon and screwed in the pillar, and being removable, the tee rest could be substituted for hand turning. To effect an extent of movement such as would be required for setting the tool to suit work having

between the feed rack and lead-screw. But in other respects it resembles, in the main, present-day rests.

The design shows the carriage with guide strips embracing a bed with veed edges, the carriage being clamped with the handle *a*. The guide screw lies within the bed, and is placed to one side for protection. The body of the rest is fitted and clamped with tee head bolts to the carriage. It supports the transverse slide, which is actuated by a hand-

screw, or by power, and this again receives the tool holder similarly actuated. The details of these are obvious without special references. The curious part of this design is the method of utilizing the lead-screw for screw cutting through the nut *b*, which is disengaged by the pin *c*; and for feeding through the tangent wheel *d*. When the clasp nut is out, and the lead-screw not being rotated, the threads of the screw are made to fulfill the function of rack teeth. This is done by turning the handle *e* which drives the bevel wheels *f* and *g*, the latter being on the spindle which carries the tangent wheel *d*.

The cross feed is derived from the same bevel wheels, being transmitted through *h* to the wheel *i*, which is always running when the rack feed is in. The cross-feed screw *k* is put into action by the lever *l* and wheel *m*.

Fox of Derby was using a rack and pinion for traversing the slide-rest about 1830.

The early loose poppet which had the mandrel screwed along its length and was turned in a block of wood, or a metal nut, was superseded by the plain cylindrical mandrel as we know it to-day, the invention of Joseph Clement, and it is said simultaneously by M. Collas, a Frenchman. The transverse adjustment of the headstock for taper turning is old, being certainly in use before 1847.

As lathes increased in weight, provision had to be made for effecting the movements of the loose poppet by power. The present simple device of a rack and pinion in front of the bed or at front and back, was not so obvious as it seems now. In a drawing of an old heavy lathe (1847), Fig. 6, by a defunct Dundee firm, a roundabout way was adopted. A rack ran along within the bed, having its teeth uppermost. A vertical shaft within the poppet turned by a pair of bevels and winch handle at the top actuated another pair of bevels in the base, the last of which on a transverse shaft carried a spur pinion which engaged with the rack.

Long after the adoption of metal mandrels and metal collars or bearings these were divided longitudinally. Whitworth designed the conical form of solid bearing, with the front cone much steeper than the rear one, which has remained standard Manchester practice for all except the heaviest lathes.

This outline brings the subject of the lathe down to living memory. In the next article it is proposed to outline the history of some of the other machine tools.

* * *

A project is on foot for building an international dam across the Niagara River to maintain the water level of Lake Erie at not less than a certain minimum height, the year round. Every Autumn the level falls so as to seriously interfere with shipping, and it is for improving the present condition that the dam is considered. If built, the dam could be used for another purpose equally laudable and valuable. There has been much agitation against the defacement of the natural beauty of Niagara Falls because of the amount of water used by the power companies which materially reduces the volume of flow over the falls in low water periods. The dam could be used to impound water at night, practically cutting off all flow for certain hours through the night and storing it up for use in the daylight hours. In this way it would be possible for the power development of Niagara Falls to be materially increased for daylight service without decreasing the normal volume of flow, the daylight flow being sufficiently in excess of the normal flow to compensate for that used by the power concerns.

* * *

Cheaper radium is promised by the discovery that the ash of lignite found in Sweden contains radium which can be extracted by an inexpensive process devised by Dr. Gustaf Hellsing. A company has been formed for exploiting the invention. According to *Engineering* it is expected to extract about 0.075 grain troy from each ton of the raw material. The technical side of the problem is fully solved and there is no doubt as to where and how the radium can be obtained, but there is, of course, the risk that the present enormously high price of radium may be reduced through fresh discoveries.

OBSERVATIONS ON THE MAKING OF HIGH-SPEED STEEL TOOLS

O. M. BECKER*

The collection and orderly preservation of data as a basis for subsequent rational deduction and intelligent procedure has long been considered an essential concomitant of the scientific method; and it is now coming to be pretty generally understood that the scientific method is also the successful business method, whether the end sought be the perfection of technical processes or the organization of a business system. The preservation of appropriate data as a guide to the production of superior high-speed steel tools by the simplest efficient methods, should, therefore, need no arguing. The sneer of the small man in a small place at "red tape"

and "over-refinement" is not heard nearly so much as formerly; and this is as it should be, especially as regards the manipulation of the new steels. The question under consideration concerns not alone the keeping of data, but, more particularly, the kind of data to be kept.

Kind of Data to Preserve

Within moderately well established limits the precise treatment best calculated to develop the highest efficiency in a tool intended for a special purpose is usually found by the "cut-and-try" method. It is desirable, therefore, that besides the record of the performance of the tool, there should be data showing the precise conditions under which the tool was treated while in process of manufacture. These conditions are comprehended in the tool record shown herewith;

once definitely known, they can be varied from time to time as may be indicated by the results obtained from the tool at work. Obviously, when a set of conditions is found which yields just the proper excellence, it is necessary only to duplicate these conditions to obtain satisfactory results. The proper conditions will then be definitely indicated in the directions accompanying each subsequent lot of tools of the kind. It will be understood, of course, that there is small value in such data and directions unless the tool manufacturing plant is equipped so as to take advantage of this information; that is, unless the plant has a variety of fur-

* Address: Berwyn, Ill.

naces and other apparatus suitable for obtaining accurate information as to conditions, and for meeting the requirements indicated upon the direction cards. Time spent in experimenting intelligently—that is, experimenting with adequate appliances, materials and data—to fit the tool most nearly to its work, and to give it treatment which will produce the highest attainable efficiency in its special work, is well and profitably spent.

Hardness or Temper of High-speed Steel Tools

Of the elements involved in tool efficiency, hardness or temper formerly was considered the most important, the design and conditions of use being little regarded. At the

Fig. 1 Planer Roughing Tool with Machine Steel Shank and High-speed Steel Cutting Edge composed of a Comparatively Thin Piece of High-speed Steel brazed to the Shank Used in the Shops of the Lodge & Shipley Machine Tool Company, Cincinnati, Ohio

present time, the intelligent making of high-speed tools involves a consideration of all these and other elements, relegating to hardness or temper its appropriate place. The extreme hardness of many of these tools has frequently led to the inference that a tool has been properly treated if it is very hard, so hard that a good file will not "touch" it. However, extreme hardness is not always an indication of the efficiency of a high-speed tool; although it is necessary in certain classes of work (cutting refractory stock, for instance), in others it not only is unnecessary, but perhaps even undesirable. As a matter of fact the largest users of the best makes of high-speed steel find that for many purposes tools do the best work and give the most efficient service when soft enough to be "touched" by a good file, and even when so soft that it will "take hold." However that may be, the file test for high-speed tools is quite valueless even in those cases where it is desirable that the degree of hardness be determined. Such tests, to be of value, would require that the files must be absolutely uniform in temper. Even the best of files, however, vary more or less in temper and hardness; and a tool passed as "hard enough," when tested by one file might easily fail to pass the test when tried by another, presumably of the same temper.

Allowances to be Made for Variations in Sizes of Tools After Hardening

Usually it is of no particular consequence, in tools of the lathe or planer type, whether the stock is exactly sized or not, so long as there is enough material to withstand the enormous strains and to prevent vibration, and consequently inferior and inaccurately sized work. In other types of tools, however, as in drills and mills, it is necessary, when ordering stock, to make allowance for the burnt skin which must be removed after hardening. While the effect on high-speed steel is apparently much less marked than in the case of the carbon steels, nevertheless the long-continued high heat in annealing affects the surface of the bars enough to make it necessary to remove the same to a depth varying more or less according to the size of the bar. In stock above an inch in thickness one-eighth inch should be added to the required size, and in large sizes, the proportionate allowance decreases rapidly.

The allowance for shrinkage of finely-sized tools during the hardening process is distinct from the allowance just mentioned. Loss in size is almost invariably the result of exposure to the air while the tool is very hot. The loss due to actual shrinkage is so small, except in large tools, as to be scarcely appreciable, and is usually negligible when the barium chloride process is used. If the hardening is done by the customary methods, a slight allowance is possibly desirable in certain cases, say in the arbor holes in milling cutters, the diameter of taps, etc. With care in hardening, even by the customary processes, the variation in a 1-inch diameter will scarcely exceed 0.0005 inch, and more likely will be less, though indeed it may be as great as 0.001 inch and even more—so much depends upon the care exercised and the method employed. It should scarcely need to be added that the holes in all mills intended for very accurate work should be ground after hardening, the mills having been first carefully centered in a chuck.

It might also be mentioned that apparent variations in the size of tools like threading dies and taps and other tools which cannot be ground after hardening, are frequently only the effects of the roughening of the surface during the treatment. The barium process very largely overcomes this difficulty and does so entirely, unless, as is generally the case, the defect is present before the hardening. This roughness usually arises from the method of cutting the threads, or teeth, as the case may be. Such threads or teeth are best, and of course most quickly, cut by milling, lubricating the cutter with thin oil. Next to this it is best to rough out the threads with a chaser, as close to size as may be, without lubricant, and then to re-cut or finish with a single-point tool held in a spring-thread holder, the threads being kept slightly lubricated with very thin oil. To compensate for the roughness often present in high-speed tools of this class, it is customary to give rather more relief than in the case of those made of ordinary steel. The increased relief minimizes the lodging of particles of steel in the surface of the cutter behind the cutting edge, which tend to act as cutters, sometimes very appreciably increasing the cut.

Extreme smoothness is also a desirable quality in high-speed drills, but it seems impossible to obtain by present methods of cutting a smoothness of surface like that of the carbon steel drills; to secure this it is necessary to polish the flutes. If the hardening is by the barium process, the polishing may be done before hardening, for that process leaves the surface absolutely unimpaired.

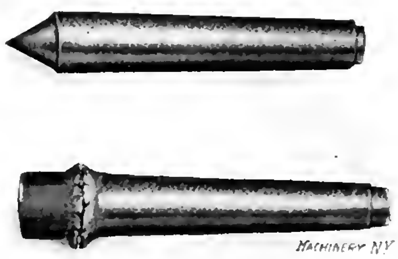

Fig. 3. Lathe Center made with High-speed Steel Point electrically welded

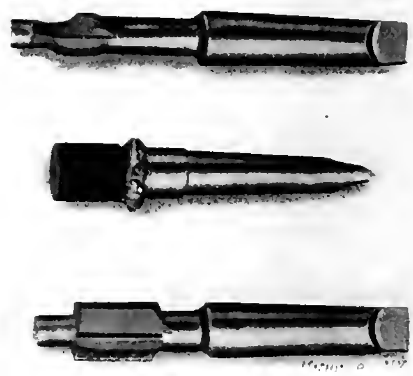

Fig. 4. Broken Counterbore Repaired by Electric Welding

Disadvantages of High-speed Steel Tool-holders

The early method of economizing in steel by using tool-holder stock rather than making the entire tool of high-speed steel, in the case of those tools whose cutting edges or points work without intermission (as those used for turning, planing and similar operations) is open to criticism, and is not

now so generally followed as formerly. A characteristic of the operation of high-speed tools is the rapid generation of heat in the cutting edge. In the case of milling cutters and kindred tools this is of small consequence, because the cutters are intimately attached to a relatively large mass of metal which conducts the heat away very efficiently. Furthermore, these cutters work intermittently, each for a very brief space of time, and for the remainder of the revolution are exposed to the air and cooled by it. The cutting edges are not allowed, therefore, to get exceedingly hot, as is the case with the edge of a turning tool run at the same speed. It is necessary that the body of such a turning (or similar) tool be large enough to conduct away a considerable portion of the heat generated at the cutting edge; and in order to do this effectively the tool must be continuous; that is, there must be no appreciable separation between the part of the tool which does the cutting and the body from which most of the heat radiates, as there is ordinarily when a small piece of steel is held in a tool-holder. There are indeed tool-holders which minimize this difficulty; but even these are not satisfactory in large sizes.

Methods of Uniting High-speed Steel with the Tool Body*

From the first, methods were sought whereby high-speed steel cutting points could be intimately combined with tool bodies of ordinary and much cheaper steels. For the most part the methods tried were ineffective and impracticable. The reasons are not well understood. The disinclination of the two steels to unite probably is due to a difference in their coefficients of expansion. There is, however, no trouble in brazing them together; and when this does not involve placing a great strain upon the brazed joint, this method does very well. Obviously the cutters are hardened before being brazed into place. A successful example of such a combination is a lathe or a planer tool made with practically no forging and with a relatively thin plate of high-speed steel brazed to the front and top to form the cutting edge. Rose and other forms of reamers and mills have been made in a similar way, the body of machinery steel being machined with recesses for high-speed blades, which are brazed into place. Such tools have been in use for several years, with satisfaction. The latter, especially, are as good as if of solid high-speed steel except when it is essential that they be re-annealed or re-hardened—which is seldom necessary.

Almost as soon as the new steels made their appearance the writer suggested and demonstrated the possibility and feasibility of welding, electrically and autogenously, a high-speed cutting point and a machinery steel tool body, the latter of such proportions, of course, as to give the requisite strength to the tool. Such tools conform to the requirement of being perfectly continuous, and the weld is practically as strong as the rest of the tool. It is feasible to forge the end to any required shape as if the entire tool were of high-speed steel; and, since in hardening only the nose is heated to a high heat, the machinery or tool steel body is in nowise impaired. The method of electrical welding, as used in this connection, is exceedingly simple. The two pieces to be welded are attached to the terminals of a circuit of suitable voltage, and the edges brought together. The resistance to the passage of the current offered by the imperfect contact sets up enough heat to melt the metal and forms a perfectly homogeneous junction. The autogenous (oxygen and acetylene blow-pipe) method is almost as simple; the flame is directed into the crevice where the two pieces are brought together, and melts the adjacent metal so as also to form a homogeneous joint.

Another method (patented) recently brought forward, somewhat resembling brazing, is asserted to give a joint fully as strong as the rest of the tool. A thin film of copper is placed along the line of the joint, and the parts to be welded are surrounded by a reducing compound and then placed in a furnace raised to a temperature of about 1,200 degrees C. (2,200 degrees F.). The copper flows freely into the interstices and is said to produce actual cohesion between the adjacent molecules, making a perfect joint, so strong that a fracture will follow a new break rather than pass through the joint.

* See MACHINERY, October, 1908, "Electric Welding of Tools."

These methods are available for all classes of tools made partly of high-speed and partly of machinery steel or other materials. Reamer and mill blades, die faces, shear blades, jack knives, etc., all are readily welded to supporting forms or backs and make tools quite as efficient as if of solid high-speed steel—and generally much more so than if the cutters or faces were attached by screws, bolts, rivets, or similar methods. Long-shank and extension drills, reamers, etc., can readily be made with the cutting parts of high-speed steel and the shanks of cheaper steel. The processes mentioned, especially the electrical, are available also for the repair of broken tools, many of which can thus be saved for further use. The repairing may involve the welding of the broken parts or the replacing of an old part by a new, as may be most expedient.

Cutting High-speed Steel

Only an expert can nick and break high-speed steel from the bar without damage to the structure adjacent to the fracture—and even an expert cannot be sure of doing so with safety; the best way, where the end is to be used for working purposes, is to cut the bar. The circular saw most frequently used does very well, though a band saw works better and rather more rapidly. Small bars can readily be cut in bundles, if held very rigidly. The saws, obviously, should, themselves, be of high-speed steel. Complaints have been made that it is impossible to saw these steels. The complaints probably originated in the use of improperly hardened saws; for there is no difficulty whatever in cutting them with suitable saws. A singular but most effective method has been employed to some extent. It consists in the use of a highly-speeded disk of tough steel. When an unused disk is first forced against the high-speed steel, the disk does not take hold well; but after being run in contact with the high-speed steel for a time it cuts perfectly and rapidly, leaving a clean burless kerf. The disk may be of any steel tough enough to withstand the tremendous centrifugal (and other) stresses set up by the pressure and the terrific speed required. Just why such a disk cuts is not exactly clear. The periphery is usually found studded with particles of the steel being cut, and the "sawdust" appears to be the result of true cutting.

Detecting Cracks in High-speed Steel Tools

Fine cracks in tools are most difficult to discover. Even the microscope often fails to disclose them. Generally they can be detected, if present, by the very simple expedient of moistening the suspected surface with petroleum, rubbing clean, and then wiping off with chalk. Some petroleum enters the cracks and afterwards sweats out, moistening the overlying chalk. The nature and extent of the cracks are thus rendered visible. This frequently is of great importance in testing lots of high-speed steel tools.

Re-forging of Worn-down Tools

Tools which have worn down so as to be useless can usually, when made of solid high-speed steel, be forged or machined down and worked into tools of smaller size, if ordinary care is exercised. It is necessary always to re-anneal prior to attempting to machine such old tools; and it is also expedient when forging them to smaller shapes. In passing, it might be mentioned that re-annealing is desirable after machining and before hardening all sorts of intricately-shaped tools, in order to relieve any possible machine-caused strains. In re-forging high-speed tools, whether for reduction in size or merely in re-fettling, it is desirable that they be heated rather slowly at first; they should not be thrust cold into a very hot fire.

* * *

An alloy of iron and thorium which possesses remarkable properties has been produced by Mr. Welsbach, the well-known inventor of the incandescent gas mantel. When struck lightly against a piece of iron this alloy emits exceedingly bright sparks, and sufficient heat is developed to ignite tinder instantaneously without the repeated efforts required with the old-fashioned flint and steel. The new thorium flint may be called an everlasting match, and will undoubtedly be very useful to explorers and tourists and for the ignition of explosives.

CALCULATION OF PILLAR CRANES*

CHARLES A. SCHRANZ†

The maximum stresses in the different parts of a pillar crane are due to the maximum load lifted (the live load) and the weight (dead load) of the crane parts themselves. Fig. 1 shows a conventional design of a hand pillar crane, and assuming, for an example, the maximum load $Q = 5$ tons, the height $H = 12\frac{1}{2}$ feet, and the radius $A = 13$ feet, the stresses in the different parts of the crane are calculated as shown in the following.

Stresses in the Boom

Fig. 1 shows plainly that the stresses in the boom and tie-bars are not due to the live load only, but that the weight

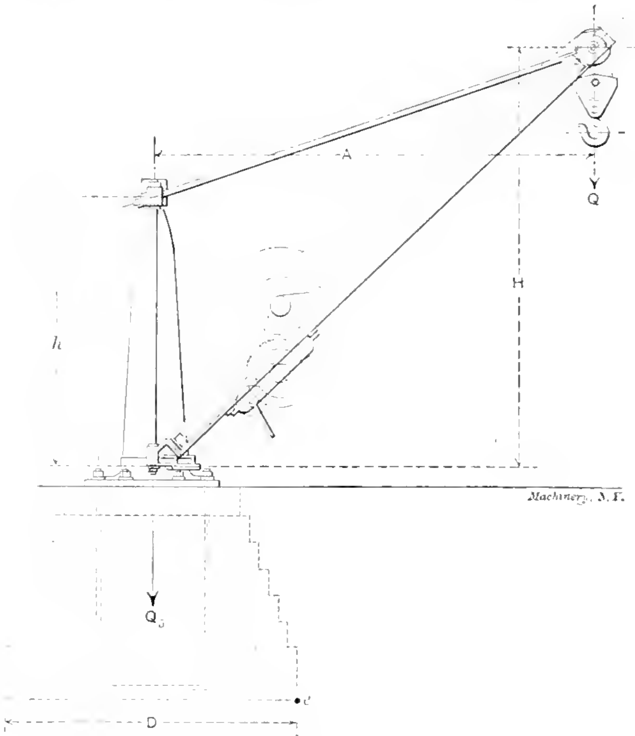

Fig. 1. General Layout of Pillar Crane

of the eccentric parts of the crane (*i. e.*, boom, tie-bars, hoist, sheave wheels, crane hook and hoisting rope) and the pull of the hoisting rope must also be considered. As it is not possible to determine the dead load accurately before the crane is calculated and designed, it must be assumed. A practical method is to assume the weight of the above mentioned eccentric parts of the crane as half of the maximum live load, and its center of gravity at a distance equal to one-fourth of the radius of the crane from the center line of the pillar. These assumptions expressed in formulas read:

$$Q_1 = \frac{Q}{2};\ \text{or}\ Q_1 = \frac{10{,}000}{2} = 5{,}000 \text{ pounds.} \qquad (1)$$

$$a = \frac{A}{4};\ \text{or}\ a = \frac{13}{4} = 3\frac{1}{4} \text{ feet.} \qquad (2)$$

in which Q_1 = the weight of the eccentric parts of the crane, and a = the distance of the center of gravity of Q_1 from the center of the crane. If the actual figures, determined after the crane is calculated, differ considerably from these assumptions, corrections have to be made.

The next step is to determine the height h of the pillar, a practical rule being to make h about 0.6 of the radius of the crane:

$h = 0.6\,A$; or $h = 0.6 \times 13 = 8$ feet, approximately. (3)

The frame diagram shown in Fig. 2 can now be drawn. According to the law of equilibrium the sum of moments of the external forces must be equal to the sum of moments of the internal forces about the same center. The moment M_i of the internal force in the boom is the product of its compressive stress C and its lever arm e ($5\frac{3}{4}$ feet) about center K:

$$M_i = Ce \qquad (4)$$

The moments of the external forces about center K are:

The moment of $Q = M = Q\,A$ (5)
The moment of $Q_1 = M_1 = Q_1 a$ (6)
The moment of $Q_2 = M_2 = Q_2 b$ (7)

Dimension b is found to be 4 feet by scaling.

Substituting the values:

$M = 10{,}000 \times 13 = 130{,}000$ foot-pounds.
$M_1 = 5{,}000 \times 3\frac{1}{4} = 16{,}250$ foot-pounds.
$M_2 = 5{,}000 \times 4 = 20{,}000$ foot-pounds.

The sum of above moments is:

$$M_s = M + M_1 + M_2 = 130{,}000 + 16{,}250 - 20{,}000 = 166{,}250 \text{ foot-pounds.} \qquad (8)$$

As explained above

$$M_i = M_s \qquad (9)$$

or

$Ce = M_s$ and transposing

$$C = \frac{M_s}{e} = \text{the compressive stress in the boom.} \qquad (10)$$

Substituting the values in above formula

$$C = \frac{166{,}250}{5\frac{3}{4}} = 28{,}910 \text{ pounds.}$$

The unsupported length of the boom scales about 17 feet, and as in this case it is made up of two channels the load on each channel is $\frac{C}{2}$ or 14,455 pounds. The inclination of the two channels towards each other need not be taken into consideration as the increase of load is very small. Consulting any handbook of information relating to structural steel we find that a 6-inch × 8-pound channel has a section area of 2.38 square inches and a radius of gyration with respect to an axis perpendicular to its web of 2.34 inches. Only this radius of gyration need be considered as the flanges of the two channels are latticed together. For the ratio of the length L of the boom in feet to the radius of gyration r in inches

$$\frac{L}{r} = \frac{17}{2.34} = 7.2,$$

which is not excessive. The elastic limit for soft steel may be taken at 30,000 pounds per square inch. Dividing the

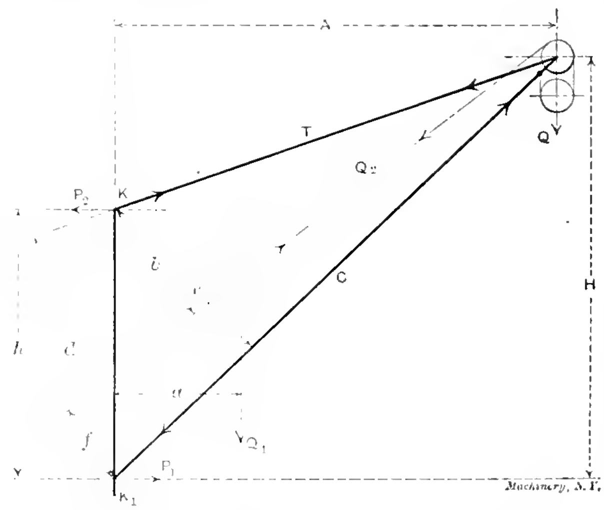

Fig. 2. Diagrammatical View of Pillar Crane

load on one channel by its sectional area the actual unit stress will be

$$\frac{14{,}455}{2.38} = 6{,}075 \text{ pounds,}$$

which shows that two 6-inch × 8-pound channels are quite sufficient to stand the load.

Stresses in the Tie-bars

To find the tensile stress in the tie-bars the same method as just explained will be used. Taking K_1 as a center of

* For previous articles on cranes, crane design, and efficiency of crane mechanism, see MACHINERY, January, 1909, engineering edition: Design and Construction of Electric Over-head Cranes, and also the articles there referred to; see also MACHINERY'S Reference Series No. 23, Crane Design.

moments and referring again to Fig. 2, the moments of the external forces are:

Moment of $Q = M = QA$. (5)

Moment of $Q_1 = M_1 = Q_1 a$. (6)

Moment of $Q_2 = M_2 = -Q_2 f$. (11)

Dimension f is found by scaling to be $2\frac{1}{2}$ feet.

Substituting the values in these formulas:

$M = 10,000 \times 13 = 130,000$ foot-pounds,

$M_1 = 5,000 \times 3\frac{1}{4} = 16,250$ foot-pounds,

$M_2 = -5,000 \times 2\frac{1}{2} = -12,500$ foot-pounds,

and the sum M_s of these moments is

$$M_s = 130,000 + 16,250 - 12,500 = 133,750 \text{ foot-pounds.} \quad (12)$$

The moment M_1 of the internal stress T in the tie-bar is

$$M_1 = Td. \quad (13)$$

Dimension d scales $7\frac{1}{2}$ feet.

Since M_1 must be equal to M_s

$$Td = M_s \quad (14)$$

and transposing:

$$T = \frac{M_s}{d} \quad (15)$$

Substituting the values in formula (15) the tensile stress in the tie-bars is: $T = \dfrac{133,750}{7\frac{1}{2}} = 17,830$ pounds.

As there are two tie-bars the load on one is $\dfrac{17,830}{2} = 8,915$ pounds. Using a safe fiber stress of 10,000 pounds per square inch, the area of one bar $= \dfrac{8,915}{10,000} = 0.892$ square inch with the corresponding diameter of 1 1/16 inch.

Stresses in Pillar

The stresses in the pillar are due to the bending moments of the loads Q and Q_1 and to the direct vertical loads Q and Q_1. The bending moment of Q and Q_1 was found by formulas (5) and (6) to be 130,000 foot-pounds and 16,250 foot-pounds, respectively. The sum of these moments is

$$M_s = M + M_1 = 130,000 + 16,250 = 146,250 \text{ foot-pounds} \quad (16)$$

or 1,755,000 inch-pounds. This bending moment in inch-pounds must be equal to the product of the section modulus of the pillar cross-section, times the safe unit fiber stress. Considering the sectional area of a hollow cylinder for the cast iron pillar, the section modulus is

$$S = \frac{\pi (D^4 - d^4)}{32D} \quad (17)$$

in which $D =$ the outside diameter of the pillar, and

$d =$ the inside diameter of the pillar.

Using a safe fiber stress $s = 3,000$ pounds per square inch, the above mentioned equation reads:

$$M_s = \frac{\pi (D^4 - d^4)}{32D} \times s \quad (18)$$

Assuming an outside diameter of 24 inches, the inside diameter d is found by transposing the formula (18):

$$d = \sqrt[4]{D^4 - \frac{32 M_s D}{s \pi}} \quad (19)$$

and substituting the values:

$$d = \sqrt[4]{24^4 - \frac{32 \times 1,755,000 \times 24}{3000 \times 3.14}} = 20\tfrac{7}{8} \text{ inches.}$$

As mentioned before, not only the bending moment, but also the direct vertical loads Q and Q_1 must be considered. As the bending moment produces a tensile stress on one side of the column and a compressive stress on the other side, the additional vertical loads Q and Q_1 naturally increase the compressive and reduce the tensile unit stress somewhat.

The unit stress in the pillar caused by the vertical loads is

$$s_2 = \frac{Q + Q_1}{\text{Area}} = \frac{15,000}{110} = 137 \text{ pounds per square inch.} \quad (20)$$

110 square inches is the sectional area of the pillar at the dangerous section

The sectional area of the pillar was calculated for a bending stress of 3,000 pounds. Adding the unit stress for the bending moment and the unit stress for the vertical loads, the actual compressive unit stress is found to be:

$$3,000 + 137 = 3,137 \text{ pounds per square inch.} \quad (21)$$

Subtracting the unit-stress produced by the vertical loads from the unit bending stress the actual tensile stress s_t in the pillar results:

$$3,000 - 137 = 2,863 \text{ pounds per square inch.} \quad (22)$$

Vertical Tie-rods

The vertical tie-rods, connecting the crosshead with the lower end of the boom, receive the vertical component of the tensile stress T in the ties, and the vertical component of the compressive stress C in the boom, or what is the same, the added loads Q and Q_1.

$$Q_3 = Q + Q_1 = 15,000 \text{ pounds.} \quad (23)$$

in which $Q_3 =$ the stress in the two vertical tie-bars.

Each of the two tie-rods receives half of this load or 7,500 pounds. Using a safe unit fiber stress of 10,000 pounds, the area of one tie-rod is $\dfrac{7,500}{10,000} = 0.75$ square inch, with a corresponding diameter of one inch.

Pintle

The reaction P_2 on the pintle (see Fig. 3) is caused by the loads Q and Q_1, whose moments about K must equal the moment of P_2 about the same center:

$$QA + Q_1 a = P_2 h = P_1 h \quad (24)$$

and this formula transposed and the values substituted

$$P_1 = P_2 = \frac{10,000 \times 13 + 5,000 \times 3\frac{1}{4}}{8} = 18,280 \text{ pounds} \quad (25)$$

The reaction P_2 produces a bending moment on the pintle, and referring to Fig. 3, this bending moment

$$M_b = \frac{P_2 L}{2} \quad (26)$$

in which $L =$ the length of the pintle. Assuming the length $L = 1\frac{1}{2} D_1$, the formula (26) reads:

$$M_b = \frac{P_2 \times 1\frac{1}{2} D_1}{2}.$$

This moment has to be equal to the product of the section modulus of the sectional area of the pintle times the safe unit stress. The section modulus for a circular section being $\frac{\pi}{32} D_1^3$, and assuming the safe unit stress $s = 8,000$ pounds the equation reads:

$$\frac{P_2 \times 1\frac{1}{2} D_1}{2} = \frac{\pi}{32} D_1^3 s \quad (27)$$

and transposing

$$D_1 = \sqrt{\frac{P_2 \times 1\frac{1}{2} \times 32}{2 \pi s}} \text{ or} \quad (28)$$

$$D_1 = \sqrt{\frac{18,280 \times 1\frac{1}{2} \times 32}{2 \times 3.14 \times 8000}} = 4\tfrac{1}{4} \text{ inches approx.}$$

and $L = 1\frac{1}{2} \times 4\frac{1}{4} = 6\frac{3}{8}$ inches.

Besides the bending moment produced by the reaction P_2 the direct vertical loads Q and Q_1 also produce stress, and this stress per square inch is found by dividing the sum of the vertical loads by the sectional area of the pintle in square inches:

$$s_4 = \frac{10,000 + 5,000}{14.19} = 1,060 \text{ pounds per square inch.} \quad (29)$$

The maximum unit stress on the pintle is then:

$$8,000 + 1,060 = 9,060 \text{ pounds per square inch.} \quad (30)$$

Foundation Bolts

Considering an axis A-A in Fig. 4, which shows a plan of the base of the pillar, the sum of the moments of the overturn-loads Q and Q_1 about this axis must be equal to the sum of the resisting moments. The latter are due to the stress in the foundation bolts and to the weight of the pillar. This weight can easily be calculated as the cross-section of the

pillar is already known, and in this case is found to be: $Q_4 = 5{,}000$ pounds. The moments of the overturning loads with respect to axis A-A are:

$$M_4 = Q\,(A - n) \tag{31}$$

or

$M_4 = 10{,}000\ (13 - 1\tfrac{1}{2}) = 115{,}000$ foot-pounds,

$$M_5 = Q_1\,(a - n) \tag{32}$$

$M_5 = 5{,}000\ (3\tfrac{1}{4} - 1\tfrac{1}{2}) = 8{,}750$ foot-pounds,

in which n = distance of the foundation bolts from the center of the crane. In this case n is found by scaling to equal $1\tfrac{1}{2}$ foot.

The sum of the overturning moments =

$$M_4 + M_5 = 123{,}750 \text{ foot-pounds.}$$

The resisting moments of the foundation bolts are:

$$M_6 = 2P_3 n + (2P_3 \times 2n) \tag{33}$$

in which P_3 equals the stress in one foundation bolt. The resisting moment of the weight Q_4 of the pillar is:

$$M_7 = Q_4 n = 7{,}500 \text{ foot-pounds.} \tag{34}$$

The sum of the resisting moments is therefore equal to

$$M_6 + M_7 = 2P_3 n + (2P_3 \times 2n) + Q_4 n \tag{35}$$

and transposing

$$P_3 = \frac{(M_4 + M_5) - M_7}{6n} \tag{36}$$

Substituting the value s, the stress on one foundation bolt

$$P_3 = \frac{123{,}750 - 7{,}500}{6 \times 1\tfrac{1}{2}} = 12{,}910 \text{ pounds.}$$

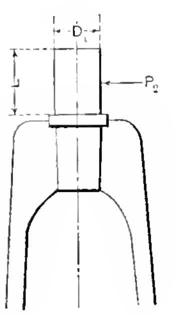

Fig. 3. Pintle of Pillar Crane

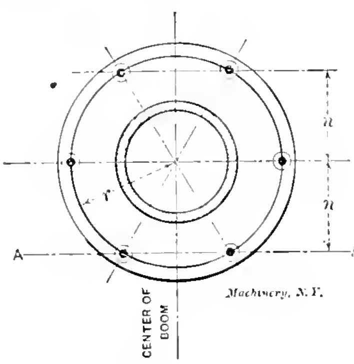

Fig. 4. Layout of Arrangement of Flange Bolts

Using a safe unit stress of 12,000 pounds, the area of one bolt is $\frac{12{,}910}{12{,}000} = 1.08$ square inch with a corresponding diameter of $1\tfrac{1}{4}$ inch.

[The calculation of the foundation bolts as here given is correct only on the assumption that the base flange of the crane and the bolts are made of inelastic materials. For a more fundamental treatment of the subject of foundation bolts, see MACHINERY, December, 1906, engineering edition: Flange Bolts (reprinted in MACHINERY'S Reference Series No. 22). For an article on the Working Strength of Bolts, which should also be considered in this connection, see MACHINERY, November, 1906, engineering edition. (Also reprinted in Reference Series No. 22).—EDITOR.]

Foundation

Referring to Fig. 1, we find the moments which tend to overturn the crane with its foundation about an axis passing through c to be:

sum of overturning moments =

$$Q\left(A - \frac{D}{2}\right) + Q_1\left(a - \frac{D}{2}\right) \tag{37}$$

This sum of the overturning moments is resisted by the moment of the combined weights Q_5 of the foundation and the pillar:

$$\text{sum of resisting moments} = Q_5 \frac{D}{2} \tag{38}$$

The equation of moments therefore reads:

$$Q\left(A - \frac{D}{2}\right) + Q_1\left(a - \frac{D}{2}\right) = Q_5 \frac{D}{2} \tag{39}$$

and transposing

$$Q_5 = \frac{Q\left(A - \frac{D}{2}\right) + Q_1\left(a - \frac{D}{2}\right)}{\frac{D}{2}} \tag{40}$$

assuming the diameter D of the foundation to be 9 feet and substituting the values:

$$Q_5 = \frac{10{,}000\ (13 - 4\tfrac{1}{2}) + 5{,}000\ (3\tfrac{1}{4} - 4\tfrac{1}{2})}{4\tfrac{1}{2}} = 17{,}500 \text{ pounds.}$$

Deducting from this combined weight of foundation and pillar the amount for the latter, we get the theoretical weight of the foundation:

$$17{,}500 - 5{,}000 = 12{,}500 \text{ pounds.}$$

Using a factor of safety of 3, the weight of the actual foundation must be:

$$12{,}500 \times 3 = 37{,}500 \text{ pounds.}$$

Having calculated the different parts of the crane as described it is good practice to test the pillar for its rigidity, as the amount of deflection must not be too great. The load on the unsupported end of the pillar was found by formula (25) to be $P_2 = 18{,}280$ pounds. The deflection X in inches is:

$$X = \frac{P_2 h^3}{3\,EI} \tag{41}$$

in which

h = the height of the pillar in inches = 96 inches.

E = the modulus of elasticity = 12,000,000 for cast iron.

I = the moment of inertia $= \frac{\pi}{64}\,(D^4 - d^4) = 7{,}257.$

Substituting these values we find the deflection

$$X = \frac{18{,}280 \times 96^3}{3 \times 12{,}000{,}000 \times 7{,}257} = 0.062 \text{ inch,}$$

or about 1/16 of an inch, which is not excessive.

* * *

INTELLIGENT USE OF LABOR-SAVING MACHINERY

It is one thing to use labor-saving machinery in order to permit rapid production and to conserve the energies of workmen, so as to produce a better product with greater rapidity, and quite another thing to use labor-saving machinery simply to avoid work. In one case there is economy of production, while in the other case there is wastefulness of production. An illustration came to our attention not long ago in the building of a fence in City Hall Park, New York. This fence is made of one-inch heavy pipe, supported in suitable posts. To prevent it being made a roosting place by loafers "anti-sit-downs" were fastened to the top rail with one-quarter inch stove bolts. To drill these holes, a portable gas engine and electric motor were provided to drive an electric drill. The cost of the outfit and a suitable charge for its depreciation undoubtedly made the cost of drilling the holes considerably greater than it would have been had they been drilled by improved breast drills, with power feed and chain support. These useful little tools are capable of putting a hole through a one-inch pipe in a very short time, and the cost of equipment is very low. Labor-saving machinery should be something more than "labor-saving"; it should be production-increasing and economical as well.

* * *

When the De Laval steam turbine was first brought into the market, the units were small and there was no condensing, and the result was a high steam consumption. Subsequent improvements, however, have tended to reduce the steam consumption so materially that this type of steam turbine now claims a place among the most economical motors. In referring to the figures below it should be borne in mind that the steam consumption refers to effective horse-power, while in many cases it is customary to give the steam consumption per indicated horse-power. One 500 horse-power turbine installed at Stockport, Great Britain, shows a steam consumption per effective horse-power of $13\tfrac{1}{2}$ pounds per hour; another of 330 horse-power installed in St. Petersburg, Russia, shows a consumption of $12\tfrac{1}{2}$ pounds per hour.

LOCOMOTIVE REPAIR SHOP PRACTICE—2

THE C. M. & ST. P. R. R. SHOPS AT MILWAUKEE

ETHAN VIALL*

In this article, which is a continuation of the one published in the August number, the practice in the tool-room, boiler, and blacksmith shops will be specifically treated, and in addition descriptions of the tools and methods employed in connection with other branches of locomotive repair work will be given.

In the tool-room, which is in charge of Gust. Gstoettner, everything is neat and up-to-date as is evident by the illustration, Fig. 38, which shows the arrangement of the gear and milling cutter rack which is a model for any shop. Flue expander segments are all made in the tool-room, and the special mandrels used to hold the segments while they are being turned, are shown at *A*, Fig. 39; some of the unturned segments are shown at the right. At *B* is shown the way the segments are held together while being placed on the mandrel.

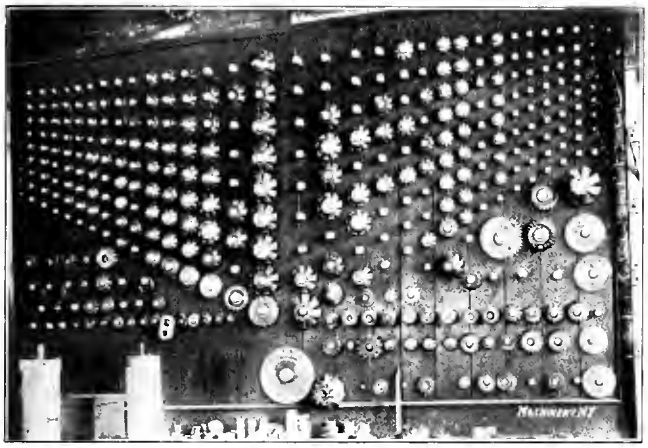

Fig. 38. Gear and Milling Cutter Rack in the Tool-room

The clamping collar shown is removed as soon as the mandrel nut is tightened enough to hold the parts securely. At *C* are shown three sets of finished segments held together by heavy rubber collars until wanted for use. The steel from which these segments are made is bought already drawn to the right sectional shape. It is then cut up into the right lengths and the ends, beveled sides and narrow edge ground on the grinder shown in Fig. 40. A special clamping device, *A*, holds the parts while the ends are being ground and another clamp *B* holds them while the narrow edge is ground. The device used to hold them while grinding the bevel, is out of sight behind the wheel.

Boiler Shop Kinks

In the boiler shop the common pneumatic flue swage used in most railroad shops, has a rapid-stroke pneumatic welding swage or die, placed on one side as shown at *A* and *B*, Fig. 43. After a new end has been placed on the flue and welding heat taken, it is placed in this die and the air turned on by means of the hand lever shown. The rapid blows complete the job in a hurry, and apparently do it just as well as the usual rolling device used for welding.

Fig 39. Flue Expander Segments and Tools used in making them

Ends of flues are cut off in the pneumatic trimmer, Fig 41, and repair ends are cut off and one end beveled in the machine shown in Fig. 44. This machine has a two-jawed pneumatic chuck *A*, for holding the flue which is being cut into short pieces. The principle of the operation of this machine can be understood by examining this and the following engraving. The bevel on one end of the pieces is obtained by using a wide cut-off tool straight on one side and beveled at about 45 degrees on the other.

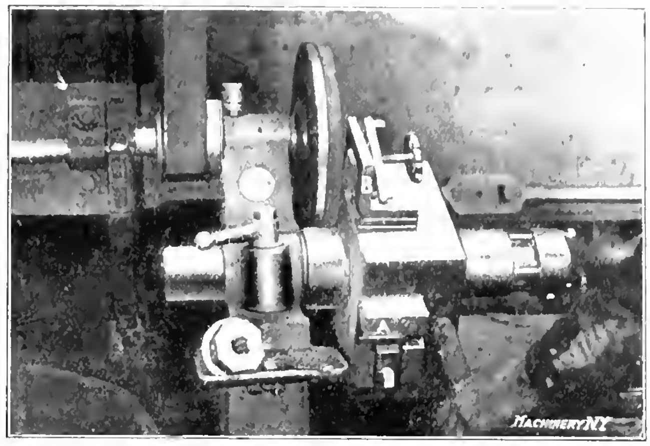

Fig. 40. Special Grinder for Flue Expander Segments

Fig. 45 is the same machine with a taper reamer placed in the pneumatic chuck *A*, for the purpose of beveling and removing the burr from the inside of the short piece of flue held by the hand clamping levers *C* and *D*. A large number of flue end repair pieces can be cut off and one end reamed in this machine in a very short time.

Assembling Springs

In the spring department of the blacksmith shop, springs are assembled and compressed ready for the band by the clamps shown in Fig. 46. After the hot band has been slipped into place, the clamp is removed and the band and spring compressed in the steam bulldozer shown in Fig. 47. While the pressure is on, the sides of the band are hammered down closely onto the spring with sledges. Pressure is kept on the band until it is cool enough to hold the spring leaves firmly together.

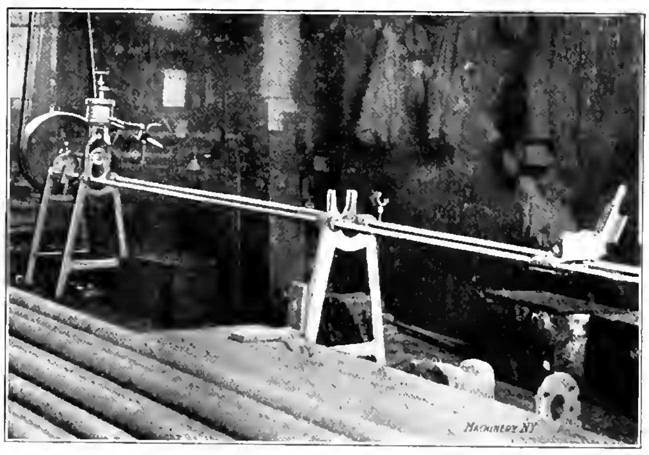

Fig. 41. Pneumatic Flue-cutter

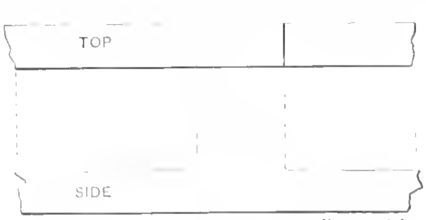

Fig. 42. The Way a Bar is upset in the Middle by a Bulldozer

Scrap metal is "baled" and then welded and forged into billets or slabs and then a number of these slabs are welded together, and forged into various locomotive parts. Fig. 48 shows nine of these slabs ready to be heated, welded and forged into a driving-axle under one of the big steam hammers.

* Associate Editor of MACHINERY.

Special Bulldozer Formers

Charles G. Juneau, who has charge of the blacksmith shop of the new car department, has some very unusual bulldozer forging and bending forms. The first piece of work here shown is really a forging job, but Mr. Juneau has contrived to do it in good shape on a bulldozer. The operation consists in upsetting the metal at the middle of a bar of iron which is afterward bent into a U-shape, the object being to give the piece more strength at the bend than would otherwise be the case, and allow for the stretching of the metal on the outside at this point. Fig. 42 shows the manner in which the bar is upset and shaped at the middle, and Fig. 49 shows how it is done, the piece in this case being intended for an axle hanger. To start with, the bar is heated at the middle for seven or eight inches; then it is placed in the machine and formed at one stroke by the ram shoving the bar against the stop *A*, which upsets it, after which the arm *B* wedges die *C* over against the other half *D*, completing the shape.

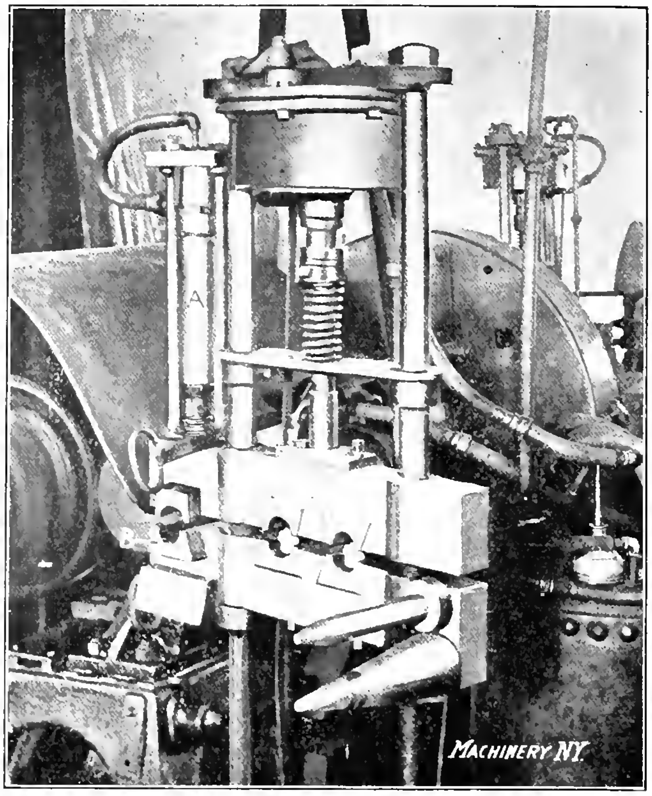

Fig 43 Pneumatic Flue-swage and Welding Die

The bars used for swing hangers, are upset in the same way, and are then bent as shown in Fig. 50, the bar being shown at *F* just as the former is starting to bend it, and at *G* is shown the way it looks at the end of the stroke. The partially made swing hanger is now placed in the former shown in Fig. 51. This engraving shows the part with one end bent around and the forming ram in position for the bending of the other end. On the first stroke in this bender the end that is farthest from the ram, is bent up far enough to be out of the way as the other end is bent around. As the metal is red hot, this bending up of the one end is easily done and as easily tapped back into place with a hammer, before placing it on the form for the final bend. The construction of this former is too clearly shown to need explanation, except that the part of the end of the forming ram, that is under the guard plate, is of practically the same shape as the part that shows, a roller being used on the contact parts of both sides of the end. The coiled spring is, of course, to keep the ram against the forming guide during the entire stroke. After the ends are bent to place, they are welded in the dies shown in Fig. 52, which are also used in a bulldozer.

Cylinder carrier brackets are cut to length, drilled and then shaped on the former, Fig. 54. A finished bracket is shown leaning against the end of the truck on which the former is placed. The bracket is located correctly in the bending form, by means of a hole drilled in the middle of the bar into which a pin in the form, operated by the small hand lever *A*, is inserted.

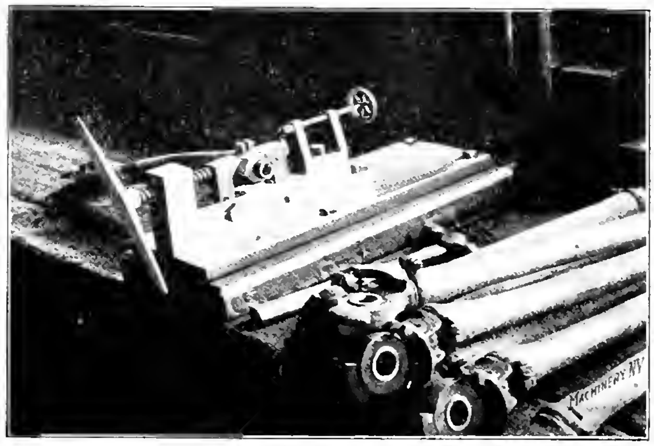

Fig. 57. Tool for Compressing Air Hose Clamp Collars

the part *B* over, forming a part of the eye. Part *D* next strikes the projecting end of the rod, bends it part way around and then coming in contact with the bevel, shoves it over, completing the eye. The recess *E* is intended to be

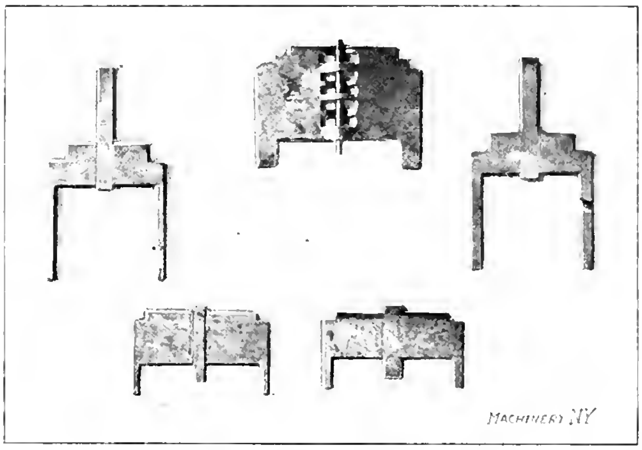

Fig. 58. Air Valve Lift Gages

Fig. 59. The Babbitting Room

used when connecting a chain to the eye-bolt, the end link of the chain being slipped into the recess and the end of the rod passed through it and bent as usual.

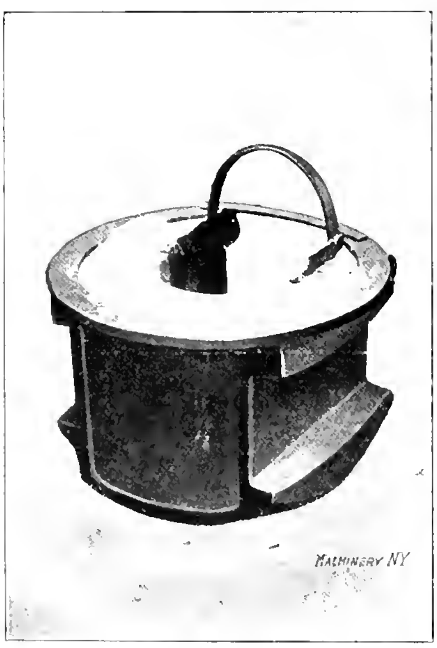

Fig. 60. Babbitting the Side of a Driving box to Compensate for Wear

Fig. 61. Heating the Driving-box preparatory to Babbitting

Fig. 62. Heating a Cross-head preparatory to Babbitting

Fig. 53 shows how hinges are made, which is very similar to the forming of an eye-bolt. The bar heated on the end, is placed in the former and locked by the eccentric hand lever *A*. On the stroke of the ram the hinged piece *B* shoves the cross-slide over, pushing the end of the bar around the form pin far enough for the part *C* to catch it and complete the bend, the final motion of the part *C* being exactly the same as that of the corresponding piece on the eye-bolt bender.

Repairing Air-brake Couplings

Air-hose couplings are forced into the ends of the new hose lengths in the little device shown in Fig. 56. The hose is held and locked by the eccentric lever *A* and the coupling is shoved into place by pulling on the lever *B*. The locking collars are compressed, while the bolt and nut are put in place and tightened, in the clamping device shown in Fig. 57.

The gages used to measure the amount to take off of the

plugs in a Westinghouse air pump, in order to allow the proper valve lift, are shown in Fig. 58. These gages are of a simpler form, but made on the same principle, as those shown in Fig. 33 (page 662), of the May number. The movable slide in the center is made of such a length, that when the shouldered end is placed in the plug opening and the center piece pushed down on top of the valve, the distance from the other end of the slide, to the ends of the fork, indicates the length the plug should be from its shoulder to its end, in order to allow the valve to lift just right. Friction alone is depended upon to hold the slide of the gage in whatever position it is set.

Babbitting Jigs

The babbitting room, Fig. 59, is a very complete little department all by itself, but under the general supervision of the machine shop foreman. Fig. 60 shows the way the sides of the driving-boxes are faced with babbitt. A special ring is laid on the box, and two pieces held in place by a loop spring, completes the "mold." Babbitt is then poured into this mold and the job is done. Before using this mold,

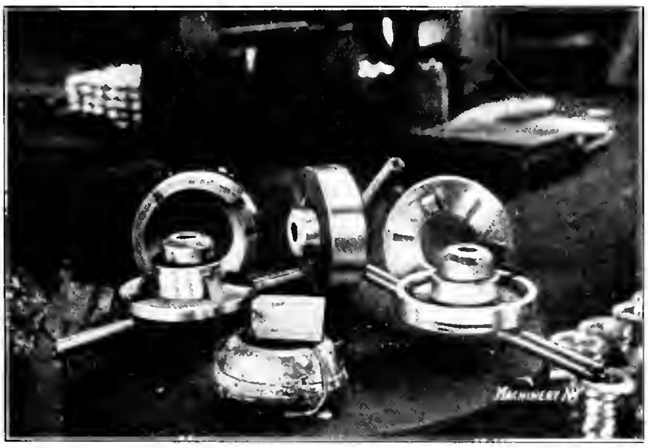

Fig. 63. Metallic Packing for Piston-rods and Molds in which it is cast

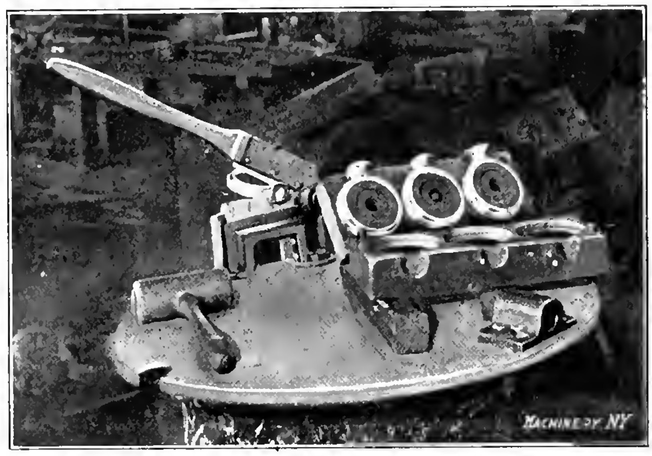

Fig. 64. Other Packing Molds and a Sprue Cutter

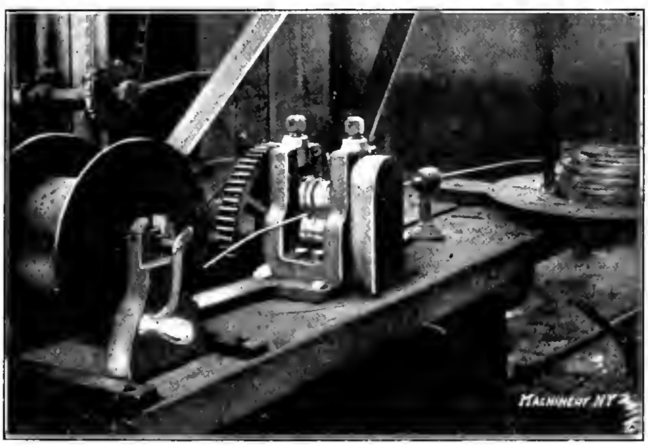

Fig. 65. Rolls for Flattening and Sizing Copper Wire for Gaskets

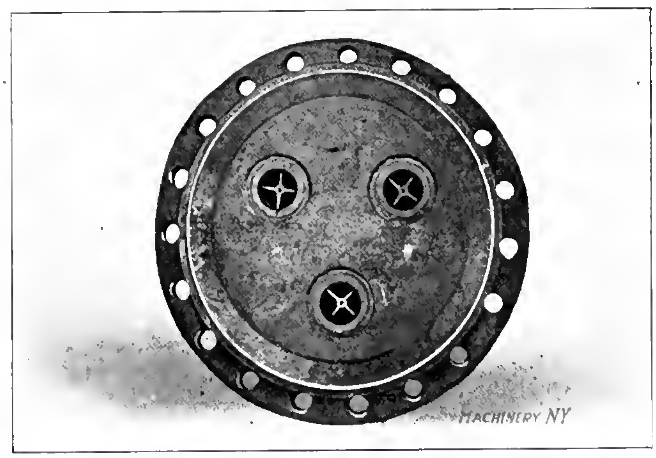

Fig. 66. A Dome Cover with Copper Wire Gasket in Place

however, the box must be heated and tinned on the side in order to make the babbitt stick properly. The heating is done as shown in Fig. 61. The driving-box is placed on a little four-wheeled iron truck and run under a big hood. A pan containing burning coke is then set on top and the heat forced down onto the side of the box by an air blast as shown. After being sufficiently heated, the coke pan is removed, the truck pushed along a short distance, and the end of the box tinned with solder and the babbitt put on as already shown.

Fig. 62 shows the heater used to heat crossheads previous to putting on the babbitt liners. These liners are molded by clamping an iron band around the edge of the surface to be babbitted, which has been previously tinned, the whole process being similar to the way the driving-boxes are babbitted.

Metallic packing is made in a department in charge of Mr. Edwards, who has been with the company nearly forty years and has patented a number of things now in common use on railroads. Fig. 63 shows a set of Edwards piston-rod packing rings, and the three molds used to produce them. Another set of packing molds and a sprue cutter are shown in Fig. 64.

Wire Gasket Practice

Considerable difference of opinion exists in various railroad shops as to the best method of making or applying copper wire gaskets for dome covers and steam chests, some lapping and brazing the ends and others just butting them together. Mr. Edwards' method is to first run the wire through flattening rolls, Fig. 65, in order to give it a uniform thickness, and then to force the wire edgewise into a groove cut for the purpose. Fig. 66 shows a dome cover in which a gasket has been inserted in this way. The ends of the gasket are beveled to about 45 degrees and are fitted closely together in the groove, but not brazed or soldered in any way.

* * *

PURE AIR LAW FOR WORKMEN

C. M. RIPLEY*

The new labor law requiring a supply of fresh air for employes of work-shops and factories, reads as follows: "The owner, agent or lessee of a factory shall provide, in each workroom thereof, proper and sufficient ventilation; if excessive heat be created or if steam, gases, vapors, dust or other impurities that may be injurious to health be generated in the course of the manufacturing process carried on therein, the rooms must be ventilated in such a manner as to render them harmless, so far as is practicable."

Mr. William W. Walling, chief factory inspector for the state of New York, interprets the law as follows:

"As defined by Dr. John S. Billings, perfect ventilation means that any and every person in a room takes into his lungs at each respiration, air of the same composition as that surrounding the building, no part of which has recently been in his own lungs or those of his neighbors, or which consists of the products of combustion generated in the building, while at the same time he feels no currents or drafts of air, and is perfectly comfortable as regards temperature, being neither too hot nor too cold. How much air is required to meet these conditions? Not less than 2,000 cubic feet per hour for each person, with the same amount per hour for each cubic foot of gas consumed whether for light, heat or power."

* Address: 45 W. 34th St., New York City.

Is this Amount Arbitrary?

Some landlords in New York City have put forth the claim that the amount of fresh air specified by the Department of Labor is an "arbitrary quantity." Several authorities on the subject of ventilation who have been consulted in the matter and who are also entirely disinterested agree that 2,000 cubic feet per hour per person is common practice and is based upon definite laws or rules which have been followed for many years in the design of ventilating systems.

The Architects' and Builders' Pocketbook, compiled by Mr. Frank E. Kidder, states that 1,800 cubic feet per hour per child should be the standard for school buildings, this amount being required by law both in Massachusetts and New York. It further states that in buildings more closely packed, and occupied for a longer period, the air supply should be from 2,000 to 2,500 cubic feet per hour per person. In giving an example of a school-room of certain dimensions, he shows that the standard amount of air would result in the air in the room being changed about eight times per hour, which certainly does not appear to be an excessive amount.

Since the above applies only to buildings where people sit quietly, or for buildings where only children congregate, it is difficult to see how the New York Department of Labor can justly be accused of an "arbitrary" action.

Mr. Percival Robert Foses, consulting, heating and ventilating engineer of New York City, states that he has found the rate of 2,000 cubic feet per hour per person a satisfactory and conservative working basis. This was used in designing the ventilating equipment of the large department store of B. Altman & Co., in the Rikers Island Penitentiary, in the Baltimore Stock Exchange, and in the new Hearst Building at San Francisco, as well as in others; and he stated that the operating expense for a system laid out on this basis has not been found excessive, and will not be if due care is taken at the time of installation.

Example of a Loft Building

In a loft 25 feet wide and 100 feet long, containing 80 workmen, and lighted with electricity, the amount of air required would be 80 times 2,000 = 160,000 cubic feet per hour. This amount of air per hour would move at the rate of about 1/4 mile per hour, and would be sufficient to change the air in the loft six times per hour, assuming a ten-foot ceiling. Since the Massachusetts and New York State laws for school rooms require eight changes per hour and since some authorities recommend even 50 per cent in excess of this, it appears that the action of the factory inspector hardly comes within the definition of the word "arbitrary."

Gas Lighting

Dr. Daniel R. Lucas of New York City states that it is a well-known law of hygiene that one gas jet will consume as much oxygen as five persons. Since electric lighting, thanks to the new high efficiency lamps, has been reduced in cost 50 per cent or more, it appears that the easiest way to comply with the labor law regarding ventilation would be to abandon gas lighting. In New York City especially this would seem advisable, as electricity can be bought by meter from the street or from the power plant downstairs.

Since the vitiating effect on the air of the average gas light is equivalent to that of five persons, it can be readily seen that the ventilation required will be reduced 5/6 by abandoning gas light, assuming one gas jet to each workman, or, stating it in another way, the landlord who clings to gas lighting must install ventilating apparatus six times as large as would be necessary if electric light were used. This calculation is also based upon conditions where one gas jet is provided for each workman.

Operating Costs

The operating cost for a ventilating system is made up of two items: (1) Power for turning fans; (2) Additional heat for incoming air. In a loft building where the tenant will pay for the power, and the landlord will pay for the extra heat required, since heat is included in the rent, the expense will be divided automatically. It will here be noticed that the adoption of electric lighting will cut down the operating expenses to a remarkable degree. This cut in expense will benefit the tenant, since a much smaller ventilating motor will be required, and it will also benefit the landlord because less air will have to be drawn in, and hence the cost for heating will be diminished.

In large systems the services of an expert heating and ventilating engineer would probably prove valuable, and it is possible to so design the equipment that a judicious "recirculation" of the air from halls and basements will effect an economy in the fuel bill. This air is seldom impure and requires much less heat than if cold air were brought in from outside. It is also possible in buildings where high pressure steam is available, or where boilers which have been run at low pressure steam can be run at a high pressure, to adopt the following policy: Provide steam engines to operate the fans and turn the exhaust steam into the heating coils, thus getting a double use out of the steam and cutting down the electricity bill. This idea could be carried still further in many instances, and economies could be made (especially in the winter) by abandoning electric pumping, and again reducing the expense for electricity. This is the stock argument of the advocates of isolated plants, who contend that great economies result in buildings of a million cubic feet or more, if engines are installed and electricity is made on the premises. It is a fact that steam at high pressure contains only about 6 per cent more heat than steam at low pressure. Thus the argument that electricity can be made and a building heated with exhaust steam, is advanced. The layman does not appreciate one very peculiar fact about steam: that at 5 pounds pressure it is only about 6 per cent cheaper to make than at 100 pounds pressure, showing that the cost does not increase in proportion to the pressure.

In the future it is probable that factories and loft buildings will be equipped with ventilating apparatus at the outset, with the ducts concealed in the walls and the fans located in the basement. A model building of this character has recently been completed at 37-43 West 26th St., New York City, in which the landlord at the time of construction had the ventilating system installed at his expense, after the design of a prominent consulting engineer. Thus the cost of operating a system and the responsibility of maintaining it in good condition does not rest upon the tenant. At the present writing (June 17) we are informed that the owners of the West 26th St. corporation, with offices at 725 Broadway, have already rented eight out of the twelve floors, a flattering reception and appreciation of the advantages they have to offer.

Importance of Pure Air in the Industries

In the report of the United States Bureau of Labor at Washington, D. C., it is shown that deaths among factory workers due to consumption were divided as follows:

Employes exposed to metallic dust	36.9 per cent
Employes exposed to mineral dust	28.6 per cent
Employes exposed to vegetable fiber dust	24.8 per cent
Employes exposed to animal and fiber dust	32.1 per cent

It was also shown that the highest consumption mortality existed among operators of grinders, and 49.2 per cent of all deaths were from that disease.

An ingenious conclusion was reached by Mr. Frederick L. Hoffman of the Prudential Life Insurance Co., based on this report. It is his opinion that by intelligent methods of ventilation and dust removal the consumption death rate among the wage earners could be so reduced as to result in an annual saving of 22,238 lives. This would add, quoting the *Engineering News*, "15.4 years of life for every death from consumption avoided by rational conditions of industrial life." Such a gain would represent a total of 342,465 years of additional life, and by just so much the industrial efficiency of the American nation would be increased. Placing the economic value of a year's life time at only $200, the total average gain to the nation would be $3,080 for every avoidable death of a wage earner from consumption, representing the enormous total of $68,493,000 as the annual financial value clearly within the range of practical attainment. Therefore, nothing within reason should be left undone as a national, state, individual, or social duty to prevent that needless but now enormous loss of human life from consumption due to the unfavorable conditions in American industry.

MAKING SOLDERLESS CANS FOR FOOD PRODUCTS

RALPH E. FLANDERS*

For a number of years, in riding out of New York on the "Shore Line," the writer has noticed on the right-hand side of the track, shortly after leaving Mt. Vernon station, an unusually neat and attractive group of shop buildings. The sign on the roof of the main building reads "Max Ams Machine Co." with some supplementary reference, which escapes the memory at the moment, relating to a process of manufacturing a sanitary, solderless can. While he has seen this sign for several years, and has always felt a twinge of curiosity at each passage, it was only within the past few weeks that he embraced the opportunity to become acquainted with the men who are working at this place and with the work which they are doing.

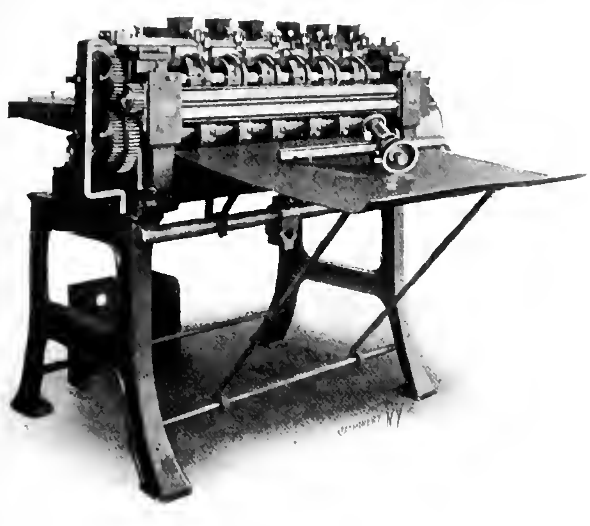

Fig. 1. Slitting Rolls with Double Cutting Edges and Self-contained Grinding Attachment

The product of the shop and the methods of manufacture were found to be fully as interesting as the exterior gave promise of. Besides the line of work indicated by the sign, which now forms but a small part of the firm's output, the shop was found to be building a general line of tools for sheet metal working. There was evidently also a lot of contract work of various kinds going through the shop, both special machinery and tools, and it was evident that the mechanics here stand ready to tackle any job in sight in the line of small and medium metal working, taking particular pleasure in undertaking stubborn problems that have long resisted solution.

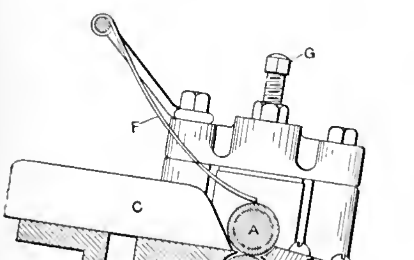

Fig. 2. Two-roll Bending Machine with Simple Adjustment for Radius of Curvature

The Ams Sanitary Can

But to get back to the sanitary cans. While this is now but a small portion of their work, it is a most interesting one, and with the permission of Mr. Ams some of the methods and machinery employed by this process are here illustrated and described. This system undertakes to make a can hermetically tight without the use of solder, brazing of any sort, or heat, the process being a cold one. This statement refers strictly to the sealing of the top and bottom of the can. The side seam is a new lock-seam which prevents any solder from the outside of the can body entering the interior of the can. The inside of the can is absolutely free from solder or acid, and a process which does not employ acids or other fluxes, or solder of any kind, has immense advantages from the sanitary standpoint.

* Associate Editor of MACHINERY.

Making the Body of the Can

The making of the body of the can will first be described. This does not differ materially from the process usually followed. Sheets of tinplate are first run through slitting rolls, such as shown in Fig. 1, and cut into strips of the proper width for the body of the can to be made. After thus being passed through lengthwise, the adjustment of the rolls may be altered, and the strips passed through again crosswise, thus cutting them into blanks of the size required.

Two or three improvements in the construction of these slitting rolls may be noticed. In the first place the cutters themselves are provided with cutting edges on both sides. This is an advantage oftentimes in setting them for work on narrow strips; and giving two edges in place of one doubles the life of the cutters as well. The principal improvement in the construction, however, relates to the sharpening of the cutting disks, which is done while they are in place in the machine. The attachment for performing the operation is seen on the receiving table in the illustration. It is a cup emery wheel, driven by a belt from an overhead drum and mounted on the swiveling holder seen on the bar beneath the table. By swinging this table down out of the way and dropping the delivery rolls, the disk cutters are exposed to the action of the emery wheel and the sharpening can be proceeded with expeditiously and effectively.

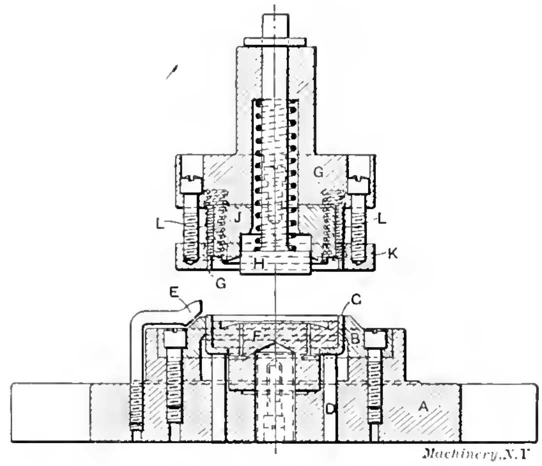

Fig. 3. Compound Punch and Die for Turning Can Cover shown in Fig. 4

After thus cutting the blanks to the proper dimensions, they are bent into cylindrical form by the rolling machine, shown in Fig. 2. This has but two rolls in place of the three often used for such work. The blank is fed from the table *C* between rolls *A* and *B*. After passing through, the edge passes the guide plate *D* and is by it turned up about roll *A*. The radius of the curvature thus produced is regulated by adjusting screw *E*, which rocks guide plate *D* about the axis of roll *B*. This machine takes the blanks as fast as a dexterous operator can feed them between the rolls.

The soldering of the side seam may be done by hand with special fixtures, or on any of the commercial machines provided for the purpose. The makers have developed an automatic machine for this work in which the cylindrical sheets are placed by hand on a series of forms, which are indexed about a vertical spindle. As they are being pressed on the forms the edges pass under brushes which lay on the acid flux. The next indexing of the spindle brings the work to the soldering iron, where strips of solder are laid along the seam, being cut off and smoothed on by a mechanically operated iron, heated by gas. In the third position the work is allowed to cool, and in the fourth it is removed from the form, leaving it ready for the next piece.

The final operation on the body of the can is that of flanging to the form shown in the sketch at *A* in Fig. 4. This flanging is done in a simple and obvious way by inserting the work in rolls, which rotate it and turn up the edge as it revolves.

Making the Covers

The can covers are blanked and formed from the sheet in a single operation by a double action die, shown in Fig. 3; the shape given to them is indicated in the upper left-hand corner in Fig. 4. A sheet is laid in the die against stop *E* in

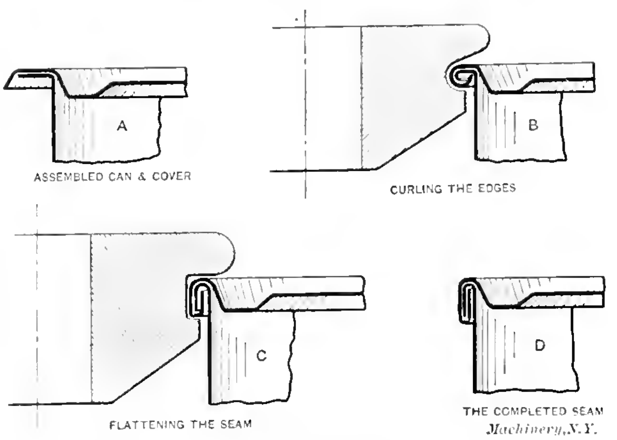

Fig. 4. The Sequence of Operations followed on the Double Seaming Machine

Fig. 3. The descent of the punch cuts out the blank between die *B* and punch ring *G*. The continued descent of the ram holds this blank firmly between *G* and pressure ring *C*, which is supported on pins *D*, which, in turn, are acted on by heavy rubber springs beneath the bed of the press. The spring plunger *H* also serves to hold the blank on the inside against

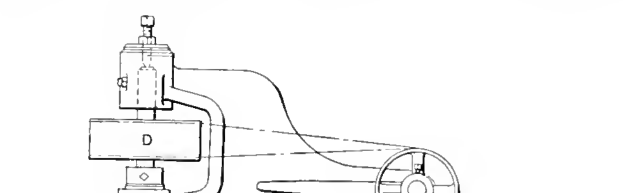

Fig. 5. Side Elevation of the Double Seaming Machine

forming die *F*. Pressure ring *K*, supported by springs *L*, has been holding the stock meanwhile. The blank thus cut out and held, is formed between dies *J* and *F* and ejected on the up stroke by the springs acting on members *C*, *H* and *K*.

As mentioned, the forming of the joint between the cover and the body is a cold process. It would be difficult to make this joint tight on a metal to metal fit, a leak being liable to occur near the seam of the body. To prevent this, the can covers are fed into an automatic machine, which deposits a very thin coating of an odorless and harmless compound in the groove of the cover, where the joint is made. This machine, which we are unable to show here, is simple and effective, and furnishes the means for rendering the can absolutely air-tight.

The Double Seaming Operation

The bodies and the covers are now ready for the seaming machine, in which is incorporated the basic feature of the process. In the old process, the can cover is made with a flange, fitting the body and soldered to it by an automatic process. In this case, however, the body and the can are rolled together into a double-lock seam by the series of operations indicated in Fig. 4. The can and cover are shown assembled at *A*. At *B* they are supposed to be held together and revolved rapidly in front of the first forming roller, which curls up the lips of the body and cover as shown. This roller then retreats and the second one comes up, flattening the seam firmly and neatly, as shown in progress at *C*, giving a result like that shown at *D*, where it is, however, shown somewhat loosely joined to more plainly indicate the construction. The seam is an exceedingly straight and neat one, and is rendered hermetically sealed by the lining process for the cap, previously described.

The machines for performing this seaming operation are shown in detail in Figs. 5 and 6, and in elevation in Figs. 7, 8

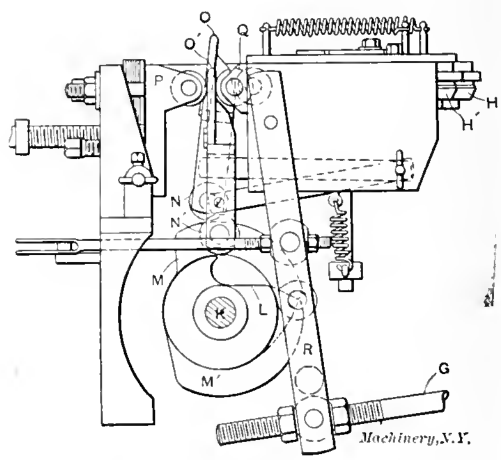

Fig. 6. The Cam Mechanism of the Seaming Machine

and 11. The can body is placed on a face-plate pivoted on spindle *E*, on which it loosely revolves. A similar face-plate is keyed to the upper spindle, driven by pulley *D* from driving pulley *A*. The cover and body are held together between these two face-plates, the pressure for this purpose being applied to spindle *E* either by hand or automatically, as will be described. As soon as this pressure is applied the can commences to revolve rapidly. The two rollers are in the position shown at *H* in Fig. 5, side by side. The mechanism for actuating them is shown more plainly in Fig. 6, which represents a view taken from the opposite side of the machine from that shown in the previous illustration.

The cam-shaft *K* (driven by worm-gearing *J* and pulley *C*, see Fig. 5) carries cams *L*, *M* and *M'*, which respectively operate levers *R*, *O* and *O'*. Lever *R*, by means of reach rod *G*, automatically raises spindle *E*, clamping the can and starting it to rotating. Levers *O* and *O'*, which are provided with wedge faces at their upper ends, as shown, enter one after the other between rolls mounted in back-stop *P* and slides *Q*. The latter furnish the support for rolls *H* and *H'*, which are thus brought successively into operation, forming the seam as shown in Fig. 4. The cam mechanism stops at the completion of the operation, and is started again by the operator when the work has been removed and new pieces placed in the machine.

In Fig. 7 is shown a machine of the same construction, but provided in addition with an automatic feed, the nature of which will be readily understood from the engraving. The cans are fed between guides on the work-table, as shown, from which they are advanced step by step by a pair of holders on each side, which advance, seize the cans, move them up into place between the spindles, open out and retreat for an-

other hold. An automatic ejector is also provided for removing the work from between the face-plates.

By the means just described, the cans are provided with a body and a bottom. They are now filled with the product for which they are to be used. It should be noticed that this

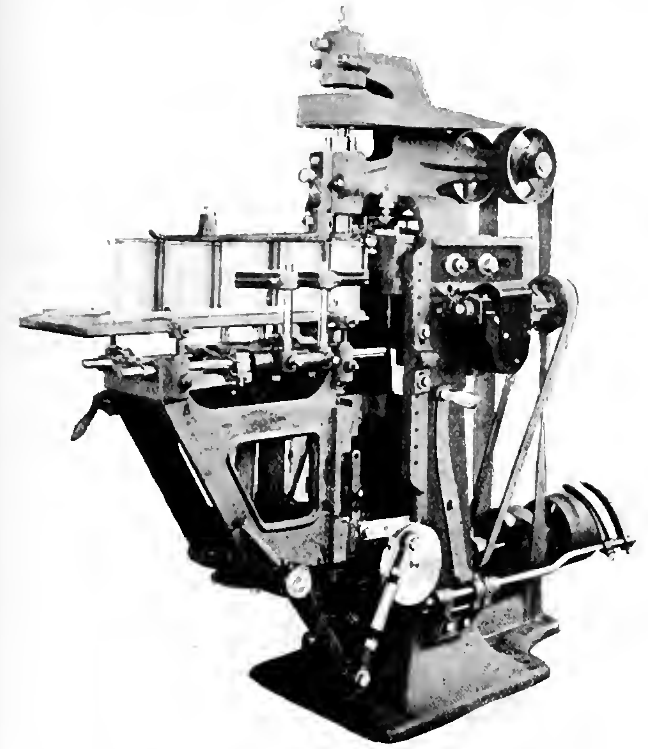

Fig. 7. Automatic Double Seamer for Cans for Food Products, from the One Pound to the One Gallon Size

filling is done through the full opening in the top of the can, instead of through a small opening in the cover, as is usual in soldered cans. This permits filling without special machinery, and without waste from slopping over outside of

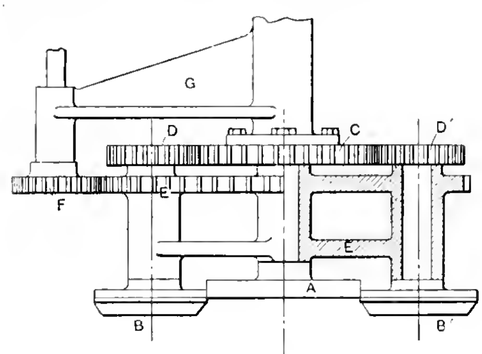

Fig. 9. Principle of the Machine shown in Fig. 8, when used for Square Cans

small openings. It also permits the easy canning of bulky materials, such as large fish, fruit, etc. After filling, the cans are again put through the same machine, and the cover is rolled and seamed into place by the same process, without the use of acids and solders, as previously described.

Seaming Machines for Square and Irregular Cans

A modification of this seaming machine is shown in Fig. 8. This operates on the principle illustrated in Fig. 9. In this machine, the can, instead of revolving, is held stationary, while the rolls are rotated and run around the edge. This is done sometimes for round cans where it is not desired to rotate the can, and it is the method always followed for square and irregular shapes of cans. The principle of the device as applied to a square can is shown in Fig. 9. A is the stationary can, and B and B' are the first and second rollers. It will be seen that these are of a contour to match the outline of the can A, when their centers are rolled about it in a circle. The face-plate A, which presses down on the can, is stationary. The frame E is revolved about it by the pinion F, meshing with gear teeth E. Journals are formed

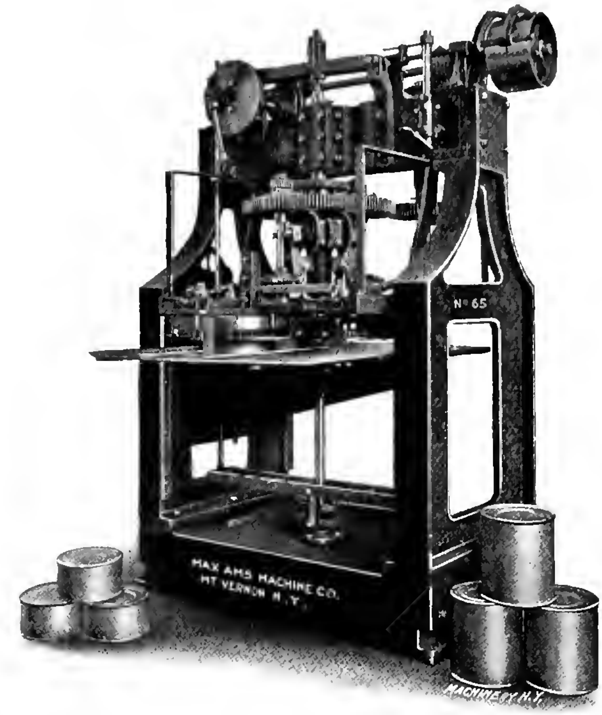

Fig. 8. Automatic Double Seamer for Large Cans for Meat, Fruit, or Paint, up to Five Gallon Size

in E for the spindles, which carry rolls B and B'. The upper ends of these spindles carry gears D and D', meshing with stationary gear C. It will thus be seen, that as frame E is revolved, rollers B and B' will also be revolved following the contour of the can and face-plate at A. The pitch lines of gears D, C and D' are shown in the lower diagrammatic view of Fig. 9.

Suitable means are provided in the machine shown in Fig. 8 for forcing first roll B and then roll B', successively in against the work, and withdrawing them at the completion of the operation. A feed of somewhat similar construction to that of the machine shown in Fig. 7 is used. These machines work with surprising rapidity, tossing the cans off so

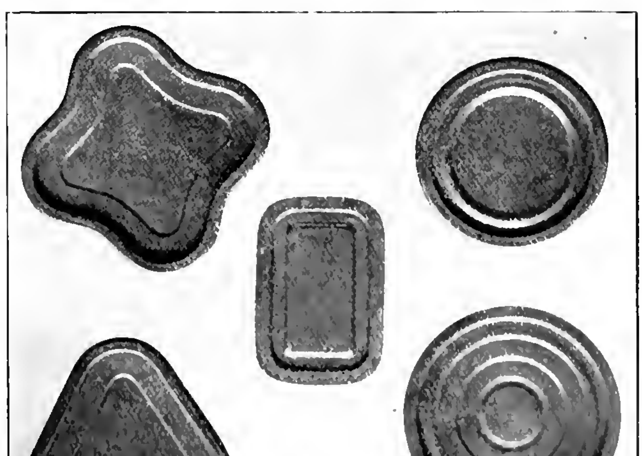

Fig. 10. An Assortment of Can Covers sealed by the Cold Process

fast that it would seem to be hard work to take care of them as they are delivered.

This last machine is not only adapted to round and square cans, but to irregular shapes of the greatest variety. A few of these are shown in Fig. 10. The American cans have been standardized to definite dimensions and capacities, and few

fancy shapes are found among them nowadays. The two covers shown at the left of Fig. 10 are of Italian origin, and doubtless exemplify the artistic instinct of the race, which will show itself in a can of preserved fish as readily as in

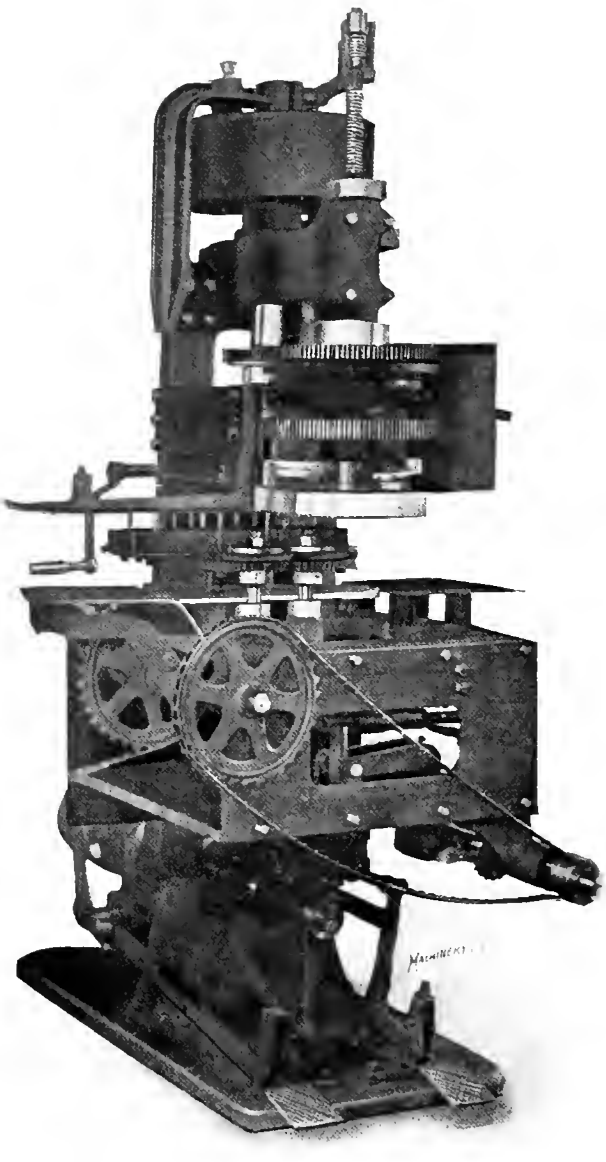

Fig. 11. Automatic Double Seamer for Condensed Milk Cans or Food Products

a marble statue or in an opera. This artistic instinct gives some difficulty to the man who lays out the rolls for forming the seam; but the job can be done to the queen's taste nevertheless, with care and experience on the part of the designer.

* * *

In the manufacture of the best grades of leather belting, a comparatively small section of a hide is used, this being a strip about 30 inches wide extending from the tail to a point just back of the shoulder, its length being about four feet. On account of the ignorance of most users of belting, and the difficulty of telling the grade of a belt except by use, certain leather belt makers are not over scrupulous as to the grades of leather entering their product, and we find not only is the section mentioned used, but flanks and other undesirable parts which are doubled with first grades in double belting. A belt made up in this manner may not in appearance be inferior to a belt made only from first-class parts, but in use it is bound to give inferior service. The use of the poorer grades with the best grades of leather belting is particularly bad. The inferior grades soon stretch, throwing almost the entire stress of belt pull on the superior grade. The result of this uneven tension is to quickly deteriorate the belt. Probably a belt made up in this manner is inferior to that made of the poorer grades throughout. Making the belt of inferior grades throughout has the merit of equalizing the stretch, keeping both parts in even tension.

A NIGHT-SCHOOL COURSE IN BLUE-PRINT READING

GEORGE A. HEPKE*

From time to time there have appeared in technical magazines and journals articles pertaining to courses as taught in night schools, in which the best way to present such courses in order to get the desired results, was discussed. I have followed these articles rather closely, but I do not remember having seen one in which the method of teaching blue-print reading is treated. No doubt, many of MACHINERY'S readers will be interested in the plan I followed in teaching the subject to a night-school class composed of pupils who were working in the different manufacturing establishments and who were handicapped by not being able to read blueprints.

The idea was to cover about the same ground as a course in mechanical drawing, but in a much shorter period of time. The pupils desired to be able to read a blue-print correctly, but they did not want to spend the time necessary to become proficient in drawing. Nevertheless, they were desirous of understanding how projections, etc., are derived. At first a temporary schedule of instruction was arranged, but this had to be departed from during the course in order to meet the conditions. The course, as originally planned, was to include twelve lessons, one each week of 1½ hour duration. On the opening night there were ten pupils in the class-room, who ranged in age from 20 to 35 years. They were all followers of mechanical trades in local manufacturing establishments, working as molders, machinists, pattern-makers and core-makers. It was evident after questioning the pupils that it would be necessary to start with elementary work. They understood an object in the plan view, but as soon as it was turned and another view projected, they were at a total loss as to what the different lines then represented. In order to present this subject of projection as clearly as possible, wooden blocks were made as shown in the different illustrations, the construction of which will be explained in the descriptions of the lessons. These blocks, together with blackboard illustrated lectures, aided greatly in making things appear simple and clear.

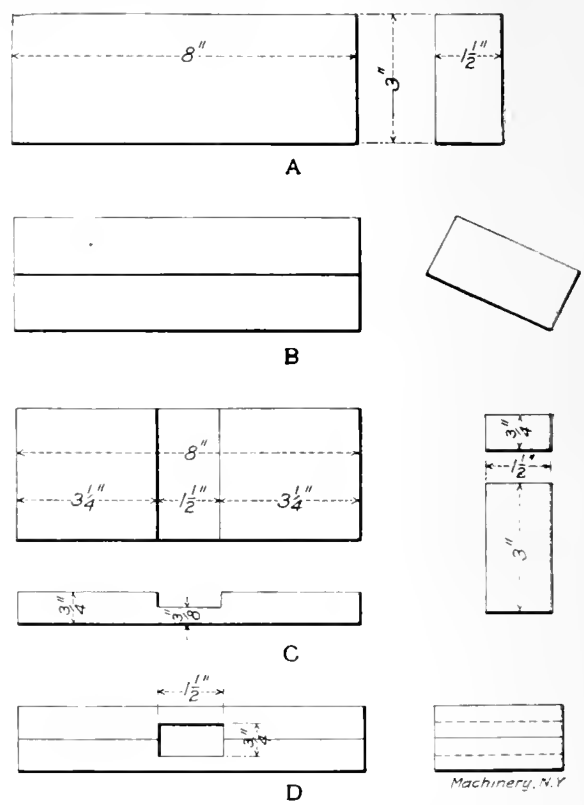

Fig. 1. Built-up Rectangular Prism used in teaching Projection

In the beginning, the difference between perspective and mechanical drawing, and why the former cannot be used extensively in mechanical lines, was explained. In begin-

* Address: 210 Chestnut St., Hamilton, Ohio.

ning the instruction in projection, a drawing of an assembled rectangular prism (built up of three parts) showing all the full lines but no dotted lines whatever, was made as shown at *A*, Fig. 1. As no dotted lines were shown, the prism appeared as though it were made of one piece, but in reality

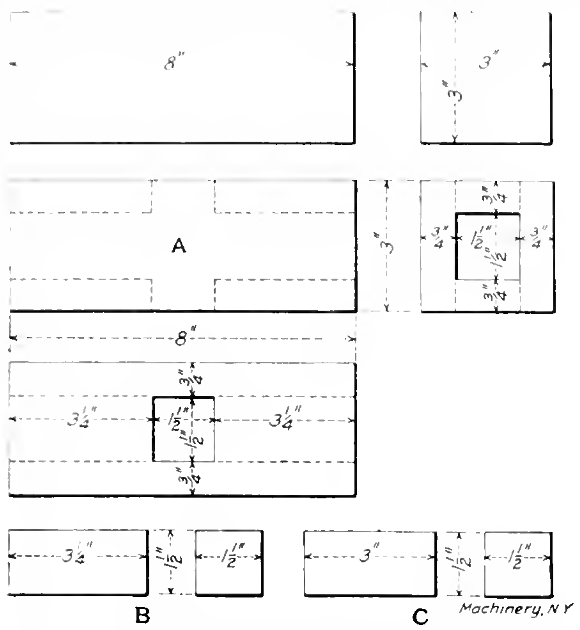

Fig. 2. Another Built-up Block with which Various Forms can be obtained for teaching Projection

it was composed of the three pieces. This prism was next projected as shown at *B*, after which it was taken apart and the pieces which formed it, projected as shown at *C*. This was done to illustrate how the channel through the center would be indicated on a drawing. Two of the three parts which form the prism were then placed together, as shown at *D*, which made it appear like a solid block with a hole cut through it. This hole gave dotted lines in the end view as shown. To illustrate the need of dotted lines, I used clear

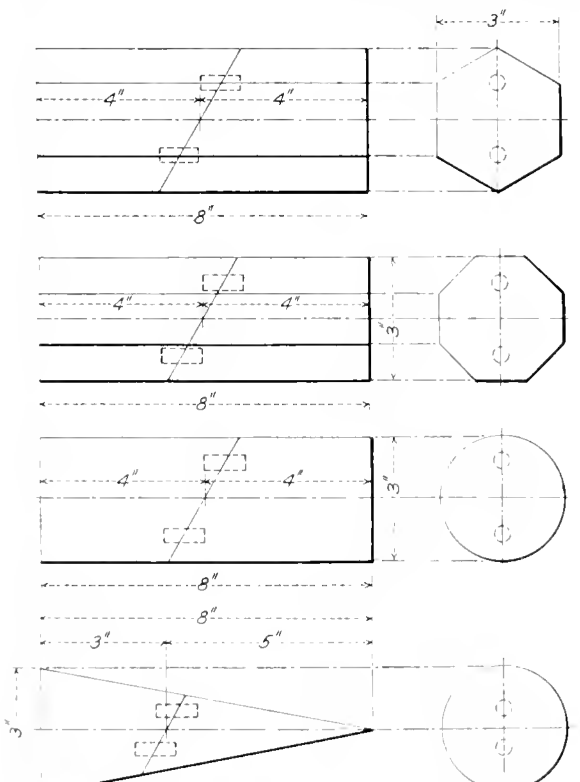

Fig. 3 Prisms, Cylinder and Cone, which were also used in teaching Projection

glass as an example, and the pupils were told that if the piece as assembled were made of glass, the lines representing the hole cut through the prism would appear full, but as the piece was made of a non-transparent substance, dotted lines were used to represent lines that did not appear to the eye.

The square prism shown in Fig. 2 was the next object used, and about the same instruction was given as with the rectangular block. This prism was composed of one piece *A*, two pieces *B*, and one piece *C*. When these pieces were put together we had a solid square prism and by taking them out, projections in which dotted lines appeared were obtained. The next objects drawn were the hexagonal and octagonal prisms, after which cylinders and cones followed in the order mentioned. With the different prisms made as shown, we were able to get quite a number of combinations and projections.

At first, only projections of the complete solid bodies were taken as shown in Fig. 3. The blocks which were held together by dowels, were then taken apart so that the projecting of angular surfaces could be practiced. As shown in Fig. 4, all the lines were designated by letters, so that the corresponding lines in different views could be easily located. These letters were found to be a great aid. The idea in giving the pupils the angular projections was to fit them so that when they encountered round bosses or pads of other shapes shown at an angle on a drawing, they would readily see how the projections in the plan or other views were derived.

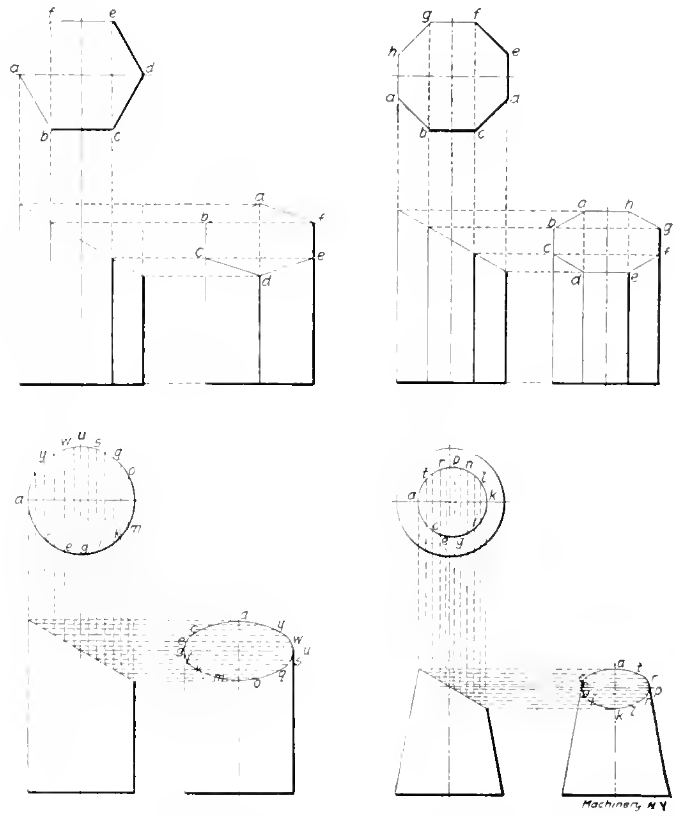

Fig. 4. The Blocks shown in Fig. 3 taken apart and used to teach the Projection of Angular Surfaces

Five lessons were devoted to the routine just mentioned and projections were covered quite thoroughly, but this work had to be supplemented by practice still to follow. It was during these five lessons that I discovered that the pupils had the most difficulty in learning in what direction the object was turned or set up to get a given view. The wooden blocks proved very effective in overcoming this difficulty, as they could be turned in whatever direction was necessary so as to correspond with the different views on the blackboard. During the five lessons mentioned the pupils were given the task of making drawings on the board of the different blocks, after a cut-out or something of that sort had been indicated upon the blocks with chalk. They did fairly well with this work, which enabled the judging of their progress, and also whether or not they understood projections.

The next step was to acquaint them with sections and sectioning. Different sections of simple objects, such as the blocks, for example, were drawn, and instructions given in following up a drawing in order to tell at just what point the section was taken when this was not indicated by letters. The type of sectioning for the different metals was also brought up, because in a great many assembly drawings

the kind of metal is not specified, the type of sectioning taking care of that.*

Taps and threads were next discussed, and the different ways of showing threads was explained. Thread pitch and lead were also brought up, and it was explained that where the number of threads and pitch are not given, it could be taken for granted that it was a United States standard thread or whatever standard the firm recognized. In brief, all of the kinks and short cuts that are in general use were explained, such as showing shafts, etc., broken, driving fits, and the method of designating bearings on shafts, with cross lines. The object in explaining all these points was to familiarize the pupils with such things, as I have discovered that the majority of mechanics have not the least idea what these short cuts and kinks represent and are often confused by them.

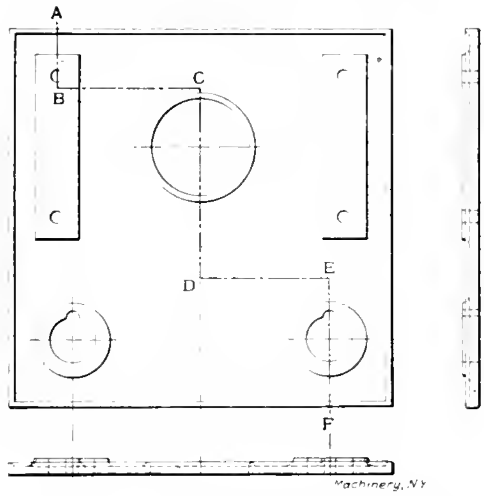

Fig. 5. Type of Drawing used for the Elementary Exercises in Blue-print Reading

The next subject treated was gearing. The different kinds of gears were described and the meaning of pitch diameter, outside diameter, pitch angle, turning angle, cutting angle, and the words addendum and dedendum, were thoroughly explained. We then took up the drilling and tapping of flanges, and all the terms of abbreviations generally used for this work, such as B. C. for bolt circle, D. C. for diameter circle, 2 Up for staggering center line, 1 Up for on center line were given. After that the method of indicating center lines and dimension lines was explained, and also that the arrows at the intersecting lines show that the piece is of the shape given on the drawing for the length between the arrows. Scaling of drawings was also treated, and the method of getting the approximate dimensions of a piece with an ordinary 2-foot rule when the dimensions are not given, and the drawing is made to scale, was explained.

Up to this point a blue-print had not been touched, for my object was to so acquaint the pupils with the various points mentioned that they would make rapid progress when the blue-print reading began. The first blue-print used was that of an engine cylinder sole-plate, as shown in Fig. 5. This simple drawing puzzled the pupils a little because of questions asked them, all the points of the preceding lessons serving as a basis for the questions. Other blue-prints of sole-plates of different types were thoroughly covered by taking sections at different points and showing these on the blackboard. As the students wanted to do a little work at home, I had them draw a section of the sole-plate through *A, B, C, D, E, F*. They did this work very well though they were somewhat confused at first.

The next lesson consisted of engine disk cranks, a governor gear-box, and other prints which were a little more difficult than those of the preceding lesson. The same tactics were followed with these prints, and the pupils were also given more home work, with the result that a decided improvement was soon noticed in their sketches. More and more difficult prints were used as the course continued, with the result that at the end of the twelve lessons, the students had a very good idea how to read a blue-print correctly, but the thing still needed was practice in order to develop this knowledge.

They were now greatly interested and demanded that the course be continued for twelve more lessons, which was granted. We resumed our studies where we had left off, always taking up something more difficult. Some of the lessons consisted of drawings of large pieces, such as engine beds and cylinders, fly-wheels and other large castings. Another line of blue-prints used were those of a 300-ton hydrostatic wheel-press. All the different parts of this press were located in the assembly drawing from the details, and the work was conducted the same as if the class were machining and erecting the complete machine. The pupils were also required to draw sections of the various parts, such as the one illustrated in Fig. 6. After finishing with the press prints, assemblies were dealt with, some of which were rather complicated drawings, until the end of the term.

I do not claim that any of the pupils were experts at the end of the course, but I think that they had a good foundation for development. Had the pupils been familiar with projections we could have covered the same course of study in a much shorter period, and also would have gained considerably more ground. Nevertheless, I am perfectly satisfied with the results when the conditions under which we started are taken into consideration. The course as outlined in the foregoing would probably not work so well in another case, as everything depends upon the men and the conditions, but it will doubtless have suggestive value.

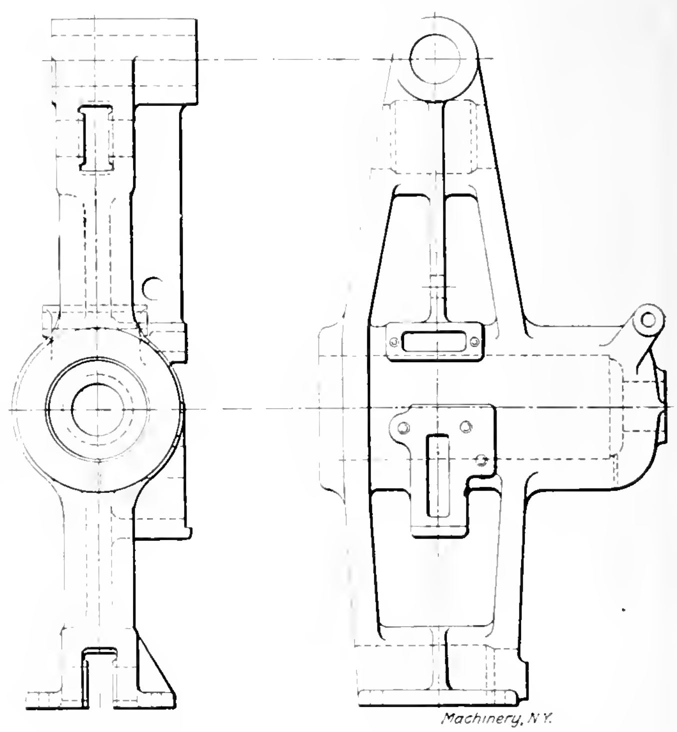

Fig. 6. Detail Drawing used in connection with more Advanced Work

* * *

Referring to the item published in the July number of MACHINERY on the use of "victimized power" in operating penny-in-the-slot machines, in which it was made apparent that the action of the operator was a necessary element in the success of such machines, attention is called to an article in the July 3 number of the *Saturday Evening Post* by Mr. Frederick Thompson, in which he points out that this is a prime factor in the success of all amusement enterprises. Those enterprises are most popular in which the people amuse themselves, the apparatus, game or device being such that the chief factors in the sport are the people taking part. The tickler, witching waves, shoot the chutes, and other devices that have proven enormously popular afford as much or more amusement to the onlookers as to those who participate in the games.

* The practice of indicating the character of materials by cross-sectioning should be abolished. There are no generally accepted forms of cross-sectioning for the common materials even, and as for the less common materials, almost every draftsman feels free to use the form that appeals most to his fancy. In all cases the material should be plainly specified by name.—EDITOR.

ELEMENTS OF ASSEMBLING OPERATIONS*

ALFRED SPANGENBERG†

The machine shop operations usually discussed by various writers have been almost entirely associated with machine work. Aside from this, and a factor of equal importance, is the subject of assembling. In its broadest sense, assembling may be defined as the operation of combining and adjusting the separate parts of each unit in such a manner that these units, when in combination, will properly perform a predetermined function. The operation of fitting is often included in the work of assembling; under ideal conditions, however, a distinct line of demarcation can be drawn, so that the term "fitting" will only apply to the operation of machining.

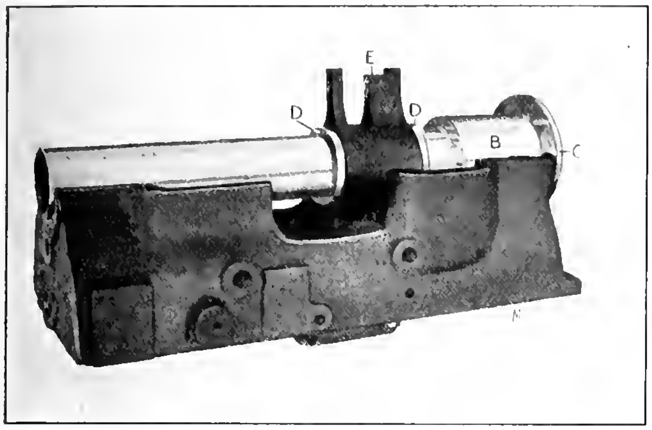

Fig. 1. Method of Gaging Clearances for Spindle Gears in a Lathe Headstock

The purpose of this article is to show the possibilities that lie in developing methods of assembling that will ensure accuracy, economy and standardization, but before giving any concrete examples, it will be well to consider briefly the elements that directly affect the cost of assembling operations. The determination of proper methods and processes of assembling are peculiarly difficult, since the elements of human judgment and skill enter so largely into this work. It is a far more puzzling proposition than that of analyzing and determining the best method for machining any particular part. For this reason, the study of assembling work requires particular care and especially keen analysis.

The Three Factors Leading to Economical Assembling

Accurate drawings, accurate machine work and the use of jigs and gages, are at the foundation of economical assembling. Without these factors, the term "manufacturing," used in its limited sense, really does not apply to the scheme of production. Much has been written on methods of dimensioning drawings and the use of limits as tending to accurate and at the same time cheap production, so that little need be said here on the subject. The system of giving all unimportant dimensions in inches and common fractions thereof, and expressing precise dimensions in thousandths of an inch with the permissible limit of variation, is worthy of wider application. This, coupled with a thorough system of inspection, will insure that the parts function properly when assembled, besides preventing a choice of methods in machining that may entail a vast amount of work when less elaborate methods will produce a job that is good enough for the purpose. While the use of limits on drawings has been unsuccessful in many cases, the principal cause of its failure probably has been due to an injudicious selection of the maxima and minima for different classes of work.

In order to insure the accuracy of the machine work, it is absolutely necessary to provide for a thorough system of inspection in the machine departments. Some manufacturers only provide for inspection of the finished product and refuse to admit the advisability of adopting the broader plan. To state an important point which the author shall want to emphasize, we must always keep in mind not only the possibility of wasted money through excessive time in having to "fit" the parts in the assembling department due to poor machining, but *especially* the waste of valuable time in having to wait for parts to be replaced that have been spoiled in machining, the error not being discovered until ready for use. In brief, it is short-sighted to imagine for one moment that anything like economical results will be obtained in assembling unless this provision is made.

The great value of, and necessity for, jigs and fixtures on duplicate work and their bearing on the cost of assembling is too well recognized to need any further comment here.

Method of Investigation and Analysis

First of all, a careful analysis of the assembly drawings should be made in order to thoroughly understand the purpose of every part of a machine. This is an important consideration and will lead to the adoption of methods that will prevent undue accuracy and unnecessary expense consequent thereto. It is a mistake to accurately align and fit parts that may be said to "fit a hole in the air." The time needed for this can be more profitably spent on those parts that require accuracy and refinement. The purpose of every part should be studied; the operation necessary to produce it can then be regulated accordingly.

A matter that should receive careful attention is the question of rigidity in fits. Those of us who have "been through the mill" are painfully aware of the fact that most workmen fail to distinguish the difference in rigidity required in the fit of a lathe spindle from that necessary in the case of a shaft for operating a clutch lever. An illustration in support of this statement is afforded in the case of an automatic machine that recently came under the writer's observation. The machine in question was built by a manufacturer having a reputation for turning out very accurate work; in fact, the fits were so tight that at times certain members of the feed-stop mechanism would fail to function properly with the result that a part of the machine would be wrecked. After these members were fitted free enough, no further trouble was experienced.

Varying conditions make the determination of proper fits and adjustments in assembling work a question of experience and judgment. As a general proposition, sliding or revolving machine elements that do not affect the accuracy of the machine's product should be fitted perfectly free, so that there will be no indication of the parts working stiff. This applies especially to spring- or hand-operated mechanisms. Sometimes,

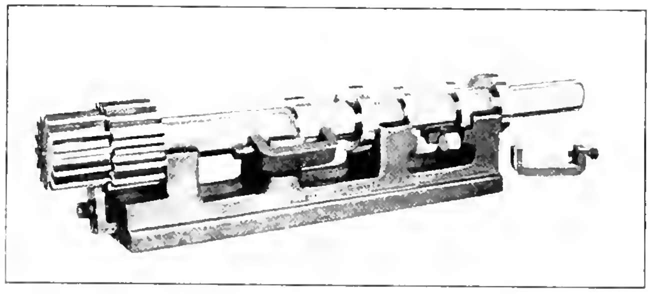

Fig. 2. Jig for Drilling Pin-holes in Collars on their Shaft, to insure Interchangeability

however, the fact that these elements are apparently fitted or adjusted too tight can be attributed to their being out of proper alignment.

The next logical step in the study of the drawings will be to map out systematic and well-defined methods and processes of assembling so that the parts may be quickly and cheaply assembled, all will be in their proper relation to each other, and that the alignment of the various parts will be perfect within the required limits. Various ways of accomplishing the object sought will present themselves successively; unless special considerations prevent it, the process that will accomplish the object sought in the most direct manner is the one to be chosen. This consideration shows the importance of a thorough knowledge of modern methods, the facilities at command, the organization itself, and special tools and appliances.

General Requirements for Efficient Work

The drawings must always be followed. No deviations should be permitted. If any mistake is discovered or change found necessary in the interest of economical assembling, then

* For additional information on this subject, see MACHINERY for February, 1909, "Application of Lifting Devices to Assembling Work," and April, 1909, "Labor-Saving Devices for Scraping Operations."
† Address: 951 W. 5th St., Plainfield, N. J.

these corrections should be approved by responsible parties and made on the drawings. The importance of this is at once apparent. Standardization without observing this rule is impossible, and neglect of it will result in lax, inaccurate, and totally misleading metheds of production. Again, in case of repairs, the new parts can be finished to the drawings with the assurance that they will fit properly. The drawings should always indicate the method of oiling a mechanism, as this matter, if left to the judgment of the assembler, may result in an inefficient system of lubrication.

If any errors are found to exist as a result of mistake in patterns or fault in casting, then these mistakes should be taken care of at once, so as to prevent a repetition on succeeding pieces. In the case of clearances this will prevent unnecessary "carving" to be done either by chipping or machining. In many instances, however, when the clearance allowed on rough castings is small and the design will not permit a change, it is unreasonable to expect avoidance of "carving."

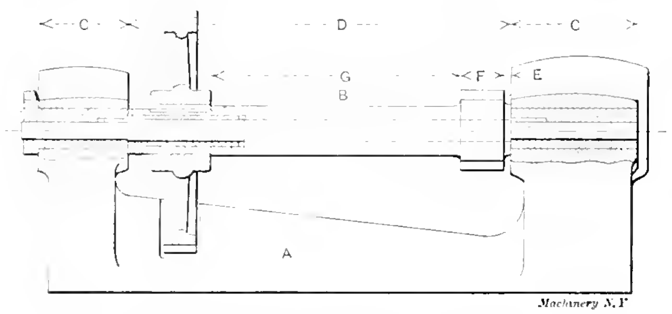

Fig. 3 Illustrating a Case where the Micrometer can be used advantageously for Length Measurements

Such cases should be anticipated before any assembling operations are commenced, and the necessary clearance made by chipping or machining so as to prevent having to take the work apart.

This principle is clearly illustrated in Fig. 1, which shows a lathe head-stock. For special reasons the clearance allowed in the head-stock casting for certain gears that run on its main spindle is very small. The gage for testing this clearance consists of a hollow arbor *B* having a locating flange *C*. Mounted on this arbor and free to turn between the collars *D* is the gage casting *E*, which has a contour 1/16 of an inch larger than that of the gears above referred to. By turning the gage it is very quickly determined whether there are any irregularities on the head-stock casting to be chipped off. The

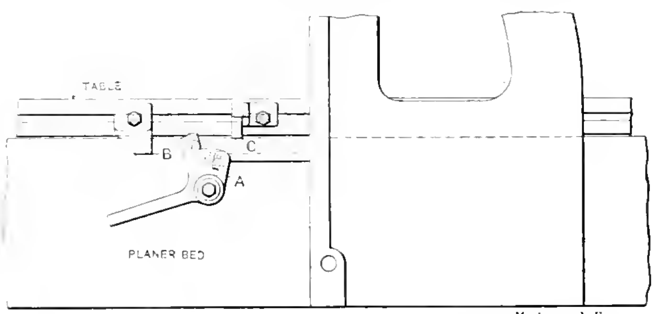

Fig. 4 Example of Work where some Fitting is left for the Assembler

advantages of using this gage are that the irregularities can be more easily seen than by using the gears and spindle; any necessary chipping is done before the assembling operations are commenced; and the gage, being light, is quickly and easily handled.

Much profitable study can be given the question of substituting the machining process for operations that are usually performed by hand, such as chipping, filing, etc. Oil grooves should be machine cut on all pieces that can conveniently be handled on a machine; tap holes can be tapped cheaper on a machine than by hand, except in the case of very small holes in large pieces; set-screw holes in shafts should be drilled on a drill press. The halftone, Fig. 2, illustrates the method of locating and drilling collars on a shaft in interchangeable work.

One example will suffice to show the possibilities of saving time in this direction. For many years it had been the practice of a certain machine tool builder to chamfer the threads on all split-feed screw nuts by chipping and filing. It will be understood that this is necessary in the case of split nuts so as to permit their opening and closing on the feed screw, the chamfer being at the joint. On a certain size nut it formerly took twenty minutes per pair by the hand method. The same size is now milled, using two cutters simultaneously, in one minute per pair, which includes clamping and removing the work.

It is, of course, unreasonable to expect to entirely do away with these hand operations, but in many instances to-day much of the chipping, filing and scraping could be avoided if proper attention was given to the matter. Probably the most notable example of the tendency in this direction is afforded in the manufacture of automobiles, where the hand operations consist merely in combining and adjusting the various elements.

Standardization

Standardization, as already pointed out and emphasized, is one of the "secrets" of economical assembling. It is a matter of common knowledge that interchangeable manufacturing is really economical manufacturing, and yet in many instances its fullest possibilities are not realized. There are many shops to-day that still cling to the old custom of "making every piece like itself." The practices of leaving stock for adjustment on the hubs of bevel gears, facing off the ends of bearings to no particular dimension, planing taper packings to fit slides that are not planed to gage and adjusting parts to fit others that are not standard, must be eliminated if economical results are expected. Some very simple form of gage, such as an inside or outside micrometer, will enable work of this character to be machined standard and made practically interchangeable at a fraction of the cost in assembling.

An example is given in Fig. 3 to illustrate this point; *A* represents an engine lathe head-stock having a back-gear quill *B* running between the eccentric-shaft bearings as shown. The length *C* of the bearings and the eccentric bushings can be made to an outside micrometer, while an inside micrometer is used to measure the length *D* between the bearings, the proper allowance being made on the quill for a running fit. An ordinary scale is used to take the measurements *E*, *F* and *G*, and, if care is exercised, the gear and pinion on the quill will line up with those on the main spindle, if the same precautions are taken in the case of the spindle shoulders and gears.

The experienced man will smile at the idea of these quills having to be adjusted by the assembler, but the author recently visited a shop building small engine lathes where this practice was still in vogue.

Errors in measurements of length are far more likely to occur and cause trouble in assembling than errors in diameter. This is probably due to the fact that in the latter case instruments of precision, such as the micrometer or limit gage, are in more common use. Standard length gages are indispensable on interchangeable work, although in instances similar to that referred to in Fig. 3 scale measurements are accurate enough. The fact is that few workmen can, or really do, work nearer than 1/32 inch with a scale.

However, there are cases met with in assembling where it is not practicable to machine all the parts standard, owing to the fact that a number of conflicting elements enter into the problem, and make it advisable to leave stock for adjustment on certain pieces. A concrete example is afforded in the case of a planer reversing mechanism, which is illustrated in Fig. 4. It is obvious that the rocker *A* must swing through a certain definite arc, the amplitude being limited by the movement of the belt shifter cam (not shown) and controlled by the lengths of the dogs *B* and *C*. It is at once apparent that there are a number of measurements which must be considered; a discrepancy in any one of them would make a difference in the working of the mechanism, and the easiest and quickest way to fit the dogs is to swing the rocker in one extreme position and scribe a line on the corresponding dog representing the cam face on the rocker; then repeating the operation in the other extreme position of the rocker. The dogs are then taken off and sawed close to the line, after which the surfaces are smoothed with a file and the steel members removed for the purpose of hardening.

Duplication

The duplication of parts in quantities is another step in economical manufacturing. For special reasons it may not be advisable to build the complete machine for stock, but in nearly every instance the standard parts can be assembled in lots and kept in stock ready to be placed on the bed of the machine when ordered. The advantages are many. First, a large reduction in initial cost results because of this production in quantities. This is due to the fact that the same operations can be performed on a number of pieces in succession. Again, the possibility of always having these parts on hand when wanted means quicker deliveries.

Methods and Processes of Assembling

The methods and processes of assembling will, of course, vary with the character of the work and the design of the machine, so that it is impossible to outline any comprehensive system with the thought that it could successfully be applied

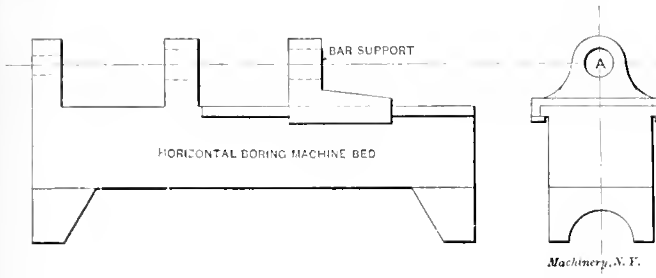

Fig. 5. A Case where some Machine Work is done after the Work is partly assembled

to all conditions alike. Indeed, a blind adherence to certain rules is liable to be a serious detriment. It is possible, however, to lay down a few fundamental principles which can safely be followed and which are adaptable to many differing conditions.

As was previously stated, the design and construction of a machine are intimately correlated, as becomes apparent when special methods needed for its construction have not been taken into account. For this reason, the designer should continually be impressed with the importance of bringing out the best possibilities of manufacture, both as to ease and cheapness of assembling, as well as machining. The tendency of modern machine design is toward the unit system of construction in which the various units comprising the driving members, feed members, etc., are self-contained, being placed in gear-boxes and bolted to the bed of the machine. This feature enables the various units to be assembled independently and simultaneously, and is an important consideration, since the shortest possible time in which any particular machine can be assembled depends upon the number of operations that can be carried on at the same time. The most notable examples of the unit system of design are afforded in modern drilling and milling machines.

On the other hand, when the design is such that the parts are more or less interdependent, it is possible to separate or classify into groups the various members so that the unit system of assembling can be followed to a certain extent. This is especially true of interchangeable manufacturing where the necessity of adjustment is eliminated.

This important feature should be emphasized that, in assembling work, it is highly advisable to provide for the same rigid sub-division of labor that exists in the modern machine department. Thus, the operations involved in assembling the units should be separated from the erecting process on the beds. In large shops these processes are carried on in different departments.

The operations involved in assembling, such as chipping, filing, scraping and fitting, are usually performed either at the vise and bench or on the floor, depending on the size or weight of the work; hence the name vise, bench and floor work.

Bench work is of a lighter nature than floor work, though it may, and often does, include the entire assembling process when the detail is small, and in case of large work many of the smaller parts are assembled at the bench and are then taken to the floor and adjusted to the other parts.

Floor work includes the erecting and assembling of heavy machines, and the machining of parts too heavy or too large to be operated on in the stationary machine tools.

In general, the sequence of operations is somewhat as follows: Work coming into the assembling department from the various sources should have all the machining operations completed, the only exceptions being in cases where it is absolutely necessary to leave stock for adjustment and where, owing to the fact that some parts are interdependent, it is not possible to carry on all the operations of machining at one time. A concrete example illustrating the latter case is shown in Fig. 5. It is obvious that it would not be practicable to bore the shaft hole A until the scraping operation is completed on the bed and carriage. In this particular case the support is bored in place on the bed.

The preliminary assembling operations of such parts as are interdependent consist of the chipping, scraping and aligning operations. Should chipping be necessary on parts that require scraping, then the chipping must be performed first in order to avoid having to take the work apart and to prevent the possibility of springing the pieces. Next in order are the scraping operations on such members as slides, carriages, ways on beds, spindle bearings, etc. This is to facilitate the lining up operations. On small work, the use of special surface plates enables the pieces to be scraped and made practically interchangeable without having to try the pieces together, while on large work the element of spring in large surface plates, besides other considerations, precludes their use. Special lifting and pulling devices such as those described in the writer's articles in the February and April issues of MACHINERY will greatly facilitate the work of scraping.

The determination of methods for quickly and easily lining up the various brackets, shafts, etc., is a matter that should receive careful thought. Whether or not jigs and fixtures are used will determine to a large extent the processes employed, although the final alignment of the brackets and bearings before the dowel pin holes are reamed, will be much the same in either case, the use of jigs saving the laying out of the screw holes. The halftone, Fig. 6, illustrates this principle and shows the method of aligning the brackets and feed-box on the head end of a turret lathe bed. Separate jigs are

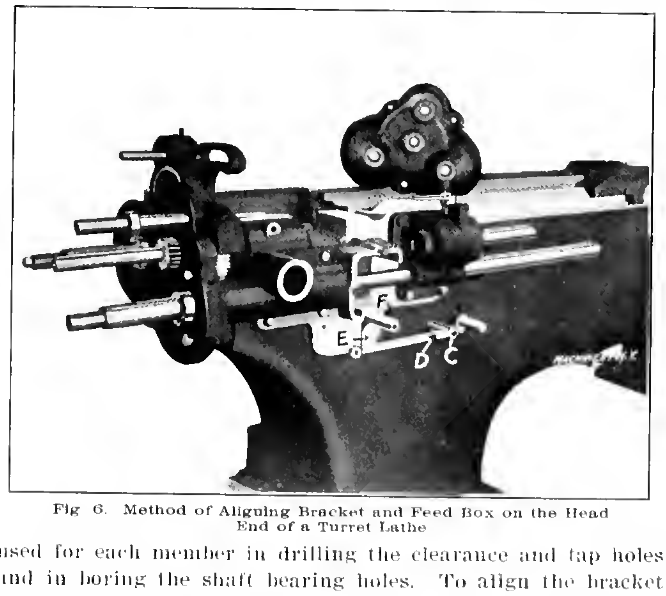

Fig. 6. Method of Aligning Bracket and Feed Box on the Head End of a Turret Lathe

used for each member in drilling the clearance and tap holes and in boring the shaft bearing holes. To align the bracket members on the bed for the purpose of drilling and reaming the dowel pin holes, special arbors are used to bring the shaft bearings in the brackets and gear-box in line with corresponding bearings in the bed. With the clamping screws only tightened sufficiently to hold the various members in place, the brackets are shifted slightly to permit the arbors to be turned freely by hand, which indicates that all the bearings are in proper alignment. The clamping screws are then tightened down, and the pinning operations completed. It should be explained that the gear-box cover is in place on its base during these operations; in Fig. 6 it is shown on top of the bed for the purpose of showing the arbors more clearly.

If jigs were not used, as explained above, the brackets and gear-box would have to be lined up and held by clamps for

the purpose of marking off the screw holes in the bed. Incidentally, the method of setting the stud C with reference to its slot for the connection D is shown. The sheet-iron gage E supports and locates the connection from the stud F.

In cases similar to that in Fig. 6 where it would be necessary to remove the shafts and gears in order to line up the brackets, it is advisable to perform this operation first. Otherwise, the units can be assembled complete, and then lined up on the bed.

The operation of assembling the individual units merely involves the chipping of oil grooves, hand reaming, fitting of keys, etc., and combining the various elements. Whether the units are sent to the storeroom or directly to the erectors, all operations of fitting and adjusting should be completed as far as possible. This will prevent the erectors from losing time by having to run to the vise and bench to fit the parts. Thus, in the manufacture of lathes, the head-stocks, tail-stocks, rests, aprons, etc., are assembled as complete units and are then sent to the erector to be fitted onto the lathe bed.

All work on the beds and such as cannot be performed when the units are fitted, is, of course, done by erectors. This includes the scraping of the larger pieces, the lining up operations as already explained and the final adjustments and testing of the complete machine.

The principal point to be observed on erecting work is to plan the method of combining and adjusting the various units on the bed of the machine so as to avoid having to take the work apart, due to neglect of some vital point. The practice of taking the work apart unnecessarily shows lack of forethought in planning the methods and processes of assembling and emphasizes the principle already outlined of mapping out the sequence of operations before hand.

A very careful consideration of all these problems and a serious attempt to solve them scientifically will bring surprising results. It hardly seems necessary to argue in favor of the adoption of the methods and processes advocated, since the experienced man will at once recognize them as being the most natural to follow. Yet the lack of effort to accomplish these results in most well-run shops (to say nothing of the poorly managed) is as singular as it is prevalent. In place of haphazard, inefficient methods must be substituted those that will lead to the adoption of standards proven by experiments and experience to be efficient, and these must be adhered to without deviation.

* * *

A German professor in a lecture on the chemical relations of aerial navigation pronounces helium to be the ideal gas for lighter-than-air airships. The professor points out that the gas is uninflammable and that it can stand a cold of —268.5 degrees C. without liquefaction. The first quality would, of course, be valuable, but as regards the second quality, its value is doubtful, as aerial navigation is not likely to put such a test on the gas used, and it would be interesting to know where the professor expects that the airships would be subjected to such a temperature, and also how he would expect the navigators to survive. Besides, the professor ought to have pointed out how to get the helium. The small quantity of one hundred gallons possessed by the Leyden University is not intended for public consumption. The professor, therefore, realizing the impracticability of helium, cheerfully advises the making of experiments with superheated steam!

* * *

The first steel plant south of Mexico is being built at Corral, Chile, and is expected to be ready for operation early in 1910. The daily capacity will be 200 tons. The machinery for this steel plant is principally of French manufacture. A fine quality of iron ore is found in large quantities within five miles of the plant, and for fuel will be used charcoal produced from the extensive forests in the vicinity; it is proposed to produce iron and steel of the highest quality. It is expected that the opening of the steel plant will encourage the development of many other industries that are dependent upon the iron and steel industries for raw materials. This will open a market for industrial machinery, and American manufacturers should keep in close touch with Chilian development for the next few years. Machinery enters the country free of duty.

THE MANUFACTURE OF GAGES*

T-Square

The introduction of our present gage system was made necessary by the development of our modern methods in the manufacture of interchangeable parts; a complete system of gages is absolutely essential to the accurate and economical production of interchangeable parts in large quantities. Some manufacturers have been slow to recognize the necessity of absolute interchangeability in their products. This has been particularly true of some machine tool makers; who

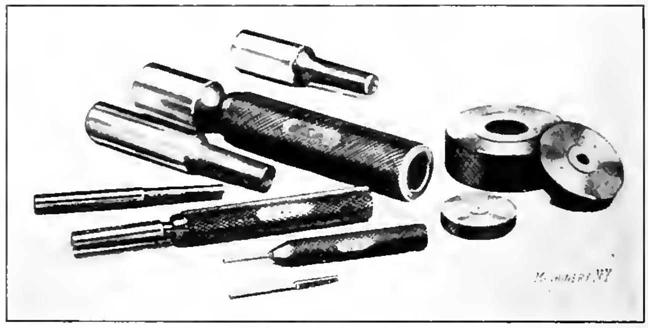

Fig. 1. Plug and Ring Gages of Approved Construction

has not seen half a dozen lathes of one make and pattern in the same shop where not even chucks were interchangeable?

Probably no class of manufacturers has more fully realized the necessity of absolute interchangeability than the makers of small firearms, and to gun makers is due much of the credit for the development of gaging systems and the training of highly efficient gage-makers. The standard methods adopted by them can, with slight modifications, be adjusted to fill the requirements of any manufacture; but the slow adoption of gaging systems is largely due to the manufacturer's prejudice which is often strengthened by ignorant or incompetent foremen who decry anything that savors of improvement, impelled by motives of fear that any innovation might carry beyond the narrow groove of their capabilities.

Principles of Development of a Gaging System

The manufacturer who contemplates the establishment of a gaging system must use the greatest care in the selection of his designer, for the question of economy hinges on the experience, foresight and ingenuity of the latter. The designer should be a man familiar with shop methods, and must be on good terms with the men with whom he must

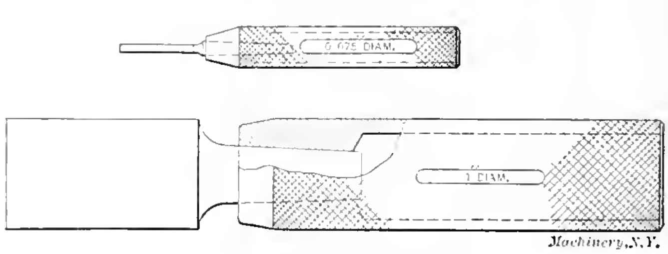

Fig. 2. Plug Gages and Handles

cooperate. In this way he will be able to gather considerable information which will be of great assistance to him in the production of efficient results.

The designer must satisfy himself that each piece being machined is handled to the best advantage, and that each cut or operation is in proper sequence. Having done this he can then lay out his gages in such a manner that each operation will have its own equipment, independent of other operations, thus insuring uninterrupted progress of the work.

In machining parts intended to be interchangeable it is necessary first to establish certain working points which are maintained throughout the entire series of operations. In some cases the working point must be shifted during the progress of the work, through the creation of a more important point after the taking of some cut, or the necessity of cutting away the original point. Very often two holes (not always neces-

* For additional information on this and kindred subjects, see the following articles previously published in MACHINERY: A Few Suggestions in Tool-Making, May, 1904; Lapping Flat Work and Gage Jaws, November, 1907; Making Thread Gages, February, 1908.

sary to the completion of the work), drilled and reamed in the piece, are used for locating it on pins inserted in the various jigs and fixtures, thus bringing each piece in like relation to the cutting tool after the proper setting has been established. And, again, it is sometimes found expedient to use one hole, and one surface, or one end and one side as holding points, and the designer must ever bear in mind that he must gage from the same point from which the piece is located or held, whenever it is possible to do so, although, of course, there are exceptions to this rule.

Should the parts on completion of the machining operations be required to pass through a system of inspection, before being assembled as a whole, which is the custom in some lines of manufacture, the gage designer is confronted by an entirely different set of conditions. He has then to do with the finished piece, and does not consider the intermediate stages. He should study the mechanism of the assembled machine, and must understand the function of each piece, and the relation it bears to all other parts; then will he first be

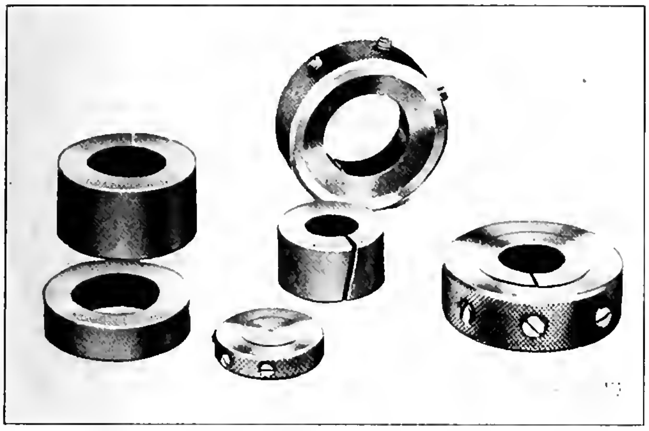

Fig. 3. Lap and Lap-holders used for Making Plug Gages

able to produce gages which will correctly test the vital points, with accurately established limits of tolerance.

The next essential to the economical inspection of parts is to limit the number of gages to as few as possible; when considering that parts are often made in lots of from 5,000 to 50,000, and each piece is to be inspected, the importance of this will be readily understood. It is *common* practice to combine gages of the simpler forms, such as a series of snap gages; or snap and profile gages, on the same plate; or a number of ring gages inserted in a plate also bearing snap or even profile gages. It is not, however, *good* practice to combine profile gages with any other type, as their longevity is much greater than that of any other form.

It is on the manufacture of the simple, but much used plug and ring gages we shall treat in this article, not with the old time machine shop conception of a gage, as something unquestioned (but often questionable) as to accuracy,

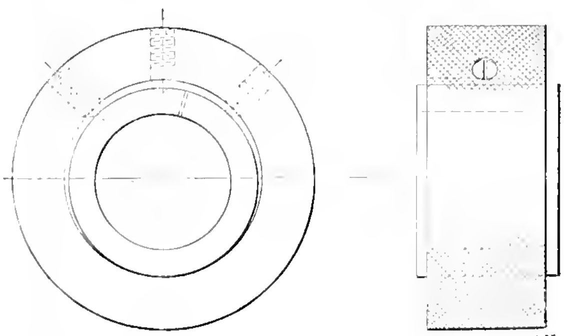

Fig. 4. Design of Lap and Lap-holders for Making Plug Gages

to be locked up in the boss' desk and brought forth only on state occasions, and given out with many solicitations for its care, and its safe return; but as something made in quantities, to be used, worn out and replaced.

The Making of Plug Gages

Our earliest, and in some cases, our latest, recollection of a plug gage is an unwieldy affair, either knurled or fluted on the handle end, and made of solid tool steel throughout, expensive to make and clumsy to handle, requiring much valuable stock in the making, and extreme care in the tempering (although the latter is always commendable as the danger of water cracks is always imminent). However, we now have a much improved design not only convenient to handle and symmetrical in form but comparatively inexpensive to make, and with the risk of loss in hardening reduced

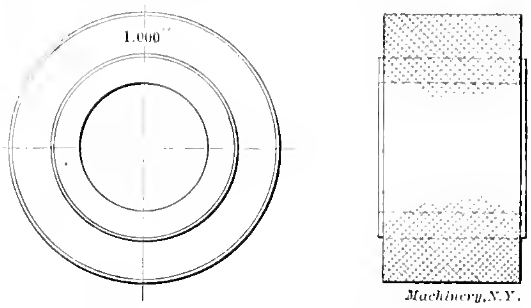

Fig. 5. Approved Construction of Ring Gages with Holders

20 to 50 per cent. This last depends first on the compact design, separate from the handle, and secondly, on the small amount of time expended up to the point of hardening, thus reducing the pecuniary loss when breakage does occur.

Although the designs of these gages, as produced by various makers, differ slightly, the fundamental principle is the same, *i. e.*, to insert the plug proper into a handle from which it can be easily removed, and replaced by another if desirable. The most popular, cheapest and best form, adaptable to plugs from 0.075 inch diameter upwards, is that with the taper shank. These plug blanks are made on a screw machine from drill rod or bar stock, by simply turning the taper shank and cutting off to any desired length, usually ranging from ¾ inch to 2 inches on the straight part. They are then centered for turning, grinding and finishing the straight portion, no further work being necessary on the shank. A number of such gages are shown in Fig. 1.

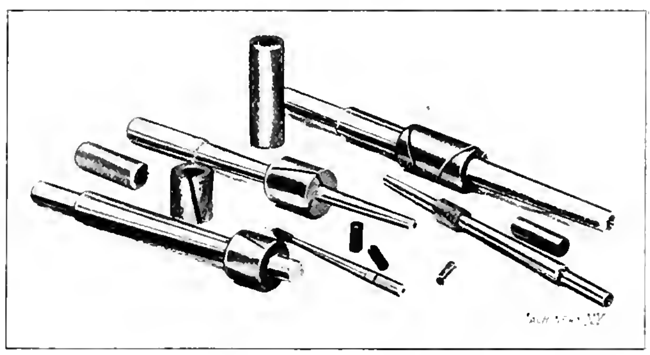

Fig. 6. Lap and Lap Arbors used in making Ring Gages

Knurled handles as shown in Fig. 2 are made in standard sizes, each accommodating a certain range of plugs. These handles, being of machine steel, can be turned out very cheaply on a hand or automatic screw machine, when, after stamping size or other desirable marking on spot flatted for that purpose, they can be blued if desired. They are then ready to receive the plug, which is simply driven lightly into the taper end, and when necessary, can be easily driven out from the rear.

Plugs ranging in diameter from 0.075 inch down, should be made from straight hardened wire, which need not be ground, but simply lapped to size, and sweated into the handle, which can be made in the same manner as for the taper shank plugs, but with the front end left solid, and afterwards drilled to suit any desired size. This method of inserting in the handle obviates the necessity of centering, turning or grinding, and the solder will be found sufficiently strong to withstand the torsional strain on a plug of small diameter. As the breakage of these small plugs is quite frequent, this will be found a very cheap and satisfactory means of production. The wire can be bought in a great variety of sizes, and for any given size of plug, wire should be used 0.001 inch larger in diameter, which will be sufficient allowance for the lap to clean up any surface irregularities

The taper shank plugs ranging in diameter from 0.075 inch upwards, are handled differently. When the blanks are made from bar steel, they should be at least 0.080 inch larger in diameter than the required finished size, as this will insure turning off the decarbonized surface of the bar, and reaching the more uniform structure beneath. In the case of those made from drill rod but half of this amount is necessary. After centering with a small center reamer (large centers should be avoided as they sometimes induce water cracks), the plugs are turned smoothly to within 0.005 inch to 0.010 inch of the finished size, according to length, and carefully hardened.

As plugs require extreme hardness, it is only necessary to reheat them sufficiently to relieve the strain after hardening, excepting those of slender diameter, which should be drawn reasonably low—about spring temper—at the intersection of the shank and body, to prevent them from snapping off while inserted, should any side strain be exerted on the handle. With the use of a little fine emery mixed with sperm or lard oil applied to a simple cast iron or copper lap, pointed similar to a lathe center, and held in the chuck of a hand lathe, the centers are then lapped preparatory to grinding.

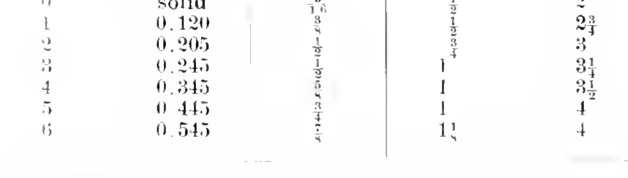
The three most desirable results in grinding are straightness, smoothness of surface, and closeness to finished size.

Fig. 7. Design of Lap and Lap Arbors for Making Ring Gages

When a good regular grinder is available the best results can be obtained, particularly if it is equipped for wet grinding; for then a piece can be ground to within 0.0002 inch of the final size, with the assurance of a perfectly smooth and even surface. An emery wheel of about No. 80 grade, with the cutting surface reduced to 1/8 or 3/16 inch in width, and kept from glazing or clogging, gives very satisfactory results.

For the benefit of those wishing to do work of this kind, and not having a regular grinding machine at their disposal,

TABLE I. PLUG GAGE HANDLES



No.	A	B	C	D
	Inch	Inch	Inch	Inch
0	solid	$\frac{5}{16}$	$\frac{1}{2}$	2
1	0.120	$\frac{3}{8}$	$\frac{1}{2}$	$2\frac{3}{4}$
2	0.205	$\frac{1}{2}$	$\frac{3}{4}$	3
3	0.245	$\frac{1}{2}$	1	$3\frac{1}{4}$
4	0.345	$\frac{5}{8}$	1	$3\frac{1}{2}$
5	0.445	$\frac{3}{4}$	1	4
6	0.545	$\frac{7}{8}$	$1\frac{1}{8}$	4

it might be said that usually 0.001 or even 0.0015 inch is not too much allowance for lapping when the work is ground in a bench lathe or other contrivance not made specially for this work. Under such conditions it is difficult to get any but a rough and uneven surface. Before grinding, the piece should be looked over carefully for cracks; those not discernible on the closest scrutiny will make their presence known in the process of grinding or lapping, but at whatever stage they develop, the piece should be immediately scrapped. Should the piece develop a tendency to run eccentric after the surface has been once trued or cleaned up by the grinding wheel, it evidently is cracked.

The object of lapping work after grinding is to give the extreme smoothness necessary to a lasting surface, and the minimizing of friction, and to correct any slight irregularities caused by the grinding wheel or due to imperfections in the grinding machine, as well as to perfect its straightness.

For plug and ring gage work, cast iron makes the best lap, and although it cannot be charged with abrasive as readily as copper or lead, it gives much better results, besides wearing much longer than the other metals. Laps for lapping plugs are made from disks ranging from 3/16 to about $1\frac{1}{2}$ inch in thickness, are drilled and reamed to a sliding fit on the ground plug, and split on one side to allow of adjustment, as shown in Figs 3 and 4. The holders, made in a few standard sizes to accommodate the different disks, are of machine steel, knurled, and having three adjusting screws to enable the operator to regulate the tension of his lap.

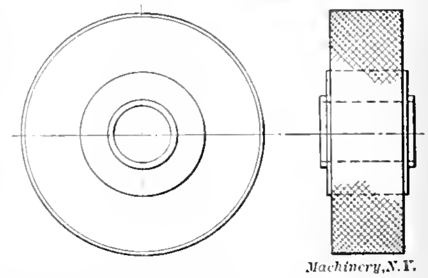


Fig. 8. Master Ring Gage with Small Collar at Mouth of Hole, which is ground off just before completing the lapping

The piece to be lapped should be running at the speed required in grinding, which varies according to diameter, and the lap adjusted at all times to grip firmly on the surface, but sufficiently free to allow its being held by the fingers. In the case of large work a wood clamp can be used. As the piece revolves, the lap is slowly drawn back and forth from end to end, and under no circumstances should this oscillation cease while the plug is in motion.

The proper abrasive to use in this operation is flour of emery, or a very fine grade of carborundum; the latter, being the faster cutter, seems more desirable. It is mixed with sperm or lard oil, to the consistency of molasses, and applied sparingly to the surface being treated, from whence it is taken up by the lap, which becomes charged as it passes over after each application.

As the operation is almost completed, however, this is discontinued, and a drop or two of oil charged with the finest particles of flour emery is substituted. This is obtained by sifting as from a pepper shaker about a tablespoonful of flour emery into a tumbler of lard oil, when, after standing an hour, the oil should be poured off, and will be found charged with the finest emery, the coarse particles having settled to the bottom. This abrasive is applied a drop at a time from the end of a small pointed stick or wire, and will make a remarkably smooth and bright finish. To the practiced hand, it requires very little time to lap a piece in this manner.

Should it be necessary to remove any quantity of metal by the lapping process, much faster methods can be employed, such as lead or copper laps charged with a coarse abrasive liberally applied; but the results will be found hardly satisfactory if accuracy is desired.

Should there be any hitherto undiscovered soft spots in the piece, they will invariably show up in the lapping, as their duller color is contrasted with the rest of the harder surface. However, it is possible for a piece to be slightly soft throughout, and finish up uniformly bright, but the softness should be discovered by file or other test at an earlier stage. In either case the piece can only be rehardened, and reworked for some smaller size, as a plug gage with a soft spot on its surface is useless.

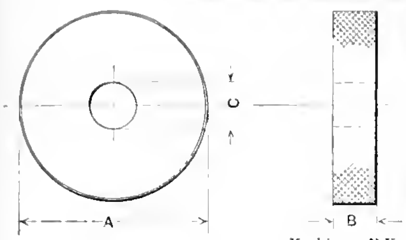
Ring Gages

When ring gages are to be made in quantity even when the quantity is small, they should be made from tool steel disks turned to certain standard diameters and cut from the bar. These blanks can be kept in stock, as well as the holders (see Figs. 1 and 5) into which they are forced after being drilled, reamed and hardened. The holders are made on a screw machine, of machine steel, requiring only to be turned, knurled, drilled and reamed with a slightly smaller hole than the diameter of the corresponding gage blanks, and cut off to length. They can be treated similarly to plug handles as to marking and bluing, as occasion demands; they can be used indefinitely by replacing the ring bushing when worn.

The gage blanks are drilled and reamed, or bored, to within 0.002 or 0.003 inch of the finished size, care being taken to have the hole as straight as possible. In handling for harden-

ing they are wired around the outside with a short piece of soft iron wire, to afford a means of handling and avoid the contact of tongs, or the necessity of passing a rod through the hole in dipping, as this latter has a tendency to cause bell mouth by retarding the action of the water within the hole. After hardening they are at once reheated sufficiently to relieve the strain, as in the case of plug gages. They are then ground on an arbor, allowing about 0.0015 inch to insure a tight fit in the holder, and are then rough lapped within 0.0005 inch of the finished size, pressed into place,

TABLE II. RING GAGE HOLDERS



Machinery,N.Y.

	Inch	Inch	Inch
1	$1\frac{1}{8}$	$\frac{1}{4}$	$\frac{5}{16}$
2	$1\frac{1}{4}$	$\frac{5}{16}$	$\frac{7}{16}$
3	$1\frac{3}{8}$	$\frac{3}{8}$	$\frac{1}{2}$
4	$1\frac{1}{2}$	$\frac{7}{16}$	$\frac{5}{8}$
5	$1\frac{7}{8}$	$\frac{11}{16}$	$\frac{7}{8}$
6	$2\frac{1}{8}$	$\frac{11}{16}$	$1\frac{1}{8}$

and finish lapped. The ends can be ground while on the arbor or on a surface grinder when in the holder, but before the finish lapping.

If the rings are sufficiently large to require grinding they should first be ground on the periphery to the proper diameter, and then on the inside to within about 0.001 inch of the finished size. As holes ground with a wheel are liable to be slightly tapering, they cannot safely be worked as close as a plug, in the grinding. It is an unnecessary expense to wheel grind rings up to ¾ inch diameter, as simple lapping gives equally good results and requires much less time.

The form of lap used (Figs. 6 and 7) is a cast iron cylinder with a taper hole, split diagonally on one side to allow of expansion as it is forced on a taper arbor, to compensate for the gradual enlarging of the hole being lapped. The lap should be about three times the length of the ring it is intended to be used in. The same rules regarding abrasive, speed, etc., apply as in the lapping of plug gages, but care should be exercised to avoid a too generous application of the abrasive as the process nears completion, for, if applied too lavishly the particles have a tendency to crowd under the edges and cause a bell mouth effect. This latter trouble is sometimes eliminated by making the rings with a slight

TABLE III. PLUG GAGE BLANKS

8	$1\frac{1}{8}$	0.400	$1\frac{1}{4}$	$1\frac{1}{2}$ to $2\frac{1}{4}$	5
9	$1\frac{3}{8}$	0.500	$1\frac{3}{8}$	$1\frac{1}{2}$ to $2\frac{1}{4}$	6
10	$1\frac{5}{8}$	0.500	$1\frac{3}{8}$	$1\frac{1}{2}$ to $2\frac{1}{4}$	6
11	$1\frac{7}{8}$	0.500	$1\frac{3}{8}$	$1\frac{3}{4}$ to $2\frac{1}{2}$	6

collar on each end (see Fig. 8), which is ground off after the rough lapping has been completed; but this is somewhat expensive, and except for master rings, hardly necessary.

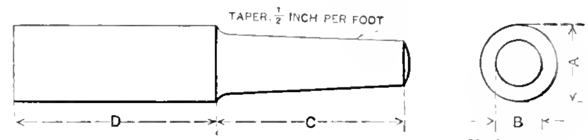
In the making of small ring gages which do not allow the insertion of a substantial cast iron lap, a tool steel lap charged with diamond dust can be used. This abrasive, which is not extensively used outside the watch factories and concerns doing work of like nature, must be used to be appreciated. It can be purchased as Brazilian bort, in a pebbly form; crushed in a suitable mortar, and graded to suit requirements; it is particularly applicable to hand or form laps, or laps for delicate or sharp corners. It is also a very rapid and smooth cutter, economical and lasting, and is readily taken up and retained on the surface of a tool steel lap to which a very small quantity is applied mixed with sperm oil, and rolled in with an extremely hard roll. Occasional rechargings are necessary as the work progresses, but in the intervals a drop of sperm oil is used on the lap.

Should it be required to make master or reference plug and ring gages, a somewhat different course should be followed than for gages intended for continual use. The method is about the same in each case, but with the former, after hardening, the work should be carried along at intervals, over a considerable time. First the rings should be cleaned up on the grinder and laid away, and later ground again, and so on during the course of a year, or even longer, where future requirements are being anticipated. This allows the metal to set, or as called by some, to season.

The Measuring and Fitting of Plug and Ring Gages

In factories not equipped with a measuring machine, some sort of standard should be adopted to which each and every workman can adjust his measuring tools. As few men measure alike, the disadvantages of varied adjustment are added, and the result is hardly conducive to uniformity. A first-

TABLE IV. RING GAGE BLANKS



Machinery,N.Y.

6	1.225	0.750	0.750 to 1.000	6

class gage maker has in his kit reserve micrometers, which are properly adjusted to the standard of his employer, and used only for reference or final measurements. This allows him to work to a remarkable degree of closeness before presenting his work for test, should a measuring machine be employed for that purpose; and where it is not, the work is usually inspected by one man, equipped with no better means of measuring than the maker's, but who serves to unify the element of touch which varies with different workmen.

Where master plug and ring gages are desired in pairs, the plug is first made to measurement, and the ring is then made and fitted to the plug. When trying the ring on the plug during the final fitting, both should be wiped perfectly clean and allowed to acquire like temperature, by lying together on a bench, or machine, or for a few seconds in cold water. The plug is then given a slight coating of rancid oil, and inserted in the ring, into which it should be a close wringing fit. When fitted properly this way, it will be found impossible to insert the plug, should the oil be removed, or even when some other kinds of oil are substituted. This rancid oil is simply the drippings of animal oil that has been used many times on some drilling or cutting operation; the older it is the better.

Should a number of plug gages of one size be required for manufacturing purposes, they should all be made to machine or micrometer measurement. It is utter folly to try fitting any quantity of plugs to one master ring if absolute uniformity is essential, particularly if they are of any considerable length, owing to the tendency of the ring to wear in the fitting. One of each lot can be tested to the ring to make sure that it conforms to the proper standard.

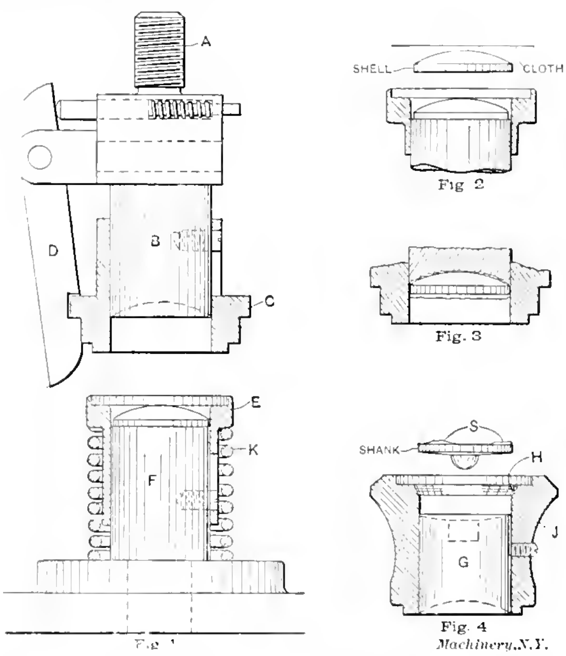
Ring gages, whether made singly or in quantity, are fitted to a master plug, which, as it wears, is comparatively inexpensive to replace, the wear being easily detected by occasional reference to the master ring.

DIES FOR COVERING BUTTONS

CHARLES WESLOW*

Charles Weslow

The dies and tools used in the manufacture of cloth covered buttons are shown in the accompanying illustrations. The particular tools shown are for covering and binding together the two parts of what is known as a "fifty line unlined tablet button." One "line" on a button gage is equivalent to 0.025 inch or forty lines to the inch. The dies are used in a foot press of simple construction, this machine being adapted for this work. The ram of the press is tapped for the threaded shank *A*, Fig. 1. The case-hardened part *B* is finished to a diameter of 49¾ lines or 1.243 inch, and its lower end is concaved according to the style of shell or button. The sleeve *C*, which is bored 0.001 inch larger than part *B*, is made of machine steel and also case-hardened. This sleeve is supported by a lever *D*, during part of the time required for the covering operation, and it is provided with an elongated slot which fits the head of a small screw, as shown. Another case-hardened machine steel sleeve *E*, similar to *C*, fits over the part *F* which is likewise similar to the part *B* except that it is convex on the upper end to conform to the shape of the inner part of the button shell. This spring-supported sleeve *E* is the lower die. The diameter of *F*, except the small shoulder at the upper end, is 0.002 inch larger than the shell, the size of which depends on the thickness of the cloth used, which in this case is ¼ of a line or approximately 0.006 inch. This size shell is made of 36-gage stock. The largest bore of sleeve *E*, which is known as "the nest," is the same diameter as the cloth blank which is computed according to the style of the button. In this case it is 69 lines in diameter.



Figs. 1 to 4. Die and Thimble for Covering Buttons and Binding Shank and Collet together

The different parts of a button are shown in Fig. 5. The cloth blank in the upper left-hand corner of the engraving, covers the shell to the right, and this covered part is locked to the collet shown below after a piece of cardboard and canvas has been placed in position as subsequently described.

In Fig. 2 the shell and cloth blank are shown ready to be placed in the lower die. When they are in position the upper die descends and picks them up, as shown in Fig. 3. The part shown in Fig. 4 is known as a thimble. This thimble, which is of tool steel, acts as a closing or curling die, at *H*, and it not only curls the cloth between the shell and the shank, but it also closes in the shell thus binding or locking the two parts together. The radius of the surface *H* is found by experiment. The shank is shown in Fig. 4 ready to be placed in the thimble. When in position it rests on the plunger *G*, which is a sliding fit in the thimble. This plunger is prevented from dropping out by a set-screw, which engages an elongated flat spot on it. The largest bore of the thimble is the same diameter as the lower outside diameter of sleeve *C*, which is the same as the recess in part *E*, which, as stated, corresponds to the diameter of the cloth blank.

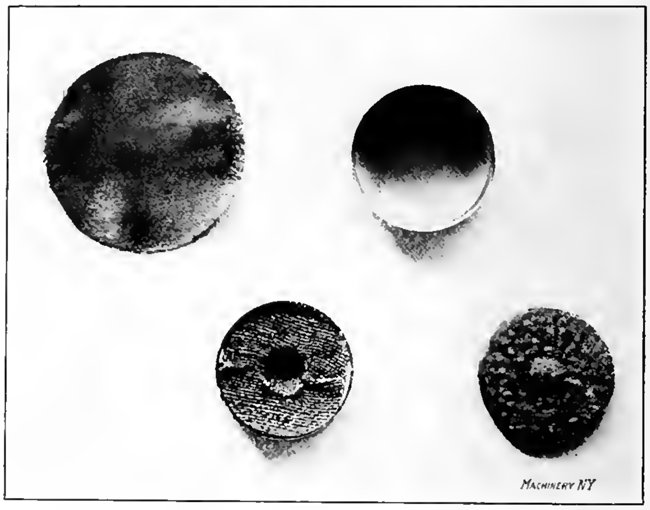


Fig. 5. The Parts of a Cloth-covered Button

Figs. 6 and 7 show the thimble in position for the second downward movement of the plunger. The thimble is put in place by hand after a shell and cloth cover have been picked up by sleeve *C* during the first stroke of the press, as shown in Fig. 3. The parts *C*, *J* and *E* are supported by the spiral spring *K*. When the upper die descends during the second stroke, lever *D* is disengaged from sleeve *C*, as shown in Fig. 7, so that the latter is free to move on part *B*, which continues to move downward when *C* rests on thimble *J*. In so doing, it forces the cloth cover to curl in as shown. Then the cylindrical part of the shell, which is now covered, strikes the curling section of part *J*, but the spiral spring now gives way to this pressure, so instead of the metal shell curling in as might be supposed, it acts in connection with part *B* to force thimble *J* down, which, in turn, acts likewise upon the sleeve *E*, which moves down until its lower end strikes the die-bed. By this time the shank will have entered the shell and carried the surplus of cloth cover with it. When sleeve *E* stops on the die-bed, part *B* continues to descend until the shoulder on it strikes the upper end of sleeve *C*; then there is nothing else for the invisible shell to do but curl in and embrace the shank, thereby locking them together and completing the button. Sufficient expansion takes place in the button, when the dies are released, to cause it to float on the top of the thimble. So it will be seen that two "kicks" or strokes of the press are required to cover a plain button.

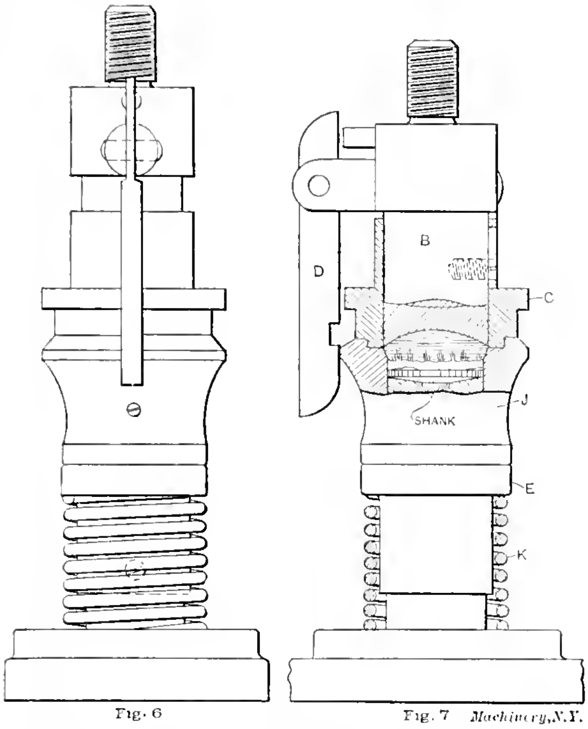
In considering the manufacture of the five parts necessary in a plain button, we will first take up the shell and collet. These are blanked and drawn up in a combination die, known as a collet die, with a double action press, but not necessarily so. Stock of from 36 to 38 gage is used to make them, which comes in sheets of various sizes in much the same manner as tin. Some manufacturers get the 14 by 28-inch size and square shear them in half for convenience. The material used for shells is given a thin coat of japan to prevent rusting, but the material used for the collets is japanned black for appearance.

The stock is fed by hand up to a knife-edge stop, which is instrumental in separating the scrap stock from the sheet.

* Address: 332 Jersey St., Harrison, N. J.

Chas. Weslow was born in Harrison, N. J., in 1876. He began work at the age of 11 years, out of necessity, and since that time he has been employed in a great many machine shops and manufacturing establishments in the East, as machinist, tool-maker, and tool designer. In this journeying, he has acquired a broad practical experience, which has been supplemented by the correspondence and night schools. The following are a few of the numerous establishments where he has been employed as tool-maker or executive: Noble & Hunt, Newark, N. J.; Western Electric Co., New York; Sloan & Chase, Newark, N. J.; Domestic Sewing Machine Co., Newark, N. J.; F. H. Richards Engineering Co., New York; Pike Adding Machine Co., Orange, N. J.; American Calculating Machine Co., Newark, N. J.; Crown Button Co., New York; Hyatt Roller Bearing Co., Harrison, N. J.; Premo-Hall Novelty Works, Newark, N. J.

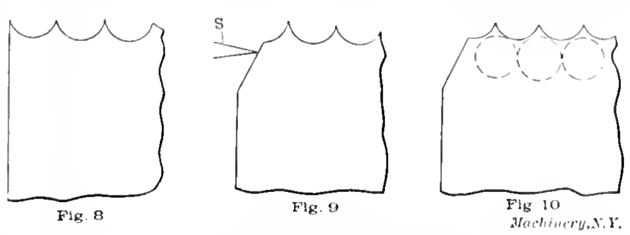
The edge of the stock, after one row of blanks has been cut, is made up of half-circular forms, as shown in Fig. 8. This rough edge, however, is placed against the gage on the press when blanking to the succeeding rows, to guide the stock as it is being fed through, the gage being long enough to make it easy for the operator to hold the stock squarely against it. The press runs about 250 revolutions per minute, and the shells are blown from the die by a strong air blast. Some use an inclined press, relying upon gravity to remove the shell, but an air blast does the work quicker, thereby allowing a speedier action of the press. This blast comes through a 2½-inch tin pipe, which is nozzled at the die. After the first row of blanks is cut from the new edge of



Figs 6 and 7. Die shown in Fig 1, with Thimble, Fig. 4, in Place

stock, the operator snips off the corner with a pair of scissors to prepare the stock for blanking the next row of holes. By carefully trimming the corner, the stock is so located by the knife-edge stop *S*, Fig. 9, that the blanks are cut as indicated by the dotted lines in Fig. 10, which, of course, effects a considerable saving in material. The first blank is cut singly to locate it properly and then the balance are cut out at a speed depending on the speed of the press. By referring to the engraving, Fig. 10, it will be noticed that no stock remains between the blanked holes. As the stock is fed forward a knife-edge stop effects a separation of the scrap from the sheet.

Another part to the button is the cloth cover. These are cut with a hand punch, which looks like a large size belt



Figs 8 to 10. The Way the Stock is located with Reference to the Stop to effect Economical Blanking

punch, and a mallet on a hardwood block. Several thicknesses of cloth are cut at one blow, and about ½ gross of the blanks are removed from the punch at one time. A good plan is to keep the cloth blanks in the position in which they are taken from the punch, in a receptacle for this purpose, instead of throwing them loosely into an open box. If the button is to be covered with a damask material, or fancy centers, as shown in Fig. 11, then the blanks are cut singly in a foot press.

The cardboard disks, which are inserted between the shell and collet, are cut on the single action power press in much the same manner as the shells are made, but they are forced through the die, while the shanks are knocked out. These "cardboards," as they are called, are rushed out "a mile a minute," no particular care being exercised, for if they crack or break, they are used anyhow, but they must be a certain

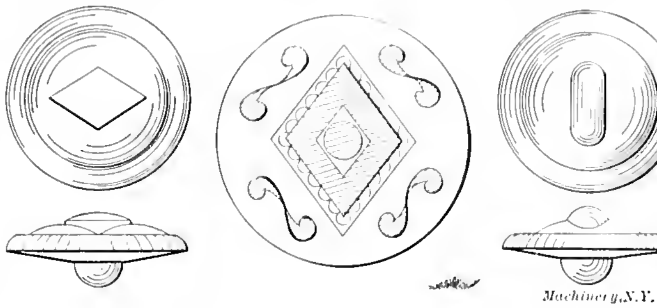


Fig. 11. Fancy Covers which are blanked singly

size to drive into the collet, to hold the canvas in position. The canvas pieces are blanked in much the same way as the cloth covers are. These parts are assembled in what is called a "machine," but it is in reality a light foot press built on the lines of general hardware.

Fig. 12 shows the style of die used in assembling the shanks. Two strokes of the press are required for each shank. The illustration also shows the shell and the canvas blank ready to be placed in the "nest." The punch *P* is shaped the same as an ordinary drawing punch, excepting the hemispherical projection provided at the end. This end is what forms the canvas stem which is sewed to a garment. In use, the collet is first placed in the nest with the canvas on top. The plunger then descends and forces the canvas into the pierced hole in the collet forming the stem. The lower end of the knurled ring *R* is turned to fit the recess in the upper end of part *Q*. This ring contains a plunger,

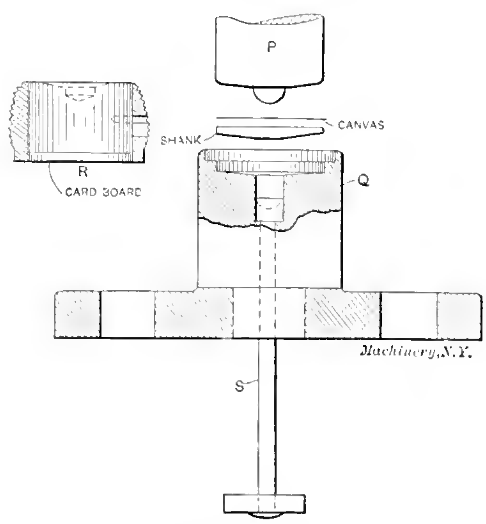

Fig. 12. Punch and Die for Forcing Canvas and Cardboard into the Button Shank

the top end of which is turned to fit the lower end of plunger *P*. The ring and its plunger are held together by a small dowel, as shown, which slides in an elongated slot in the ring. While the operator is forcing the canvas into place, this ring, which is held in the right hand, is being used to pick up a pasteboard disk, while the left hand secures another canvas and collet for the next button. After the first stroke of the plunger *P*, the knurled ring is inserted in the recess in *Q*. The second stroke, through the plunger in ring *R*, imparts a blow to the pasteboard, which is driven into the shank. The small plunger *S* is a simple form of knock-out for ejecting the shanks. Celluloid buttons are assembled in the same style die except that celluloid covers are first heated to make them pliable so they will curl and bend.

Good tool-makers are in demand for this work, and the writer knows of concerns who were offering $24 and $30 a week for competent men. As far as the writer knows, Williston of East Hampton, Mass., is the original covered button manufacturer, now known as the United Button Co.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall,
Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month, give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

SEPTEMBER, 1909

PAID CIRCULATION FOR AUGUST, 1909, 20,453 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

INVENTING AS AN OCCUPATION

From time to time our mail brings a woeful tale from a disappointed inventor who has devoted a number of years and considerable money to the perfecting of some device which the world has not duly appreciated. Many inventors spend years on the development of an idea which to them appears to be of great value. Often, too, they sacrifice the employment by which they earn their daily bread. It is but natural that the inventor who has thus devoted his time and perhaps all of his savings to the development of a new idea should be discouraged when he finds that he can realize little or no returns from his invention. As a rule he thinks that he has been unjustly treated by those to whom he has submitted his idea and often regards the manufacturer as an enemy because the compensation offered is from his point of view inadequate.

In many cases the inventor sees from one viewpoint only. He has not the advantage of wide experience and knows little or nothing of the costly organization necessary for marketing goods. Inventing should seldom be considered as an occupation to which a man can profitably devote all his time, except in cases where the inventor's genius is of an extraordinary degree. The inventors who succeed as a rule retain employment in regular occupations while they perfect their inventions during spare time, the inventions being incidents in their regular occupations, or by-products, as it were. When an inventor works under such conditions he is more likely to correctly estimate the value of his inventions, and not be bitterly disappointed because his inventive genius is not highly appreciated.

A man who has true inventive genius cannot help being an inventor, but he should avoid living in expectation that one brilliant idea will make his fortune and enable him to live ever after free from all pecuniary cares. The hope of "striking it rich" is a common fault of many inventors. If they must invent, let them content themselves with moderate returns for their ideas, placing each in the best market possible, but not feeling disappointed if a large fortune is not realized from an idea that to the inventor seems very valuable.

Advice is cheap and is generally disregarded by those who could best profit by it. But notwithstanding, we cannot help suggesting that inventors of ordinary ability should retain their regular occupations while developing their ideas. They will be happier and their chances for success will be greater than if they give up profitable occupations hoping to produce something which will make a large fortune. The trouble is that inventors as a class are a somewhat irresponsible lot to whom a steady job is distasteful. Steadiness of character and genius are rarely found combined in the same individual, and doubtless much that has been said here will be of little value to the class most in need of advice.

* * *

MACHINE SHOP INTERCOMMUNICATION

There is no trade or profession so closely identified with the development of new inventions as that of the machinist and the tool-maker. Embryonic ideas are gradually developed through a series of experiments with their assistance, and when the model is finally completed, the tools and machines for its manufacture have to be constructed. The position of the up-to-date machine shop, therefore, is of the first importance in industrial development. It is this importance which has made it absolutely imperative that the equipment of machine shops be of the highest type in labor-reducing machines and time-saving methods.

One of the many important time-saving devices developed within the past few years, which merits the careful attention of shop managers, is the automatic intercommunicating telephone. Its installation in a plant means that machine shop superintendents are no longer subjected to the many annoyances occasioned in the past by the crude methods of communication in use, such as unreliable hand-bells, buzzers, unsanitary speaking tubes, etc.

The very nature of the modern machine shop organization with its various departments covering a large ground area demands that some quick method of communication be installed that will put every department in close touch with any and every other department. It should not be necessary for the foreman of, say, the milling department to go to the foundry to ascertain why certain castings required for a rush order have not reached him. His time is too valuable to be thus wasted. Again, the shipping department, located perhaps in a remote part of the works, should be in as close touch with the superintendent as the drafting-room just outside his office.

The automatic intercommunicating telephone, of which various forms are now on the market, brings all the departments of the modern machine shop in close touch with each other without involving charges for attendants. With its use a higher standard of efficiency can be obtained, and almost all the benefits of personal interviews can be enjoyed without the necessity of leaving one's own department. The old walking-talking method of communication between the superintendent and subordinates may be abolished and the time thereby saved devoted to other details. Orders can be transmitted and received almost instantaneously, and mistakes practically eliminated, or at least reduced to a minimum on account of the facility provided for readily securing directions and checking up doubtful information. The telephone should not, of course, be used to transmit orders of which a record is required. All such orders, requisitions, data, etc., should be transmitted in writing only; but the telephone can be made a most valuable means for explaining points not clear in written communications or which perhaps need modification in some detail to fit a certain condition.

Another advantage of the telephone not unimportant is the ready means it gives for locating the superintendent or others who may be making a tour through the works. In a few moments all the stations can be called up if necessary, the desired persons located, and any communication transmitted or information obtained with promptness.

All the foregoing and much more is common knowledge in the works where the telephone is an indispensable fixture, but notwithstanding its manifest advantages we still find many plants, otherwise up-to-date, which are sadly deficient in modern means of intercommunication. The defect can be remedied at small expense, and the saving effected will soon more than pay the cost.

THE HUMAN ELEMENT

ANALYST

Among the potent factors that impel a manufacturing concern toward the goal of commercial supremacy, is one that is often overlooked, but more frequently ignored—the human element. Employers sometimes forget that there is such a thing as a moral law and that it does not pay to violate it, and some superintendents and foremen have been imprudent enough to take undue advantage of the recent industrial depression to enforce methods and policies vitally affecting the workman's daily life, without regard to the human element that enters into his makeup, and which of necessity must be reckoned with later on.

As a consequence the men usually "take it out" by giving the company a bad reputation among their fellow-workmen, and it is a fact that some of the concerns which complain of the difficulty of securing and keeping good men, owe their troubles largely to this cause. The reputation of a shop for being "white" or otherwise spreads far and wide, and good men usually know pretty accurately whether it is a desirable place to work in or not. This often materially affects the establishment concerned, especially when good men are scarce. Business men have their commercial agencies and reports for ascertaining the reputation and standing of other concerns. Workmen do it by a different, but just as effective a method, and the superintendent or foreman who thinks he can treat men unfairly and not suffer for it makes a great mistake. The foremen, especially, should always remember that they are the direct representatives of the firm to the workmen, and that the men base their opinion of the company largely upon their opinion of the foremen. The workmen's promotions and increases in pay depend upon the foremen's characteristics and knowledge; their daily life and career are subject to his control, his caprice and vagaries. The character and ability of the foremen affect the workmen more directly than any other factor in the shop organization, and as a result have a direct effect upon their efficiency and disposition toward the company. Of course there are always two sides to a story. Many of the complaints come from men who are chronic fault finders, and who never would be satisfied with any conditions, however advantageous; so that before giving credence to these reports, one should always be certain that the facts are substantiated by reliable evidence.

We often hear of the tendency of workmen to limit their output and effort, and of their neglect to work for the good of their employers. This is usually the complaint of the manufacturer who does not consider the human element of sufficient importance to merit his attention, and who refuses to put himself in the other fellow's place and to build up an organization along lines which would mean encouragement and inspiration to his employes.

Another factor of great importance in its effect upon the human element, is the question of handling men so as to get the most out of them without incurring their enmity.

Ignorance of details will sometimes cause the management of a concern to entrust the important position of superintendent to the man who can talk loudest and make the greatest show on a little knowledge. Such a man is apt to possess an exaggerated sense of his own importance, coupled with jealousy of those who suggest any improvement in method or process. Add to these failings surreptitious dealings with foremen and workmen, and you have three of the greatest causes of trouble in a shop, resulting oftener in a spirit of hostility than of cooperation between superintendent, foreman and workman.

It sometimes happens that a superintendent makes the serious mistake of ignoring his foremen to a certain extent in order to display his authority, and instead of entrusting the details of the work to the foremen, gives orders directly to the workmen; so that the workmen lose respect for and confidence in their foremen, and the latter become mere figure-heads, without any authority except in minor details. In some cases this is necessary because of the incapacity of the ordinary foreman, but it is always advisable when practicable to give instructions through the foreman, and if he is not competent to run his department without such assistance he should be replaced by one who is.

It frequently happens that a superintendent desiring to retain the full credit for an innovation, makes the mistake of refusing to confer with different members of his organization in regard to any suggestion they may be able to offer, and attempts to force his plans through. Such action usually meets with covert opposition. His assistants, perhaps familiar with some obstacle in practice which he has not considered, say nothing and allow the experiment to fail, "because they weren't asked." In this way the small jealousy that impels one man or group of men to underrate the work done by others, often works incalculable loss to the employer. The fact must be recognized that, nine times out of ten, the joint advice of several men conversant with a subject is superior to any plan developed from one man's brain.

In every organization there should be a head and a strong one; but singularly enough the method often adopted in manufacturing establishments is to place all the responsibility on one superintendent and neglect to surround and strengthen him with a body of efficient foremen, who might be advisers of great value. In adopting such a policy the management fails to recognize the great benefit to be derived from securing the advice of a number of the best qualified men upon important matters, and from giving the foremen an opportunity to show their value, which with most men means increased ability to handle the problems submitted to them.

In contradistinction to the method of management portrayed above, is the shop organized along lines that enlist the cooperation of the personnel, that develops the latent ability of each man; a shop where all plans are based primarily upon the human element of the men who are affected. The sympathetic support of the foremen and workmen *must* be secured. The best qualified superintendent will not achieve the degree of success that should be attained unless he is supported by the foremen, job-bosses and workmen. To enlist their support, they must be consulted frequently concerning the difficulties encountered, and encouraged to suggest ways of overcoming them; they must be made to feel that the methods are their own, and their interest in the work recognized. Thus difficulties will quickly disappear, and ways and means for overcoming unexpected obstacles will soon be discovered.

Nothing is more vital to the progress of an enterprise than that its executive force should work in unison. Then the balance of the shop will generally do likewise. Let there be discord and lack of harmony among the heads of a concern and there will be an instant lining up of forces in opposition, one against the other, which will cause the entire organization to disintegrate and lose much of its efficiency. The only cure is coöperation, since the work of each man is related to and interlaced with the work of all. The spirit of "getting together," if fostered, will be the chief factor in developing the strong men in the organization, and it should always be remembered that the habit of concerted action can be cultivated—gradually, perhaps, but easily—if proper attention is paid to it.

It must be conceded that the humanitarian, fair-minded policy of management is the greatest stimulus to the ambition of the workmen, and that a loyal, interested force of workers, impelled by a feeling of good fellowship to do their level best, constitutes the concern's best asset, and is the greatest and strongest factor making toward success.

* * *

It is evident that Bleriot's exploit in flying across the English Channel has stirred the imagination as has no land flight of equal distance, and that it has also greatly stimulated the progress and development of aviation.

The enthusiasts see in Bleriot's flight the beginning of a new era in which man will conquer the air, and in which the sea, "that parts nations asunder," will no longer be a hindrance to his movements. To us there is something essentially fine, heroic and conquering in the vision of the Frenchman's exploit; it shows man overcoming the seemingly insurmountable through his control of natural forces, made possible by the development of mechanical engineering. The machinist can rightly claim a large share in this latest triumph of mechanical flight.

THE TESTING OF FILES AND TOOL STEEL*

The following inquiry regarding files has been made not merely for the benefit of the file-maker, but quite as largely for the benefit of the buyer and user of files. The subject, therefore, is treated from the standpoint of a practical engineer without any special knowledge of file making.

The testing of files is accomplished by means of a special machine (see description in MACHINERY, December, 1907, engineering edition) which records the endurance and metal-removing qualities of the file on a piece of paper wound around a cylinder, thereby producing diagrams as shown in Figs. 1 and 2. In these diagrams the horizontal distances represent the number of strokes made by the file tested, and the vertical distances the number of cubic inches of metal removed during the life of the file. The curves drawn in Fig. 1 show the life history of two files from the time when they were new until they were completely worn out. It will thus be seen, for instance, that one file removed somewhat over eight cubic inches of steel in 108,000 strokes, after which the file was incapable of removing any more metal. The other file removed the same amount of material in the first 16,000 strokes, and was still in good condition, removing a total of 14 cubic inches in 42,000 strokes before worn out. In Fig. 2 is shown even a more striking comparison, and here the great variation in the amount of work possible from files of different quality is exhibited. The two sides of one file removed 10 and 3 cubic inches, respectively, of cast iron before becoming too blunt to cut, while one side of another file reduced to filings nearly 20 feet of a cast iron bar one inch square before unable to cut. These examples indicate that file testing is a matter of considerable importance in shop economy, particularly in the assembling department where a great deal of time may be wasted by using inferior files.

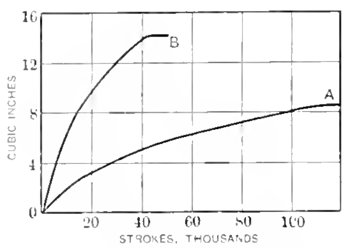

Fig. 1. Diagram resulting from File Tests on Steel, made on the Herbert File Testing Machine

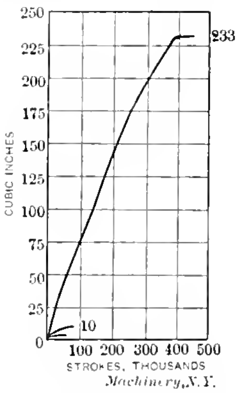

Fig. 2. Diagram resulting from File Tests on Cast Iron

The files are tested until they slip over the surface of the test bar without cutting, this condition being shown by the curves taking a horizontal course. Tests which are stopped before this point is reached may give a false impression as to the relative merits of files. It may happen that two files cut equally well during the first 50,000 strokes, and if the tests were stopped at this point the files would be considered equal. If the tests were continued, one file might cease cutting at 60,000 strokes, and the other continue for 400,000 strokes, thus showing a great difference in their durability.

Results and Conclusions of File Testing

Among the results obtained by the file-testing machine, perhaps none is of more interest than the discovery that the two sides of a file are seldom equal in efficiency and durability. Fig. 3 shows the curves for the two sides of the same file, one of which accomplished three and one-half times as much work and made four times as many strokes as the other. Such results are common. File-makers generally explain this difference as due to a variation in the sharpness of the chisel used in cutting the files. If a great variation is thus found between the sides of a file, it is likely that equally great variations will be found between individual files in the same lot, this being an evidence of lack of uniformity in the manufacturing process. One of the most important services, therefore, that is rendered by the file-testing machine to makers and users of files, is that of showing the great difference caused by minute variations in the shape of the file teeth, variations which can scarcely be detected by examination, and which can only be eliminated by extreme care in all the processes of manufacture.

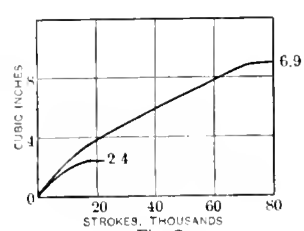
It has been assumed that a file made of good steel is a good file. The teeth, of course, are expected to feel sharp, but beyond this very little attention has been paid to their shape. The file-testing machine has shown that the shape has a far greater influence than the quality of the steel, not only on the rate of cutting, but also on the amount of work that can be got out of the file. Fig. 5 shows the curves obtained from tests where five files were worn out at practically the same number of strokes (110,000). The amount of iron filed away varied very greatly. These variations in rate of cutting are more marked on cast iron than on steel. The best file in Fig. 5 cut when new at the rate of 14 cubic inches per 10,000 strokes, while the poorest file cut hardly more than ½ cubic inch during the same number of strokes, the material being cast iron. On steel a rate of 6 cubic inches per 10,000 strokes is rarely exceeded.

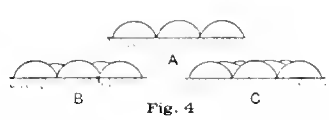
The rate of cutting is given by the slope of the curve and depends almost exclusively on the shape and sharpness of the teeth and on their relation to one another, and is not affected by the quality of the steel. As many files cut at a very slow rate when considerably worn, it is economical to reject files at a fairly early stage of bluntness.

Factors Determining Efficiency of Files

The chief factors by which the cutting efficiency of a file is determined are:

1. Sharpness of teeth.
2. Slope of the front face of the teeth, or rake.
3. Slope of the back face of the teeth, or clearance.





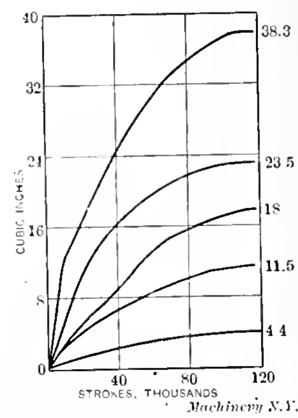


Fig. 3. Curves resulting from Tests of Two Sides of the Same File cutting the Same Material. Fig. 4. Arrangement of File Teeth, due to Variation in Ratio between "Up-cut" and "Over-cut." Fig. 5. Five Files of Equal Durability, but Unequal Capacity for Removing Metal

4 and 5. Angles of the two cuts relative to the axis of the file.

6. Pitch or coarseness of the cut.

7. Ratio between the pitch or number of cuts per inch in the "up-cut" and in the "over-cut."

At first sight it would seem that the sharpness of the teeth would be the most important factor in cutting efficiency, but the experiments indicate that this is not the case. Two files equally sharp, and thus cutting equally fast when new, do not show the same efficiency.

The slope of the front face of the teeth on commercial files as made at present is very rarely vertical, but in almost all cases there is a negative rake varying from 3 to 25 degrees. Experience with lathe and planer tools would lead one to expect that a tool with considerable negative rake would be exceedingly inefficient on almost all materials, and it is surprising that such a tool cuts at all under such light pressure as can be applied by hand on a file. Nevertheless it is a fact that files with considerable negative rake not only cut, but take off very satisfactory curled chips. The reason

* Abstract of paper by Edward G. Herbert, read before the Manchester Association of Engineers, March 27, 1909. For description of the file-testing machine referred to, see MACHINERY, December, 1907, engineering edition.

for this is probably that the file tooth is presented to its work at an angle, owing to the slope of the cut across the file. This gives a slicing cut, which probably accounts for this efficiency.

The slope of the back face of the tooth, or clearance, is very difficult to measure because it is not a plane surface, but the angle is very important in relation to the durability of the file. A file which is worn out has the tops of its teeth flattened or rounded. When the area of contact of the teeth with the work attains a certain value, great pressure is required to cause the teeth to "bite" the metal. The amount of work that can be obtained from a file, therefore, depends largely on the volume of teeth available for wear before this limiting area is obtained.

Examination of commercial files show that these angles are extremely variable, and it is certain that uniformly satisfactory results cannot be obtained unless correct angles are ascertained and maintained, leaving nothing for the variation of judgment on the part of the workmen. The pitch or coarseness of the cut does not seem to influence the efficiency of files to any great extent. Very coarse files, however, are almost always inefficient, probably because of the difficulty of raising very large teeth, which are at the same time sufficiently thin and sharp. Very smooth files, on the other hand, cut slower and do less work than those of somewhat coarser cut, but in some cases surprising results have been obtained from smooth files also.

It may not be generally known that the two cuts on a file differ in pitch. Suppose a file had 25 cuts in the chief or "up-cut." If it has also 25 cuts per inch in the secondary or "over-cut" a cross-section of the file would appear as at *A*, Fig. 4, each tooth standing immediately behind a tooth in the row in front, and all the teeth lying in straight rows parallel to the axis of the file. Such a file would leave on the surface of the work a series of furrows with ridges between them. Now suppose that there be 25 cuts per inch in the "up-cut," but the "over-cut" is made with 16¾ cuts per inch. Then the appearance of the cross-section would be as at *B*. Each tooth now lies opposite the space between the two teeth in the row in front. The teeth in the first row still make a series of furrows, and the teeth in the second row work on the ridges between these furrows, planing them off and leaving a fresh series of furrows, but the file would be inefficient because the ridge between any two teeth would be too large to be taken off at one cut by the teeth behind. If the number of teeth per inch in the "over-cut" is increased to 19, the effect will be as shown at *C*; the ridges between the teeth in the first row are divided between the teeth in the second and third rows behind. This subject of the ratio between the "up-cut" and "over-cut" is likely to be one of the most important factors in file efficiency, but it has not as yet been thoroughly investigated.

Efficiency of Files on Various Metals

It has generally been assumed that a good file is good for all classes of work, brass, cast iron or steel. Some difference of opinion on this subject has been expressed, and there has been a fairly general agreement that a file for brass should have the "up-cut" nearly at right angles to the axis, although this is by no means a general rule. In view of this a series of experiments was planned to ascertain whether there is one particular cut which is best for all metals, or whether each metal requires a special cut to produce the best results. For these tests a number of files were ordered from several makers who were asked to cut them in the manner which they considered most suitable for cast iron, steel, brass, and general work, respectively, each maker supplying a number of files for each purpose.

In the experiments each file was tested on brass, cast iron, mild steel, annealed tool steel and "normalized" tool steel, the last being subjected to heat treatment which would make it uniform in hardness throughout its length without actually annealing it. In one case a brass file gave the best result on brass, but this was the only instance where the best result on any metal was obtained by the file intended for that metal. On the test on cast iron, for instance, two files intended for steel cut more than three times as fast as the files intended for cast iron. On the "normalized" tool steel (not annealed) the cast iron file gave best results. The conclusions of these tests, therefore, showed:

1. The subject of files for specific purposes has practically received no thorough attention. As a rule, files cut for specific purposes gave poor results on the materials for which they were intended, and good results on materials for which they were not intended.

2. Files especially well adapted for any one metal did not give good results on other metals.

3. Files which showed average efficiency on all metals were rather inefficient on all.

4. The tests clearly show that the ductile metals, such as mild or annealed steel, are most easily worked with a sloping cut, which usually produces curled filings. Cast iron and hard brass require a much less sloping cut. Brass files, in fact, should have an "up-cut" almost at right angles to the axis of the file.

5. As a general conclusion, therefore, it appears that it would be advantageous to have files especially cut for various metals and keep them on the work for which they are intended. Most files intended to cut all metals are decidedly inefficient on them all.

It will rest with the user to make the first move in the matter. The file-maker is naturally reluctant to double or triple his stock and to make files for all the existing sizes, shapes and cuts in two or three distinct styles, suited to different metals. The difficulty may involve a slight increase in the price of files, but the increase in efficiency will be out of all proportion to the increase in cost.

Another evidence of the un-uniformity of files and the incomplete understanding of the subject, even by file-makers, is shown by the fact that sometimes files of two or three different qualities are sold by the same maker at different prices. In most, though not in all, cases where such files were tested, it was found that the cheapest grade gave the best result, and the most expensive the worst. This is probably explained by the fact that by a "good" file, the file-maker almost invariably means simply a file of expensive steel.

Most of the leading British file-makers are now investigating, with the aid of the testing machine, the various problems connected with file efficiency. This investigation is attended with special difficulty. Apart from the quality of the steel there are at least eleven important factors, all having an influence on efficiency: seven angles, the sharpness of the chisel, the force of the blow, the coarseness of the cut, and the ratio between the two cuts. It is possible to make an infinite number of combinations of these eleven variables, and an alteration in any one of them is likely to affect several of the others. The problem is, therefore, greatly simplified if a simple file tooth can be isolated and its cutting efficiency measured under constant conditions while progressive changes are made in its shape and in the angle of its presentation to the work.

A Tool Steel Testing Machine

The simplification of the problem mentioned is made possible by the use of a recently-designed tool steel testing machine.

The principle of the tool steel testing machine will be understood from the diagram, Fig. 6, in which *A* represents a tube of steel or other metal, suitably guided and rotating about a vertical axis, while its lower end rests on a fixed abutment *B*. A cutting tool *C* is held in a vise *D*. The vise is mounted on knife edges *E*, lying in the plane of the end of the tube. By means of a screw *F*, with a movable weight and scale, the tool can be caused to press upwards against the edge of the tube with any desired force, and cut it away with a turning action.

The tube is held in contact with the abutment *B* by means of a weight *G*, the downward pressure of which is always greater than the upward pressure of the tool. As the tube is turned away by the tool, it is fed downwards by the weight *G*, so that the end of the tube, though it is constantly being turned away, is constantly held in contact with the abutment *B*, and the point at which cutting takes place is therefore

stationary. A dashpot *H* is connected to the vise to prevent jarring or vibration.

Turning now to the illustration of the machine in Fig. 7, it will be seen that the tube is driven by a spindle, which receives its motion through cone and friction disk gearing, capable of giving it a wide and continuous range of speeds. A paper-covered drum, mounted beside the column of the machine, is driven from the spindle through worm and spur speed reducing gear. Vertical movements of the spindle are communicated through a fine chain to a pencil mounted on a vertical sliding bar.

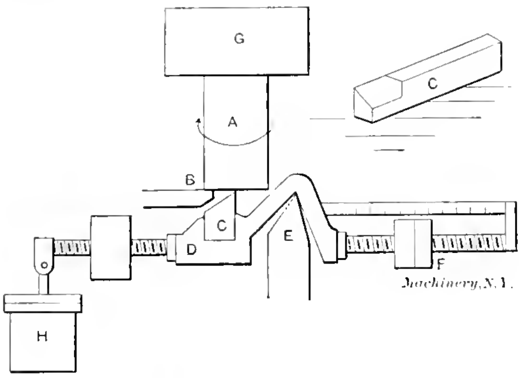

Fig 6. Diagrammatical View of Action of Tool Steel Testing Machine

When the machine is set in motion, the pencil draws a diagram, in which horizontal distances represent the number of revolutions made by the tube, and vertical distances represent vertical movements of the spindle—*i. e.*, the length of tube turned off by the tool. The slope of the line at any point represents the rate at which the tube is being turned away, which is conveniently expressed in inches per 1,000 revolutions. In practice the tube is ¾ inch diameter and ⅝ inch bore.

By means of this machine it will be possible to ascertain what is the theoretically correct shape for a single file tooth for any particular metal. This information having been obtained, it will rest with the file-maker to ascertain by means of the file-testing machine what combination of theoretically correct file teeth gives the best maximum efficiency and durability to the file.

In the machine shown, the cutting of metal is reduced to its simplest and most elementary form. A straight cutting edge is pressed with a known force against a metal surface of constant width and unvarying hardness, moving at known constant speed, and being cut away at a rate which is graphically recorded. It is evident that the tool continues to cut until it reaches a definite degree of bluntness, when the pressure against the teeth will be insufficient to cause it to penetrate the metal. At this moment it will slip over the surface without cutting, and on the diagram this condition will be shown by the curve becoming horizontal.

Results of Experiments with Tool Steel Testing Machine

The results of these experiments are not, as yet, definite, but so far the results serve to show the character of the information that may be expected, and its bearing on the file tests. A series of tests made to ascertain the effect of variations in the clearance angle or slope of the back of the file teeth, with the front without rake, confirmed in a striking manner the condition that mere sharpness is relatively an unimportant factor in file efficiency. A second conclusion to be drawn from the tests is that the clearance angle has very little influence on the rate of cutting. The most striking feature of the tests is, however, the great difference in the duration and in the total amount of metal removed, showing that 0.05 cubic inch could be cut away with 5 degrees clearance in 100 revolutions before the tool ceased cutting, against 3.7 cubic inches of metal removed in 3,800 revolutions with 25 degrees clearance. Considering that all these tests were made with the same tool, the conclusion previously arrived at that durability of the file and the amount of work it is capable of doing depends far more on the shape of the teeth than on the quality of the steel is confirmed, and it would appear that the chief factor influencing the durability and output is the clearance angle or slope of the back of the teeth. The tests, however, indicate that there is a limit beyond which the clearance angle cannot be increased with advantage. When the clearance angle was greater than 25 degrees, the output and durability began to decrease. This was due to the fact that the edge of the tool broke away, indicating that the tooth was too weak; but it must not, therefore, be assumed that a clearance of 25 degrees is a practical limit. The tests were made with a pressure of 25 pounds, and this pressure applied to a single file tooth probably represents usage more severe than a file would be subjected to.

The results obtained also indicate how files of superior steel may give poorer results than files of inferior steel. In the case above, a tool of the same quality of steel removed in one case seventy-four times as much metal as in another case, the difference being merely a difference in clearance angle. Now it is a well-known fact that a high-carbon steel is much less ductile than one of less hardness. Consequently the high-carbon steel does not flow so readily when struck with a chisel; the burr which forms the working part of every file tooth is much lower, or in other words, the clearance angle is less. Thus it may easily happen that the extra durability of the steel is far more than counteracted by the lack of clearance, and a file of very good steel may give exceedingly poor results as a cutting tool if not properly cut with a clear understanding of the requirements of the durability and efficiency of files.

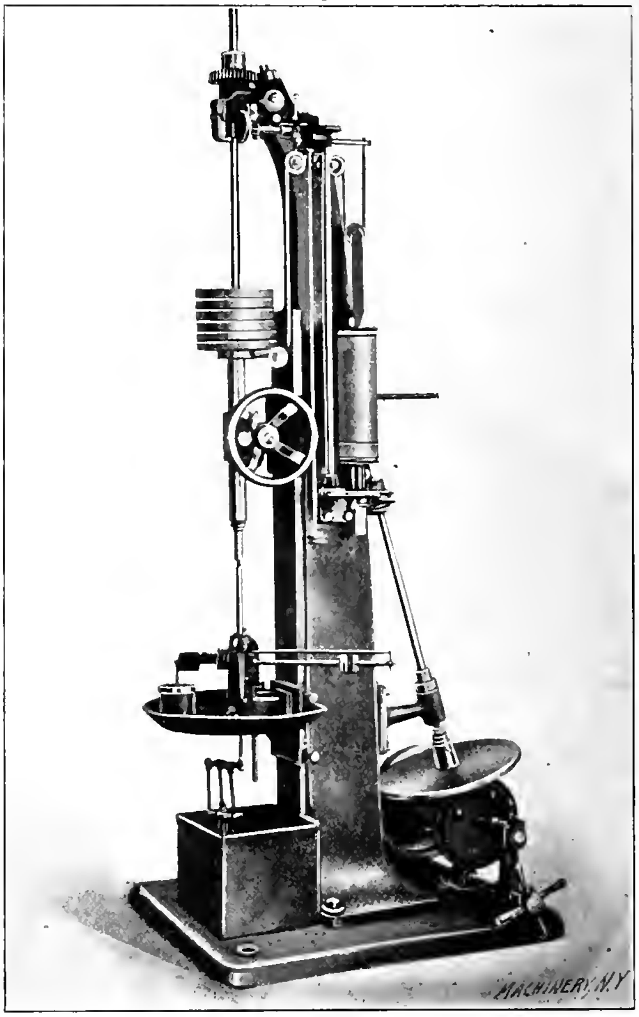

Fig. 7. Tool Steel Testing Machine

A series of experiments was made with a view to ascertaining the effect of varying degrees of rake and slope on the efficiency and durability of file teeth, the term slope being used to indicate the angle at which the up-cut lies across the face of the file. Only two slopes were experimented with —a slope of 90 degrees, corresponding to the cut of a file intended for brass, and a slope of 70 degrees, such as is commonly found in files intended for general work.

Each of these slopes was tested in conjunction with three different degrees of rake, *viz.*, a negative rake of 15 degrees, as commonly found in file teeth; a zero rake, the front face of the tooth standing at right angles to the surface of the work, a condition occasionally approached in file teeth; and a positive or forward rake of 15 degrees, a condition which is never found in file teeth, though experience with other cutting tools points to this as the correct form for cutting most metals. The same tool was used throughout, so as to eliminate any variations due to difference of temper or quality in the steel. Each test was made with a freshly sharpened edge, and was continued until cutting ceased. The pressure of the tool on the work was in all cases 25 pounds, the cutting speed 30 feet per minute, and the clearance angle of the tool 20 degrees in all except two of the tests.

The results of these tests showed that an extraordinary difference in the output of the work can be obtained in the same tool by a relatively slight variation in its cutting angles. Contrary to what might be expected, these variations have much greater effect on the output than on the rate of cutting. It was also noticed in these, as in all other tests made with the machine, that mere keenness of edge had very little effect on the efficiency. All the curves obtained were approximately straight lines, and cutting ceased abruptly with very little previous loss of efficiency.

Conclusions of Tests Relating to Shape of File Teeth

In relation to commercial file-making, the most important conclusion of the tests appears to be that the least desirable results of all were obtained with the tool which most closely resembled the commercial file tooth. The best results of all were obtained with a form of tooth which can probably be reproduced without great difficulty, but which appears never to have been adopted. This tooth would have a positive front rake of 15 degrees, and a clearance of 5 degrees. It was previously shown that the clearance angle is a most important factor in determining the total output and that the tool with no rake and only 5 degrees clearance will do only a very small amount of work, but it appears that a tool with the same clearance angle and with positive front rake will do an exceptionally large amount of work with great efficiency, and it is probable that by slightly increasing the clearance angle the output will be still further increased without undue weakening of the cutting edge.

Some caution will, of course, be necessary in applying the results just described to the art of file-making. These tests were made with what was practically a single isolated file tooth with a straight instead of a rounded cutting edge. The file is a series of round-nosed tools, lying very close together, and it may be found that a file with a positive rake will have a tendency to choke up with filings to such an extent as to neutralize its greater efficiency. The progress must be made by systematic experiments, confirmed at every step by the file-testing machine.

The results first described have a bearing on other cutting tools besides files. Of all the tool forms experimented with, among those that gave the smallest output of work was one having no front rake. This, however, is the usual form of tooth for milling cutters. There seems to be no reason for making milling cutters without front rake, except the well-known propensity of human beings to follow in their forefathers' footsteps. Milling cutters with front rake have been made and tried, and have given good results, and yet it is impossible to buy such cutters without having them made to order.

The Testing of Tool Steel

We now pass to the consideration of that function of the tool steel testing machine from which it derives its name and which may prove to be of greater practical importance than any other—the testing of the quality of tool steel. The slope of the curves produced on the diagram in the testing machine indicate the rate at which the test tube is being cut away by the tool point, and it is evident that this rate is governed by several factors: the speed and quality of the test tube, the shape and position of the tool, and the force with which it is pressed against the tube. Any alteration in any one of these factors will affect the rate of cutting and the slope of the curve, which therefore serves as an absolute check on the uniformity of the mechanical conditions. The remaining factor in the test is the quality of the steel, and a moment's consideration will show that this does not affect the rate of cutting at all. So long as a number of tools are equally sharp, they will all cut at the same rate under the same conditions, no matter what steel they are made of; but the tool which is made of the best steel will remain sharp longest.

The results of experiments on carbon steel and high-speed steel are shown in Figs. 8 and 9. At slow speed (30 feet per minute) the carbon steel lasted four times as long as the high-speed steel. At a somewhat higher speed (40 feet per minute), the high-speed steel tool lasted twice as long as the carbon steel. These tests were repeated, but the same results were obtained. Up to a certain limit all tools with increased speed not only did more work per unit of time, but lasted a greater number of revolutions. Another interesting experiment was carried out with a blunt tool. It was tested until it ceased cutting at 40 feet per minute; when the speed was increased to 85 feet per minute the same tool immediately began cutting faster, that is, removing more metal per revolution than when it was quite sharp and working at a lower speed. This indicates that there is a definite state of bluntness corresponding to each speed. These are a few of the many curious facts that have been brought into prominence by the tool steel testing machine. They may or may not have an important bearing on the art of cutting metals, but it is necessary to bear them in mind.

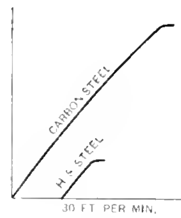

Fig. 8 Comparison of Durability of Carbon and High-Speed Steels at Low Cutting Speed

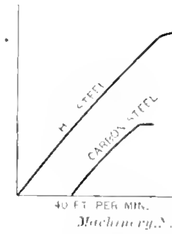

Fig 9. Comparison of Durability of Same Steels at Increased Cutting Speed

The conclusions also throw an interesting light on the relative value of ordinary carbon and high-speed steels for various tools. For files, for instance, having a low cutting speed, it is likely that special alloy steels are of but little value. While it may not be assumed that all alloy steels are inferior to carbon steel for file making, it is evidently unsafe to assume that because a certain steel has given good results, say, for twist drills, it would be suitable for cutting tools used under totally different conditions. For instance, reamers are generally used for a slight scraping cut at a low speed, precisely under conditions for which high-speed steel seems to be least suited, and for such tools the high quality steel appears to be unwarranted. It may be too soon to dogmatize, but there seems to be reason for caution in the application of high-speed steel to the manufacture of such tools as reamers and milling cutters for light finishing work.

Another experiment showed that the maximum duty could be obtained from a carbon steel at the cutting speed of 50 feet, by a good high-speed steel at 85 feet, and from one of the new British high-speed steels at 140 feet per minute cutting mild steel. This latter result was unexpected, since no increase in the working speed was claimed by the makers of the new steel, but only an increase of durability at the speeds at which high-speed steel is ordinarily used. The tool steel testing machine can also be used for ascertaining the wear of metals, the efficiency of the various lubricants in cutting operations to preserve the edge of the tool, and for testing the hardness of metals.

The testing for hardness is accomplished by a drill loaded with a certain weight, and the rate at which it penetrates the material under investigation is used as a measure of hardness. This test is by no means new, but it has often been regarded with some distrust, because the sharpness of the drill is a variable factor in the result of the test as ordinarily applied. The production of considerable quantities of

test bars for the file and steel testing machines has called for some accurate method of judging hardness (using that rather vague term to denote resistance to the action of cutting tools), and the drill test has proved itself during nearly two years of continuous use the most sensitive and reliable test available.

The distributing influence of the varying sharpness of the drill is eliminated by adopting a definite rate of penetration on a standard reference bar. Suppose the rate of penetration of half an inch per 1,000 revolutions to be adopted, the load on the drill is adjusted until this rate of penetration is obtained on the standard bar. Tests on the materials under investigation are then made, and any variation in the rate of penetration, beyond certain predetermined limits, leads to the rejection of the material. Periodically a return is made to the standard bar, and any loss of penetration due to blunting of the drill is corrected by increasing the load. In practice a considerable number of tests can be made on ordinary materials without perceptible blunting of the drill. The sensitiveness of the test depends entirely on the rate of penetration adopted. A drill so lightly loaded as to be on the point of slipping gives a hardness test which is probably more sensitive than any other. In this connection it is interesting to note that drills of high-speed steel have proved quite unsuitable for the drill test, as they lose their sharpness much more rapidly than drills of carbon steel, under the extremely light cuts that are essential for a sensitive test.

The results put forward in the foregoing have been confirmed by repeated experiments, and are believed to be reliable as far as they go, but important facts may be undiscovered and those phenomena which have come into view may be only parts of larger phenomena which cannot be seen in their true perspective until they have been investigated from every side, and under widely varied conditions of experiment.

* * *

SIZES OF PIPE MAINS FOR HOT WATER HEATING*†

CHARLES L. HUBBARD‡

In the accompanying Supplement three sets of curves are given for determining the sizes of pipe mains for hot water heating. Two of the diagrams are for gravity circulation where the water is moved under a low head, the motion being due solely to the difference in temperature between the supply and return. The third diagram is made up for the usual range of velocity and head employed in forced hot water circulation actuated by means of a pump. In all cases the capacities are for pipe lengths of one hundred feet.

Volume of Water to be Moved

The volume of water to be passed through the supply main in a heating system may be found by the following equation:

$$G = \frac{E \times H}{8.3 \times (T - T_1)}$$

in which G = gallons per hour,

E = efficiency of radiating surface (170 for direct, 400 for indirect, and 1,000 for hot blast heating),

H = square feet of heating surface,

T = initial temperature of water (commonly taken as 180 degrees),

T_1 = final temperature of water (commonly taken as 160 degrees).

Example.—A heating system has 5,000 square feet of direct heating surface, and 1,000 of indirect; how many gallons of water (G_1) must pass through the main per minute, assuming a drop in temperature of 20 degrees?

$$G_1 = \frac{(170 \times 5{,}000) + (400 \times 1{,}000)}{8.3 \times 20 \times 60} = 125 \text{ gallons.}$$

* For additional information relating to heating and ventilation, see the following articles previously published in MACHINERY: Calculations of Fans and Heaters, June, 1908, engineering edition; The Heating and Ventilation of Machine Shops, September, 1907, engineering edition; and also the articles referred to in connection with the one last mentioned. See also MACHINERY'S Reference Series No. 39: Fans, Ventilation and Heating.

† With Data Sheet Supplement.

‡ Address: 283 Central St., Auburndale, Mass.

Head to Produce Flow

The head to produce flow may be found by the equation

$$H = D \times h \times 0.000365,$$

in which

H = head in feet, producing flow,

D = difference in temperature between supply and return,

h = height or elevation of the heating surface above the boiler.

Example.—A certain quantity of heating surface is located at an elevation of 50 feet above the boiler; what is the available head for producing flow through the supply riser if the drop in temperature between the supply and return is 30 degrees?

$$H = 30 \times 50 \times 0.000365 = 0.55 \text{ feet.}$$

When the radiation is all on the same floor, the elevation h may be taken as the vertical distance between the center of the radiators and the center of the boiler. If it is equally distributed on several floors it may be taken as though it were all located upon the central floor.

If unevenly distributed, the *average elevation* may be found by the equation

$$h = \frac{A \times h_a + B \times h_b + C \times h_c}{A + B + C}$$

in which A, B, and C are the square feet of radiation upon the several floors, and h_a, h_b, and h_c the corresponding elevations of the radiators located upon these floors.

In computing the length of mains, provision must be made for the frictional resistance due to bends in the pipe. In practice it is customary to consider an elbow equivalent to increasing the length of the pipe 60 diameters, and a return bend equivalent to 120 diameters.

The size of main required to supply a heating system or group of heaters depends upon the square feet of radiation, the elevation above the boiler, the drop in temperature of the water in passing through the radiators, and the length of run. Taking the examples previously given, and assuming the length of the mains to be 200 feet, what size of pipe will be required?

Gallons per minute 125; available head to produce flow 0.55 foot. As the run of pipe is 200 feet long, the head per hundred feet is $\frac{0.55}{2} = 0.27$ foot. From diagram II in the Supplement we find that a flow of 125 gallons under a head of 0.27 foot calls for a pipe between 5 and 6 inches in diameter, in which case the larger size would probably be used.

Forced Circulation

In case of forced circulation the mains should be of such size that the total head required to overcome the friction will not exceed 50 feet, the usual range being from 30 to 50 feet. The velocity of flow is usually made from 5 feet per second in the smaller sizes (2 to 3 inches) to 10 feet per second in the larger sizes (6 to 8 inches).

The table in the Supplement gives the capacity of different sizes of pipe for varying velocities of flow through them.

* * *

In spite of their conservatism and proverbial "slowness," our British friends have achieved remarkable results in the running of fast trains, and on the Great Western R. R. results are obtained which are not equalled by any regular American service. Between London and Exeter, a distance of 174 miles, three expresses run daily without a stop, in exactly three hours, or at an average speed of 58 miles an hour. A fourth train on the same route makes the same run at an average speed of 56.3 miles per hour. It is not unusual for the total load back of the tender of these trains to be 400 tons.

* * *

The new radium institute of Great Britain has placed an order for a trifle over one-quarter of an ounce of radium-bromide, the price for which is not less than $150,000, or at the rate of $570,000 per ounce, or over $9,000,000 per pound. Some conception of the enormous labor involved in the extraction of this mineral is afforded by considering the price of a pound given as the wages of 15,000 men working one year of 300 working days at $2.00 per day.

THE COMMERCIAL AIRSHIP—A CRITICISM

FORREST E. CARDULLO*

In an article entitled "The Commercial Airship," in the August issue of MACHINERY, Mr. McCready reviews briefly the disadvantages of the heavier-than-air machines, and of the gas-inflated airships, stating that both are impractical for commercial work. As a substitute for them, Mr. McCready proposes a type of airship consisting in principle of a metallic reservoir of large volume from which air can be exhausted, lightening it by the weight of the air so exhausted. Obviously, if this contrivance is to be successful, the weight of the metal envelope must be less than that of the displaced air, and since the reservoir is to be exhausted of air, it must be strong enough to resist the external air pressure, which is 14.7 pounds per square inch or 2,117 pounds per square foot.

Now it follows that the material to use in the construction of this airship is that which has the greatest strength for a given weight. This material will be one of the alloy steels having high elastic limit and tensile strength. Aluminum is lighter, but is also weaker in much greater proportion. Many alloys of low specific gravity present advantages in certain types of construction, but pound for pound, they are not as strong as the alloy steels. Such alloy steels weigh about 480 pounds per cubic foot.

The form of reservoir which contains the largest volume within a given bounding area is the sphere. Consequently for a given volume and thickness of wall, a sphere will make the lightest reservoir. Also, since the compressive stress is the same in every cross section of the wall cut by a radial plane, the sphere will have the thinnest wall of any shape of the same diameter. It is apparent, then, that no lighter construction could be made than a perfect sphere without bracing. If the sphere is perfect, and the external pressure uniform, bracing is theoretically unnecessary, and no possible system of bracing can be devised which would make a sphere stronger for the same weight, than its theoretical strength, calculated on the assumption that it is perfect in form, homogeneous in material, and subjected to a uniform pressure. Hence if a spherical reservoir cannot be made light enough and strong enough to perform the desired service, no other form of reservoir will be possible.

Volume of 1 pound of air at 62 degrees F. and 14.7 pounds pressure per square inch = 13.141 cubic feet.

Volume of a sphere = $0.5236\, d^3$.

Area of a sphere = $3.1416\, d^2$.

Area of its great circle = $0.7854\, d^2$.

Circumference of its great circle = πd.

Diameter of a sphere having a displacement of 1 pound of air at 62 degrees F. at sea level = 2.93 feet, which is found as follows:

$$13.141 = 0.5236\, d^3$$

$$d = \sqrt[3]{\frac{13.141}{0.5236}} = 2.93.$$

Its area will then be

$$3.1416 \times 2.93^2 = 26.97 \text{ square feet.}$$

Assuming that the steel weighs 480 pounds per cubic foot, and further that the shell will weigh exactly one pound, we find for the thickness of the shell

$$\frac{1}{26.97 \times 480} = 0.0000772 \text{ foot.}$$

or $0.0000772 \times 12 = 0.000926$ inch, or the thickness of our shell will be a trifle less than one-thousandth part of an inch.

The area of the great circle of this sphere will be

$$0.7854 \times 2.93^2 = 6.74 \text{ square feet.}$$

and the pressure upon it, at 14.7 pounds per square inch, is

$$6.74 \times 14.7 \times 144 = 14,270 \text{ pounds.}$$

The circumference of the great circle is

$$3.1416 \times 2.93 = 9.205 \text{ feet or } 110.5 \text{ inches.}$$

It therefore follows that the cross section of the shell on the great circle is $110.5 \times 0.000926 = 0.1023$ square inch.

The compressive stress produced in this cross section by the pressure of the air is therefore

$$\frac{14,270}{0.1023} = 140,000 \text{ pounds per square inch.}$$

Now it is obvious that we have hardly any substance sufficiently strong to construct such a sphere, and certainly there is no substance sufficiently strong to construct a sphere able to float in air and in addition lift 55 per cent of its own weight, when interior bracing is added to prevent collapse.

Mr. McCready states in his article that the vacuum system becomes proportionately more practicable and efficient as the size of the airship is increased. Let us see if this is true.

$$\text{Stress} = \frac{\text{pressure on great circle}}{\text{cross section at great circle}} = \frac{0.7854\, d^2 \times 14.7 \times 144}{3.1416\, d\, t} = \frac{529\, d}{t}.$$

$$\text{Weight of 1 cubic foot of air} = \frac{1}{13.141} \text{ pound.}$$

$$\text{Volume of } \frac{1}{13.141} \text{ pound of steel} = \frac{1}{13.141 \times 480} = 0.0001585$$

cubic foot.

Cubic feet of steel in shell = $0.0001585 \times 0.5236\, d^3$.

Area of shell = $3.1416\, d^2$.

$$\text{Thickness of shell} = t = \frac{0.0001585 \times 0.5236\, d^3}{3.1416\, d^2} = 0.000026\, d.$$

$$\text{or the stress} = \frac{529\, d}{0.000026\, d} = 20,300,000 \text{ pounds per square foot,}$$

and is independent of the diameter.

One point alone in regard to the construction advocated in the article referred to will serve to show its futility. The figures for a proposed vacuum airship are given as 150 feet diameter by 750 feet long. The weight of the cylinder, fittings and machinery is given at 270 tons. *If all of this 270 tons were utilized as a 700-foot steel column, keeping the ends of the cylinder apart against atmospheric pressure, the stress in the column would be 163,000 pounds per square inch.*

The truth of the above assertion may be demonstrated as follows: The area of a circle 150 feet in diameter is 17,671 square feet. On each square foot there will be a pressure of 2,117 pounds, or a total compressive stress, tending to force the ends together, of 37,400,000 pounds. Assuming the column to weigh 270 tons, or 540,000 pounds, its volume will be 1,125 cubic feet, and if it is 700 feet long, allowing for the conical ends, its cross section will be 1.6 square foot or 230 square inches. Now the stress in the column = $\frac{37,400,000}{230}$ = 163,000 pounds per square inch.

This stress looks rather excessive in a column 700 feet long. The following figures in regard to the stress in the walls, normal to an axial plane are, however, even more illuminating.

The strongest and lightest construction that we know of in the case of a cylinder subjected to external pressure, is that used in the Morrison corrugated furnace. The reason it is so strong is that the cylinder wall furnishes its own bracing. Let us suppose that the airship is built on this principle, and that the whole 270 tons is put into self-bracing wall. Then, the weight of cylinder wall per foot of length will be $\frac{540,000}{700} = 771$ pounds. This 771 pounds of metal will form a band around the cylinder $150\,\pi = 471$ feet long, and its volume, if of steel, will be $\frac{771}{480} = 1.6$ cubic foot. Its cross-section will then be $\frac{1.6 \times 144}{471} = 0.5$ square inch.

The total stress in this band will be one-half the pressure of the air upon 150 square feet (*i. e.*, the area of the projection of a section of the cylinder one foot long upon the axial plane) which is $\frac{150 \times 14.7 \times 144}{2}$ or 159,000 pounds. The stress per square inch is then $\frac{159,000}{0.5}$ or 318,000 pounds.

We are forced to the conclusion that no ingenuity of construction will make such an airship able to support even its own weight, unless we construct it of some unknown material having a strength many times greater weight for weight than that of the strongest steel.

BUSY MAN'S METHOD OF KEEPING A NOTE-BOOK*

JOHN S. MYERS†

Ideas unapplied to a useful purpose are worthless. A man's mind may be as full of ideas as a dog's fur of fleas and yet the man derive no more benefit from those ideas than the dog does from the fleas. Now the more busy the individual, the greater the number of ideas which crowd around the court of judgment crying for deliverance, and the greater the number of other people's ideas that are recognized as good; yet, at the same time, from the very nature of the case, the less time the individual has to devote to the useful

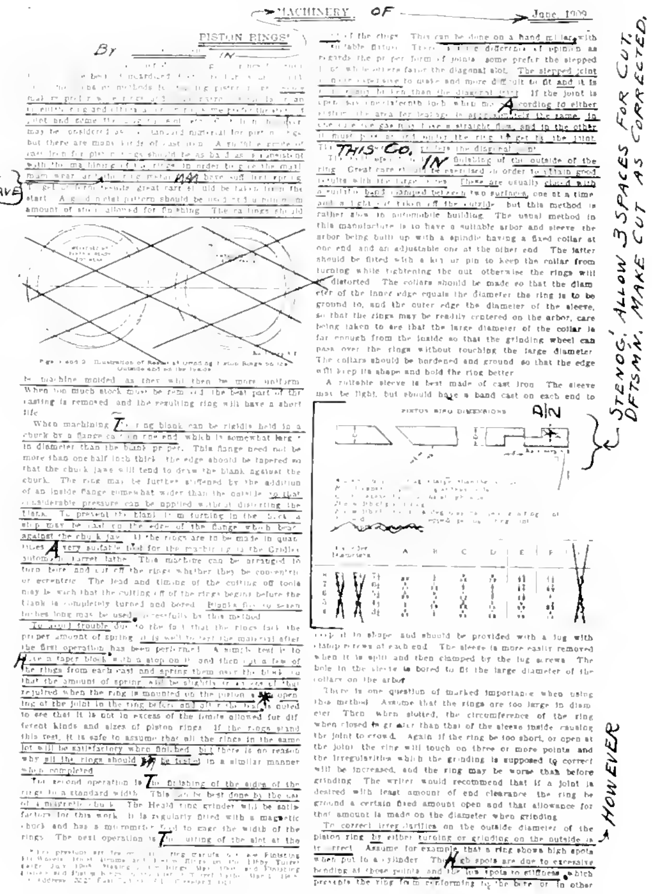

Fig. 1. Reproduction of Portion of Article, in June, 1909, Machinery, showing Underscored Matter to be copied by the Stenographer

application of those ideas. Nevertheless, if you have an idea to develop do not take it to a man of leisure, for he will not have time to consider it, but take it to the busiest man you know and you will find he can and will take time to pronounce judgment thereon.

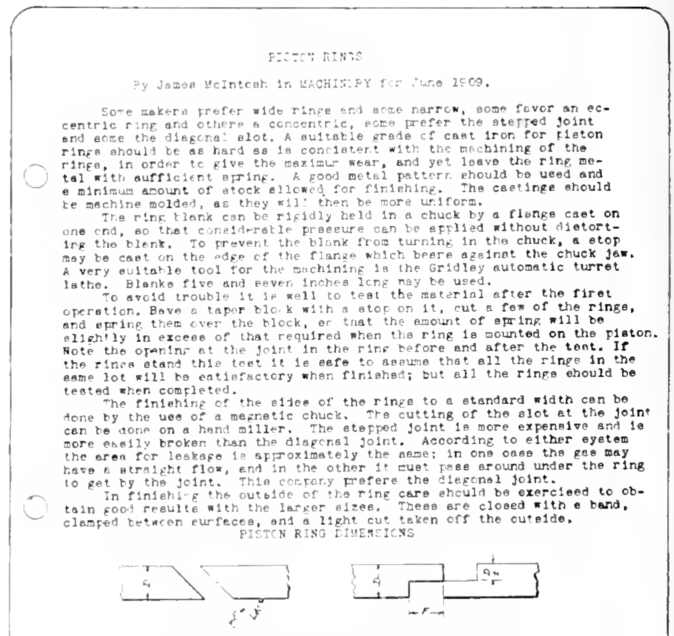
Now, in the matter of note-books, the chief draftsman of a concern should be the man best fitted for the compilation of all matter of a mechanical or constructive nature, but, at the same time, he is the one man whose mind is already burdened with excessive detail; how, then, is he to do anything in this line? The answer obviously lies in the proper direction of efficient help.

The writer once worked for a large concern that employed a librarian; the librarian had charge of the vaults, storage and recording of all drawings, correspondence, trade literature, etc. It was the duty of the assistant librarian to conscientiously peruse all the trade magazines, catalogues, etc., in search of salient or pertinent information, and all such was clipped, pasted to cards, referred to the proper officer of the company and afterwards carefully filed. The magazines were all subscribed for in duplicate so that there was always an unmutilated copy on file to refer to for the complete text of an article any clipping was made from.

But most concerns would not care to go into the matter so extensively, and even those who could and would might find, as the writer did, many mountains in the way of best results. I therefore take pleasure in presenting to the readers of MACHINERY an inexpensive scheme for the busy man to compile a note-book in neat form with the minimum expenditure of his time and nervous energy.

The scheme as outlined is for the *very busy man;* for those who have more time to devote to it I would suggest that they simply do more of the work themselves and leave less to their help.

1. Direct that all magazines, catalogues, etc., be left on your desk as received.
2. Glance through each as received and mark or note any article of promise which you think may contain matter of especial interest to your line of work.
3. After so marking, throw the magazine or article in a box or drawer especially devoted to the purpose.
4. If the concern is very large have several of these boxes or drawers labeled *Mechanical, Structural, Electrical,* or any other classification that may suit your commercial conditions.
5. Instruct your squad bosses or specialists in various lines to dispose of the material in the following manner:
7. Squad foreman will at stated or convenient intervals go over all matter in his box or folder and carefully read all marked articles, and if he finds matter worthy of noting he will underscore the salient or pertinent matter with such corrections, notes, etc., as will enable a stenographer to transcribe same in a condensed form.
8. The stenographer will typewrite the underscored matter on standard loose leaf note-book paper, using a black ribbon and a sheet of carbon paper *reversed,* so that blue prints may be made.
9. The squad foreman will read over such transcribed matter and make any necessary corrections.



PISTON RINGS

By James McIntosh in MACHINERY for June 1909.

Some makers prefer wide rings and some narrow, some favor an eccentric ring and others a concentric, some prefer the stepped joint and some the diagonal slot. A suitable grade of cast iron for piston rings should be as hard as is consistent with the machining of the rings, in order to give the maximum wear, and yet leave the ring metal with sufficient spring. A good metal pattern should be used and a minimum amount of stock allowed for finishing. The castings should be machine molded, as they will then be more uniform.

The ring blank can be rigidly held in a chuck by a flange cast on one end, so that considerable pressure can be applied without distorting the blank. To prevent the blank from turning in the chuck, a stop may be cast on the edge of the flange which bears against the chuck jaw. A very suitable tool for the machining is the Gridley automatic turret lathe. Blanks five and seven inches long may be used.

To avoid trouble it is well to test the material after the first operation. Save a taper block with a stop on it, cut a few of the rings, and spring them over the block, so that the amount of spring will be slightly in excess of that required when the ring is mounted on the piston. Note the opening at the joint in the ring before and after the test. If the rings stand this test it is safe to assume that all the rings in the same lot will be satisfactory when finished; but all the rings should be tested when completed.

The finishing of the sides of the rings to a standard width can be done by the use of a magnetic chuck. The cutting of the slot at the joint can be done on a hand miller. The stepped joint is more expensive and is more easily broken than the diagonal joint. According to either system the area for leakage is approximately the same; in one case the gas may have a straight flow, and in the other it must pass around under the ring to get by the joint. This company prefers the diagonal joint.

In finishing the outside of the ring care should be exercised to obtain good results with the larger sizes. These are closed with a band, clamped between surfaces, and a light cut taken off the outside.

PISTON RING DIMENSIONS

A = amount piston ring is larger than the cylinder
B = thickness of piston ring at heavy side
C = thickness of piston ring at light side
D = width of piston ring
E = width of cutter for 45 deg. diagonal opening in ring joint
F = width of cutter for stepped opening in ring joint

Cylinder Diameters		A	B	C	D	E	F
8	7-1/4	7/32	1/4	9/64	9/16	15/32	11/16
7	6-1/4	3/16	7/32	1/8	1/2	13/32	19/32
6	5-1/4	5/32	3/16	7/64	3/8	11/32	1/2
5	4-1/4	1/8	5/32	3/32	5/16	9/32	13/32
4	3-1/4	3/32	1/8	5/64	7/32	7/32	5/16

To correct irregularities by turning or grinding on the outside is, however, incorrect. High spots are due to excessive bending at those points, and low spots to stiffness. If we reverse the method and grind on the inside the irregularities will be corrected, for these stiff portions will become weaker and tend to bend more and the stresses in the ring will be equalized.

The table gives piston ring dimensions based on experience. The width D may be increased in wearing surface, but tabulated dimensions give satisfactory results. The inside of the ring should always be machined. The practice of annealing ring blanks does not seem desirable, as stresses due to cooling are remote with a ring blank of uniform thickness.

Fig. 2. Reproduction of Note-book Page, showing the Form in which Condensed Matter appears. Typewritten on Thin Paper with Carbon reversed on Back, thus making Copy that will blue-print well

10. The boy in charge of the note-books will see that blueprints of this matter are inserted in the several note-books kept in the office for general reference, and that special marked copies be delivered to foreman, etc., in charge of work upon which the articles especially bear.

To make the method perfectly clear I have selected at random an article in the June issue of MACHINERY, underlined it as would be done before passing to the stenographer. A reproduction of this underlined and noted article is shown in Fig. 1. In Fig. 2 is shown a reproduction (reduced) of the notes as transcribed by the stenographer.

* For articles previously published in MACHINERY on this subject, see "Envelope System for Filing Data," June, 1906, and "Binder for Preserving Articles of Special Interest," March, 1909.

† Address: 2456 Almond St., Philadelphia, Pa.

SIMPLE AND AUTOMATIC STOP-PINS FOR PRESS WORK

H. A. S. HOWARTH*

The stop pin occupies a position of much importance among the accessories of the blanking die. Upon its design and adjustment depend both the quality and the quantity of the output of the press. Hence it is fitting that some attention be given to the consideration of it. By proper selection from the types to be described it is possible to secure a large output of blanks without recourse to more expensive apparatus. The several forms of stop-pins enumerated in the following list will be described in order, their proper uses being noted together with their merits and faults: The plain fixed stop-pin; the bridge stop-pin; the simple latch; the spring toe latch; the side swing latch; the positive heel and toe latch; the gang starting device.

These devices are capable of giving under the proper conditions, the maximum output of blanks. With the exception of the first, they can be used with either hand feed or automatic roll feed.

The ideal output of one blank for every turn the press can make in a day is never realized, with single dies. The delays

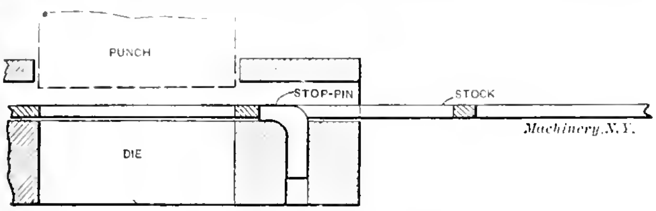


Fig. 1. A Plain Fixed Stop-pin

which arise from so many sources have to be studied carefully and eliminated so far as they contribute to unnecessary expense. In addition to improper design and poor adjustment of the stop-pin, other causes of small output are: Lack of skill; inconvenient arrangement of the new stock, the blanks and the scrap; inefficient methods of oiling the stock; and poorly made or poorly designed dies. A skillful operator, if given a little freedom, will usually arrange the stock distribution quite well, but the design and adjustment of the dies and the stop-pin usually devolves upon the toolmaker.

Plain Fixed Stop-pin

The plain fixed stop-pin, which is the simplest form, is indicated in Fig. 1. With it the operators become so expert that they are able for several minutes at a time to utilize every stroke of a press making 150 revolutions per minute. This stop is best suited to the use of strip stock in simple dies, because a miss will then cause no serious delay. The time between finishing one strip and starting the next affords the necessary rest for the operator. The concentration required is very intense—especially for the novice. When but a few blanks are made from a die at one time, and when changes of dies are frequent, this simple stop-pin is the most economical. Then too, it would not be feasible to use this stop-pin for coiled stock and expect the operator to finish the coil without

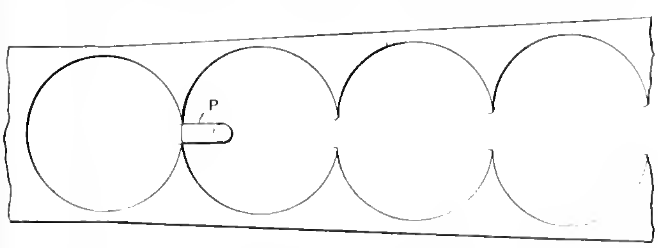

Fig. 2. Fixed Stop set close up to the Die so that there is no Stock between the Blanks

a rest or a miss. There is, however, one method of using this stop which permits of a maximum output: That is to allow no metal between the blanks. Then the stop-pin will extend clear up to the die and be high enough so that the stock cannot jump it. Each blank will then part the scrap at the stop-pin and allow the stock to be pulled along to its next position. This arrangement is shown in Fig. 2, with the stock parting at the pin *P*. This method is widely used on simple work where the edge of the blank does not have to be perfectly uniform. Where the die has least to cut it will wear away most on account of the thin pieces of stock that crowd down between the punch and the die. Small drawn cups are made in this way. The blank is cut by the first punch and held by it while a second punch, within the first, draws the blank through another die and forms the cup. This

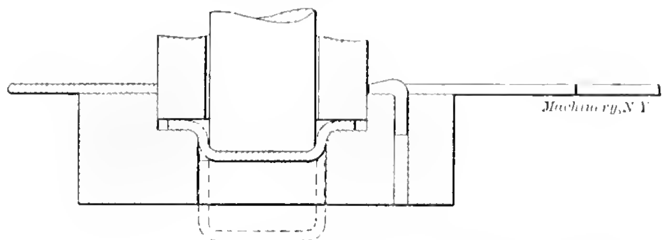

Fig. 3. Example of Work to which the Stop shown in Fig. 2 is adapted

is shown in Fig. 3. The stock feeds to the right and each cup, as formed, pushes the one ahead of it through the die as indicated by the dotted lines.

Bridge Stop-pin

The bridge stop-pin, shown in Fig. 4, is perhaps the most efficient and easiest to operate of all. It is also the simplest in design. The stop-pin *P* projects downward from a bridge *B* that extends over the stock which is being fed to the left. Provision is made for the blank (or scrap, as the case may be) to fall out under the bridge. Its use is limited, however, to that class of work which cuts the stock clear across and uses its edges as part of the finished blank. As here shown, the scrap is being punched through the die and the blank when cut falls down the inclined surface shown. When the

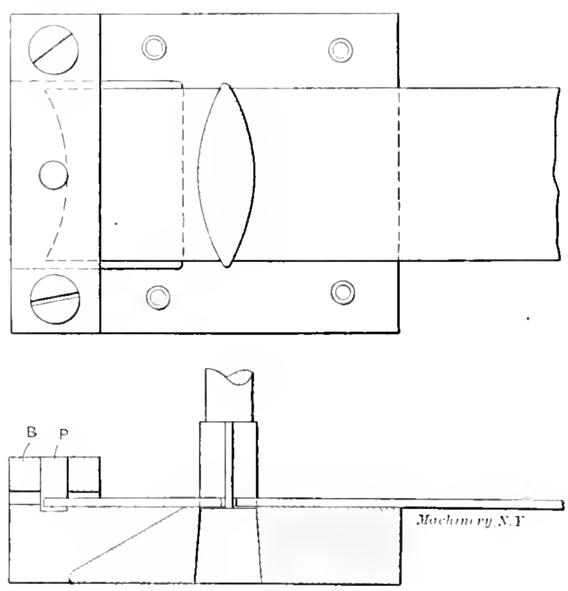

Fig. 4. The Bridge Stop-pin

blanks are simpler and have straight ends the die may be so arranged that each stroke finishes two blanks, one being punched through the die and the other falling outside down the incline. Little skill is required of the operator; he simply has to be sure to push the stock up to the stop-pin each stroke.

The Simple Latch

The simple latch is shown in Fig. 5. It is suited for dies that have pilot-pins. The latch is lifted by the down stroke of the punch and is lowered again as the punch rises. Hence it is evident that, if used with dies without pilot pins, the punch must reach the stock and hold it before the latch lifts. When its lifting is thus delayed it will lower before the punch withdraws from the stock and will fall in the same place it lifted from. The stock will then not be fed along. But if a pilot-pin is used, it may be set so as to enter the guide hole just before the latch lifts. The latch may be set to lift before the punch reaches the stock. It will then fall after the punch withdraws from the stock, and sufficient time may be allowed for the operator to feed the stock along. This device is best

* Address: Box 171, South Bethlehem, Pa.

suited for use with automatic feed rollers because the timing of the operations would be more uniform; whereas if the operator does not pull the stock with uniform speed the latch is apt to drop too soon or too late. Another manner of operating this simple latch is to give it its motion by means of a

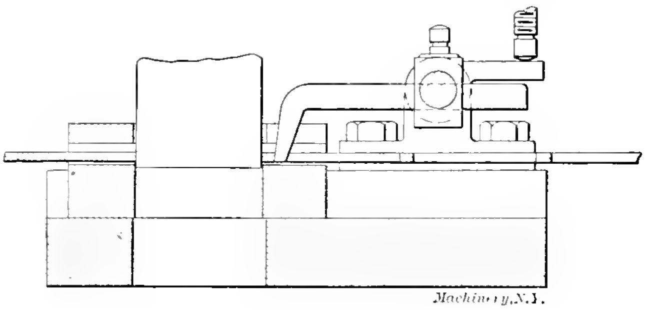

Fig. 5. The Simple Latch Form of Stop

cam or eccentric on the press shaft. When thus driven its motion can be very carefully timed, irrespective of pilot-pins. This style is also best suited for automatic roll feed. New presses are often provided with this attachment.

The Spring Toe Latch

The spring toe latch involves but little change from the simple latch. Fig. 6 shows it clearly with an enlarged detail of the spring toe. This latch may be used very successfully with hand feed and there is little danger of the stock getting

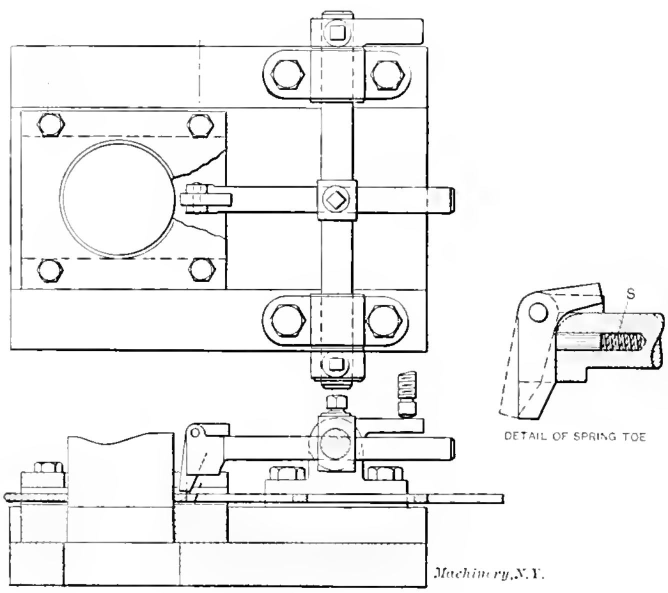

Fig. 6. The Spring Toe Latch Stop

by it too fast. Its operation is as follows: As the punch lowers and starts to cut the blank, an adjustable screw on the ram or punch plate lifts the latch. Its spring toe snaps forward and when the latch lowers, it rests on the scrap left between two blanks; hence it cannot fall back into its former place. When the operator pulls the stock along the latch toe drops into the next hole and brings the stock to a stop at the proper point, compressing the light spring *S* as it does so. This design is simple, rigid and effective. The spring toe here shown is preferable to the design which follows because it is light and requires but little tension on the stock to bring it to a stop.

The Side Swing Latch

The side swing latch is shown in Fig. 7 and it is but a modification of the latch shown in Fig. 6. When the punch descends, an adjustable screw hits lever *L* and lifts the latch. The whole rod *R* then springs forward till collar *C* stops against *B*. When the latch lowers it rests on the stock as did the spring toe latch. As the stock is pulled along the latch drops into the next hole and acts as a stop again. In this style the tension on the stock must be greater than with the spring toe latch because the whole rod *R* has to be pulled along against the spring *Q* until collar *D* stops against *E*. If this design were modified, however, so the side bearings would be used only for allowing the latch to swing, the toe could be constructed like the spring toe latch and would then be quite as effective as this type, though not so rigid.

Positive Heel and Toe Latch

While the two previous automatic stop-pins rely on gravity or a spring to bring them back in position, the heel and toe latch is positively operated. It is shown in Fig. 8, with the stripper removed. Its distinctive feature, which recommends it for use on a large variety of work, is that it is impossible for the stock to slip by it faster than one blank per stroke of the press. This is a very important matter when combina-

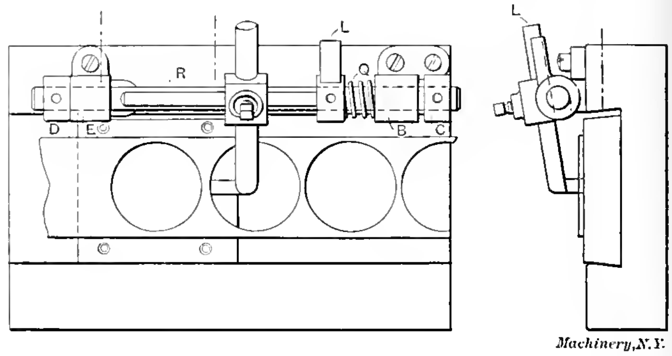

Fig. 7. The Side Swing Latch Stop

tion or gang dies are being used, because the pilot-pins so widely used require the guide holes to be punched just ahead of them. If the stock slips too far, the guide holes pass beyond the pilot-pins, and when the punch descends, the pilots punch their own holes, throw down a heavy burr and cause a delay—if nothing more serious.

Fig. 9 shows the catch in position to stop the movement of the stock at its point *A*. The stock is feeding to the right. The conical-pointed pin *B* is pushed by the spring *S* so that

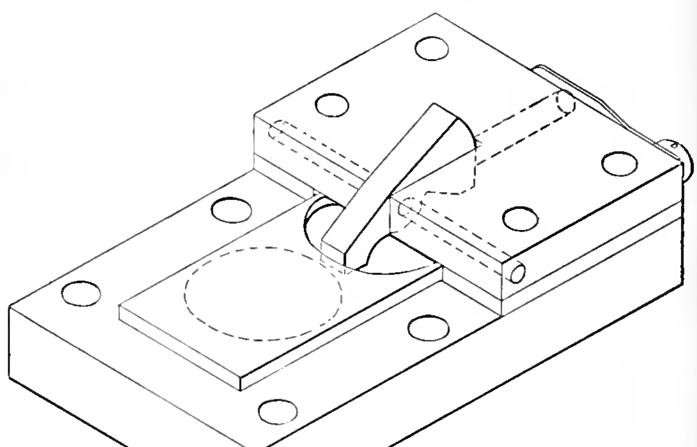

Fig. 8

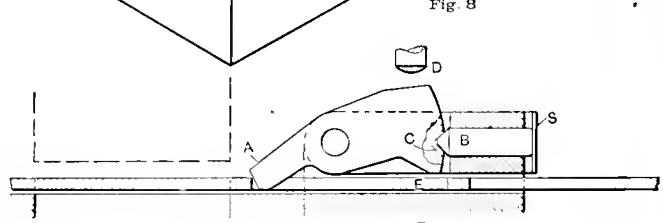

Fig. 9

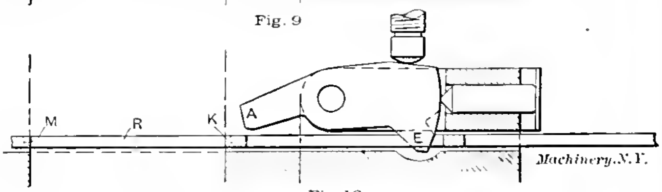

Fig 10

Figs. 8, 9 and 10. Positive Heel and Toe Latch which prevents the Stock from moving more than One Blank per Stroke of the Press

it engages a conical depression *C* in the end of the catch. By this means the toe of the catch is pressed against the die. As the punch descends to cut the next blank an adjustable screw on the punch plate presses on the top of the catch at *D* and causes the heel to lower and the pin *B* to disengage the

notch C. The position of the catch is now shown by Fig. 10. Its heel E has been lowered into the hole left by the previous blank. It is held in this position by the pressure of the point of B. While this is sufficient to hold the catch in its new position, it offers but little resistance to its return to its original position. The stock may now be moved along. The metal K, left between two successive blanks, engages the heel E of the latch and lifts it easily. This causes the notch C to engage with the pin B and the catch snaps back into its first position. The toe A falls into the new opening R, and M comes to a stop against it. Since the metal K, between two successive blanks, cannot pass the heel of the latch without raising it, and since the heel E cannot rise without lowering the toe A far enough to catch the stock, it is evident that the action is positive.* Hence the stock cannot jump ahead faster than one blank at a time. In constructing a stop of this kind care must be taken to allow under the heel E, Fig. 9, but little more height than the thickness of the stock. The length of the catch from toe to heel should be less than the opening left by one blank; then there will be no difficulty in starting the new ends of strips or coils. If necessary, however, the catch may be made so as to measure a little less than two or more openings in the stock. In such a case the catch would have to be tripped by hand until the first piece of stock K, between two blanks, had passed under the heel E. This would cause delays which would amount to considerable in the case of strip stock.

This style of stop-pin has been used successfully with gang dies cutting blanks from brass 1/32 inch thick, and cold rolled steel 1/64 inch thick. In the case of the steel blanks,

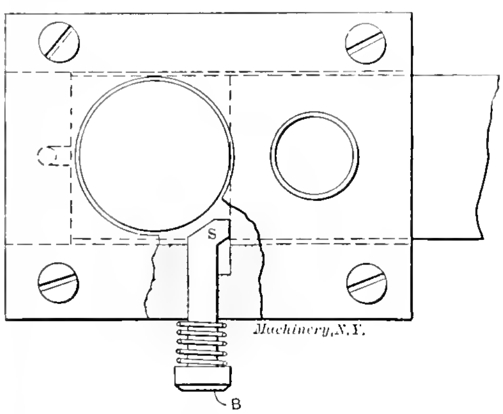

Fig. 11. Starting Device for a Gang Die

reels were used and the scrap was wound on a reel as it came from the die. By keeping the proper tension on the scrap, the stock was pulled through the die and kept against the stop-pin. Four thousand blanks per hour were made by this means. In view of the thin stock used and the fact that the dies were of the combination type, this was considered first rate. The stop-pin had to be set accurately because the thin stock prevented the pilot-pins from shifting it much in aligning it. Other precautions taken on account of the thin stock were to make the toe broad and to fit the stripper close to the front edge of the toe.

The Gang Starting Device

The devices so far described serve to stop the stock when it has passed the blanking punch. But there are many cases where two or more operations are performed on a piece before it reaches the blanking die and the usual stop-pin. The operator usually gages the proper positions by watching the end of the stock through openings in the stripper, but it is better to have temporary stop-pins that can be used for that purpose. Fig. 11 shows a starting device for a gang die with two punches. When starting a strip the button B should be pressed. This brings into action the temporary stop S, which locates the stock properly for the first operation. It is then released and springs back out of the way. The stock is then advanced to the regular stop-pin. As many of these side stops may be used as are necessary. Not only do they save annoyance and time, but they add to the life of the dies by preventing the partial cuts due to the stock entering too far at the start.

TWO FEED-STOPS OF WIDE UTILITY

C. W. D. AND W. B.

The authors make no claim of originality for the simple feed-stops here illustrated, nor is it desired to convey the impression that these stops are new or novel in their construction; experienced toolmakers will recognize them at once as "old acquaintances." There are certain points concerning

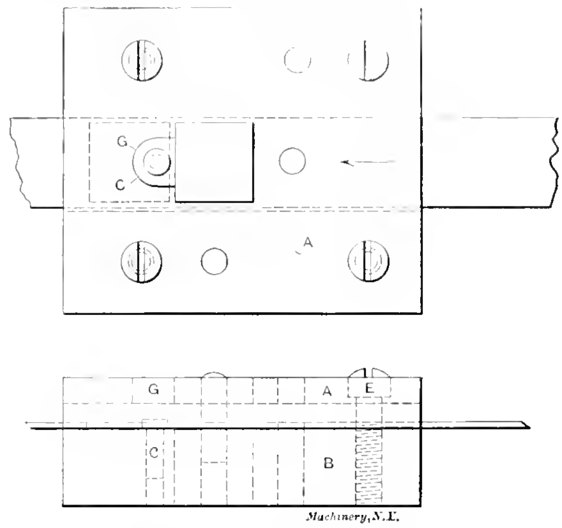

Fig. 1. Improved Form of Fixed Stop-pin

them, however, an explanation of which will be of benefit to those who are not experienced in punch and die work.

Fig. 1 shows a fixed stop-pin C, which is the most common of all feed-stops. It is the particular form of this simple stop to which we wish to call attention. The common way to make a fixed stop-pin is to bend over a piece of steel rod and drive it into the die. This appears simple enough, but we can say from experience that it is not so simple as it looks. As much as two feet of steel is sometimes used up in an attempt to make a bent stop-pin about one and one-quarter inch long. The difficulties and disadvantages connected with making a bent stop-pin are as follows: First, the difficulty of bending the pin at right angles without breaking it or bending the part to be driven into the die; second, after the pin has been made and hardened it is apt to break in driving it home to its place in the die because of its uneven shape; third, in driving the pin into the die it is apt to swing around out of its proper position making it necessary to knock it

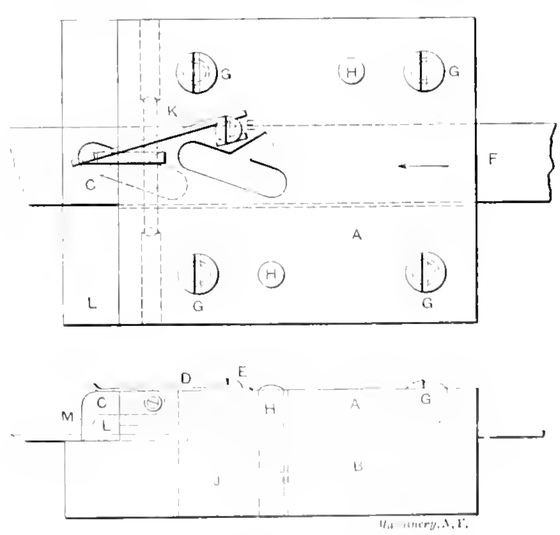

Fig. 2. Latch Stop-pin of Simple Design

around again and thus increasing the chances of breaking it. Every time the die is ground, this difficulty is experienced and the result is, frequent breakage and consequent loss of time in waiting for new stops. All these difficulties are overcome by making the style of pin shown in Fig. 1. This is simply a shoulder pin turned to a nice snug fit in the die. The shoulder, which acts as the stop for the stock, may be made

larger or smaller in diameter according to the width of scrap desired between blanks. This stop is quickly and easily made, is easily taken out and put back again after grinding the die, and it will last as long as the die itself. It is a good idea to cut a hole through the stripper *A* directly over the stop-pin as shown at *G* so that the operator can see the pin when the press is in operation.

The stop shown in Fig. 2 is excellent because of its simplicity, and also because of the great variety of work to which it may be applied. This stop is of the latch variety, but it differs from most stops of this type, in that it requires no mechanism to lift it. It is not operated by the action of the press nor by the punch, as is generally the case with latches. Its construction is simple. A hole is drilled through the stripper *A* to receive the pin *K* which passes through a hole in the stop *C*. The stop swings upon this pin. A light flat spring *D* is fastened to the top of the stripper so that the end of the spring rests on top of the stop. In securing this spring to the stripper, it is only necessary to place one end under the head of the screw *E* with a piece of the same material under the opposite side of the screw as shown in the plan view. By this method the spring can be quickly and easily attached or removed, and a straight piece of spring material can be used. The stripper, of course, should have dowel pins in it to insure its coming back in the same position every time the die is ground. The dowels and screws are shown at *H* and *G*, respectively. The stripper should also

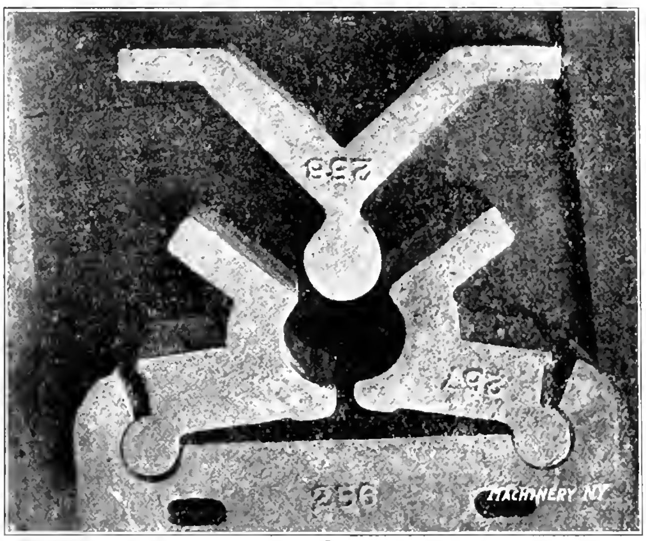

Fig. 1. Former for Making the Bracket shown in Fig. 3

be cut off at the stop end as shown at *L* so that the stop will be outside of the stripper and in full view of the operator. The action of this stop is as follows: The stock *F* is fed to the left, and as the punched strip passes the stop, the point of the stop *M* drops or rather springs into the hole made by the blanking punch. The operator then pulls the strip back against the straight outer edge of the stop, and holds it there until the next blank is punched. This process is repeated at each stroke of the press, the scrap between the blanks being pushed past the stop each time and then pulled back against it. The inner bevelled edge of the point *M* causes the stop to lift as the scrap between the blanks is pushed against it, while the outer edge, which is at right angles with the die, prevents the stop from lifting when the edge of the scrap is pulled back against it.

By this simple stop the operator can feed the stock at will without waiting for the operation of a mechanically-lifted stop, to say nothing of the time that is saved by not having to adjust an automatic stop. An operator, known to the authors, can make about 40,000 blanks per day with dies fitted with this form of stop on a press making about 100 strokes per minute. These stops are used only on hand-fed work.

Aluminum coins are to be circulated in France. The mint is ready to issue five and ten centime pieces of this metal. They will, of course, be much lighter than the ordinary coins, and have the advantage that they will not oxidize.

COMPOUND BENDING FORMS FOR THE BULLDOZER

ETHAN VIALL*

A short time ago, while visiting the shops of the Danville Car Co., at Danville, Illinois, the superintendent, Mr. H. C. Teipel, showed me several interesting bending forms which the shop foreman, Mr. A. S. Hesse, had made for use on their bulldozers. The forms shown in Fig. 1 are especially inter-

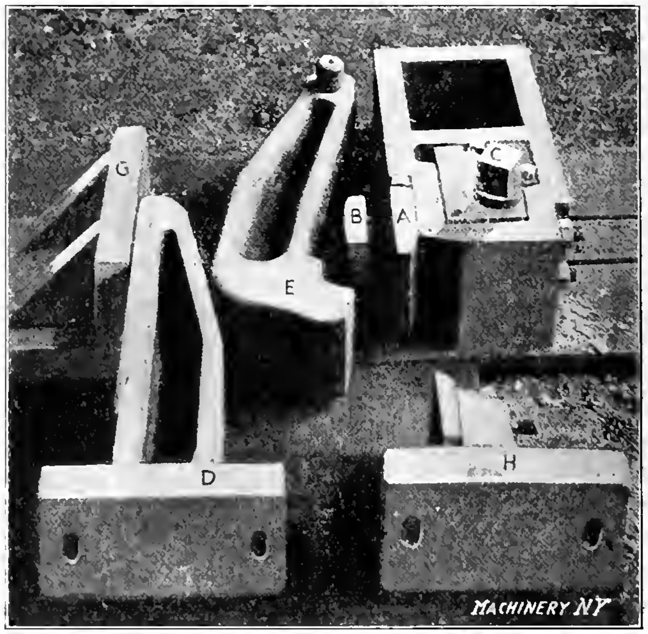

Fig. 2. Combined Former and Shear for Bending and Trimming the Gibs A, Fig. 4

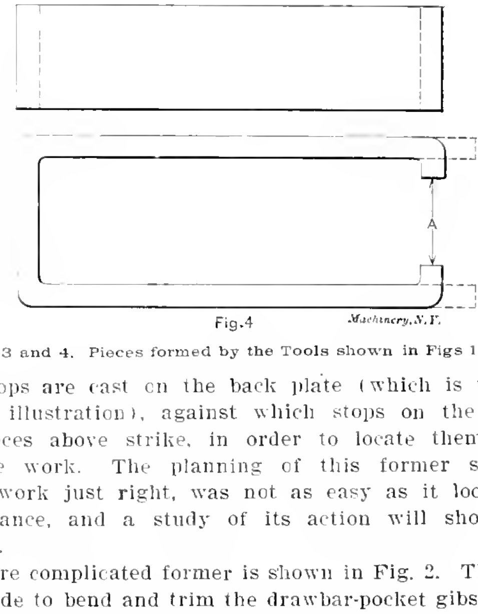
esting from the fact that they were so cast that no machining was necessary in order to assemble them ready for use. Possibly a little filing was needed, or a small lump or two had to be knocked off with a hammer and chisel, but that was all. This device is intended to form the bracket, shown in Fig. 3, but a number of other brackets or hangers, can be made with formers constructed on the same principle. It will be noted



Figs. 3 and 4. Pieces formed by the Tools shown in Figs 1, 2 and 6

that stops are cast on the back plate (which is the lowest in the illustration), against which stops on the wings of the pieces above strike, in order to locate them properly for the work. The planning of this former so that it would work just right, was not as easy as it looks at the first glance, and a study of its action will show several reasons.

A more complicated former is shown in Fig. 2. This former was made to bend and trim the drawbar-pocket gibs *A*, Fig. 4. In using this former the bar is placed between part *A* and

* Associate Editor of MACHINERY.

the clamp-jaw *B*, which is tightened by turning the eccentric *C*. The gib is now bent by the part *D*, which is fastened to the bulldozer ram, shoving over the gib-former *E*. During the bending of the gib, the part *D* is steadied and guided by the part *G*, which is bolted solidly to the bed of the bulldozer. The end of the gib is trimmed off by the shear-blade on part *H*, which slides past the outer edge of the blade on part *A*.

The adjustable male and female parts of the radius bender, shown in Fig. 5, are used to bend iron parts that would otherwise require about twenty different forms.

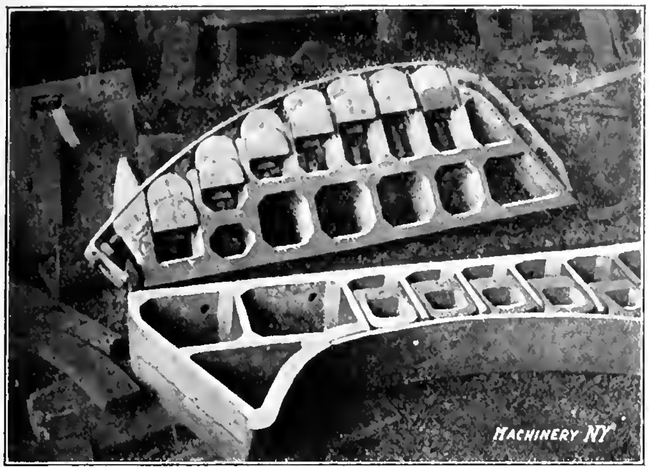


Fig. 5. Adjustable Bending Form

The draft-gear yoke-bender shown in Fig. 6, was made in the Ft. Wayne shops of the Pennsylvania Railroad and is only slightly different from those used elsewhere for the same purpose. The wings *A*, *A*, and the parts *B*, *B*, used to push them around during the stroke of the bulldozer ram, are all pretty well cored out to lighten them. The iron to be bent, is clamped between the form *C* and the sliding part *D* which is operated by the lever *E* turning an eccentric located in the block *D*. The yoke shown in Fig. 4, having straight ends as indicated by the dotted lines, is the product of this tool.

* * *

SPECIAL CENTERS FOR TAIL-STOCK

WALTER GRIBBEN*

The tubular shaft of tool steel, shown in section in Fig. 1, was so long in proportion to the diameter of the hole that it could not very well be turned on a standard bench-lathe arbor, and rather than make a special arbor of extra length, the tail-stock fixture shown in longitudinal and cross section in Fig. 2 was made to do this job. It has since proved remarkably useful on many other jobs, and is now considered a standard appliance in my bench-lathe outfit.

The body *A* is made of rectangular steel, with a 3/16-inch hole bored and reamed its entire length. The taper shank is turned true with the central hole, and fits the tail-stock spindle the same as an ordinary center. The binder *B*, and screw *C*, with the lever handle *D*, will hold any piece of 3/16-inch round stock, or any special piece with a 3/16-inch round stem, so that it will be in line with the live spindle.

For the job shown in Fig. 1, the plug *E*, Fig. 2, was made, the shank *F* being an easy fit in *A*, while the part *E* is 1/4 inch in diameter at its outer end, and slightly tapering, so that it is about 0.001 inch larger on the inner end. The part *E* was hardened, tempered, and polished smooth, while the part *F* was left soft. This plug answered as a dead center for the end of the tubular shaft to run on while turning the outside. As a driver for the other end, a piece of rod larger than the hole in Fig. 1 was held in the live spindle and turned to a tight wringing fit in this hole. This left the outside of the work entirely free to operate on, including the turning of both ends at one chucking, which insured all the parts being true with one another. The slight taper on *E* provided for any fine gradation between a running fit and a tight fit to be obtained on the tail-center end, by adjusting the tail-spindle back or forward.

* Address: 311 Halsey St., Brooklyn, N. Y.

In work of this character, no attempt is made to preserve the driving plug for subsequent jobs, as it does not need to be hardened, nor does it need to be polished. It is a comparatively easy matter to turn one up each time it is needed, and it is then sure to run true. They are generally made on the end of a stock rod, and after the job is completed, the driving rod is put back in stock. This, of course, is from the jobbing point of view, and not from a manufacturing standpoint.

The hardened steel plugs, similar to *E*, are made for each job as it occurs, and are preserved for future use. Fig. 4

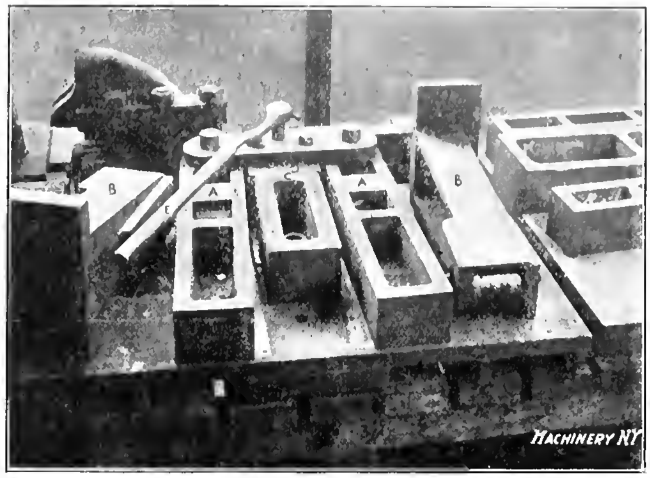

Fig. 6. Draft-gear Yoke Former

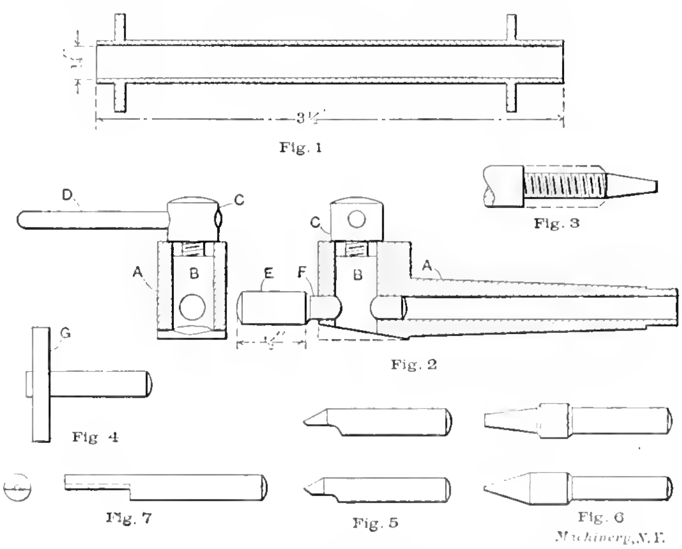
shows a sheet brass disk *G*, soft soldered onto a short piece of 3/16-inch wire, the edge of *G* being turned true after soldering on. This makes a convenient kind of center on which to run the end of a long piece of drawn brass tubing while truing the end, or cutting a thread on the outside.

Another use to which the tail-center, Fig. 2, is put is to hold short, stubby, flat drills for starting a true hole in chucked work. If the hole is in thin work, it may be drilled clear through with one of these flat drills, but if a hole has to be drilled in some distance, it may be started with one of the flat drills and finished with a twist drill.



Figs. 1 to 6. Special Tail-center for the Bench Lathe, and Auxiliary Attachments

In the outfit of plugs to go with Fig. 2 there are two male centers cut partly away to different amounts, as shown in Fig. 5, a female center with a much smaller hole than in the regular female center, and a 60 degree countersink for centering shafts. Some of the plugs are special in their nature, as shown in Fig. 6, and are hardly worth keeping. These were made for turning shafts that were to run on pointed screws of a special angle, and as only one shaft of each kind was to be turned, the plugs were not even hardened, but were left soft and kept well lubricated when in use. The stock from which one of the screws was to be made was chucked and its point turned to the specified angle, as in Fig. 3. A small dog was then clamped on the part shown

dotted. This made a live center on which to turn the shaft, one of the plugs shown in Fig. 6 being used as a dead center. After the shaft was completed, the pointed screw was turned down for the shank, threaded and cut off, thus performing a double duty, as live center first, and as a finished screw for the completed machine afterwards.

Having to make a tap 0.040 inch diameter and 100 threads per inch, a piece of 3/16-inch brass rod was drilled lengthwise about $\frac{1}{2}$ inch deep with a 0.040 drill, after which the outer end of the rod was cut partly away, as shown in Fig. 7, leaving about two-thirds of the original diameter of the hole in the brass. When this was clamped in the tail-center, Fig. 2, it made a very good steady rest, or back rest, for the slender wire to run in while doing the threading. The threaded part of the tap was only $\frac{3}{8}$ inch long. Of course, a hardened steel plug would have answered much better, but the job was in a hurry, and the brass plug was more quickly made, and was plenty good enough.

The part shown dotted in Fig. 2, is cut away to clear the turning tool when finishing the end of a tube or a solid shaft with a straight hole in the end. The central hole in Fig. 2 goes all the way through, but it does not need to. It was made that way because it was easier to get all the parts true, the hole being made first. Since making this fixture, it has occurred to me that it would have been an excellent device to use on a lathe that I worked on many years ago, which was somewhat out of alignment. In that case the central hole would be bored in place after the taper shank was fitted to the tail spindle, taking the precaution, of course, to mark the fixture and the tail spindle, so that the fixture would always be placed, when in use, with the same side up as when it was bored.

* * *

MACHINE SHOP PRACTICE*

LAYING OUT WORK—2

Before laying out a machine part it is first well to consider its particular requirements in order to obtain a definite idea of the relation that the various surfaces must bear to one another when the part is finished and assembled; and, as the method of procedure is governed somewhat by the way in which the part will subsequently be machined, it is also advisable to first determine the most practicable method of machining, before beginning to lay out the work. As an illustration of the kind of work which the machinist is often called upon to line out, we have selected the engine cross-

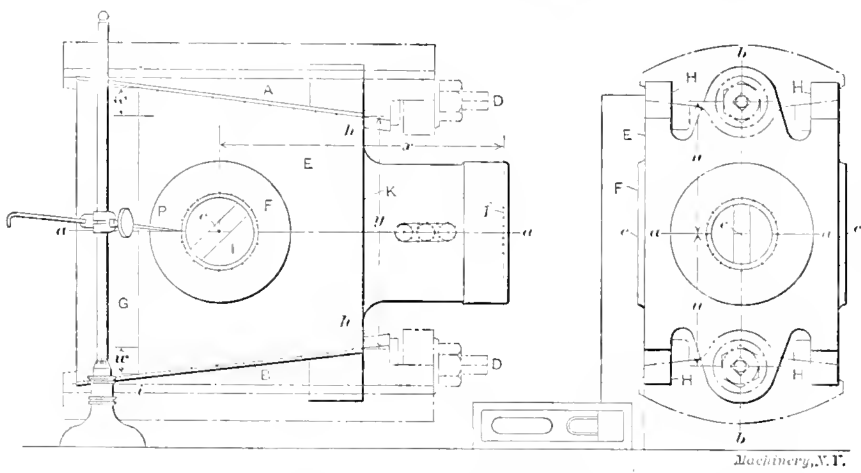


Fig. 1. Laying Out a Cross-head

head shown in Fig. 1, which is a type widely used. The shaded portion represents the main casting, and the dot-and-dash lines the shoes, or gibs as they are sometimes called, which are adjusted along the inclined surfaces *A* and *B* when there is too much play between the guides and the cross-head. In this particular case the principal requirements are that the axes of the piston-rod hole and the wrist-pin hole be at right angles; that the axis of the wrist-pin hole also be at right angles with the vertical center line *b-b*; that the inclined surfaces *A* and *B* have the same inclination to the center line *a-a* and be equi-distant from it; and that the guiding surfaces *H* be parallel with the axis of the piston-rod hole. Keeping these requirements in mind, we shall proceed to locate lines on the casting indicating the finished surfaces. After inserting centering pieces in the cored wrist-pin hole on each side and in the piston-rod hole as shown, locate the points *c* and *e* central with the outside of the bosses. A coat of whiting and alcohol, or chalk, should next be applied to those surfaces upon which lines are to be drawn. The casting is now ready to be set in an upright position on the surface plate, as shown in the illustration. The blocks which would be required to support it in such a position have not been shown, in order to avoid a confusion of lines.

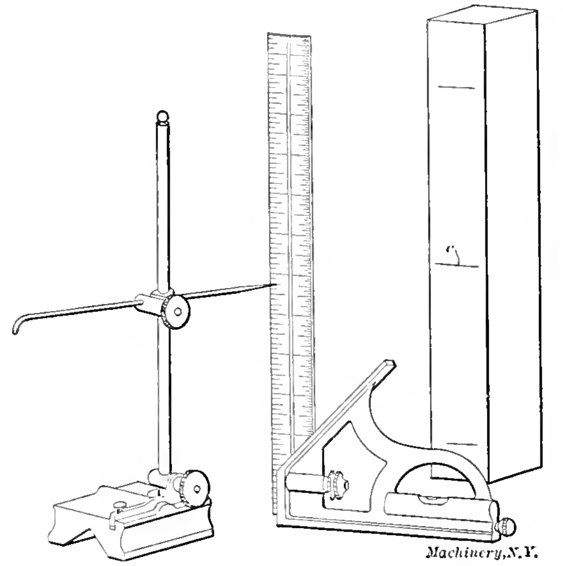

Fig 2. Setting the Surface Gage to the Dimension u, Fig. 1, by the Combination Square

The rough sides of the casting are set at right angles to the surface plate by the use of a square, as shown in the end view. The center *c* and the two centers *e* (see end view) are now set in the same horizontal plane by the use of the surface gage *G*. This is done by inserting the pointer *P* of the gage in one of the centers and then moving the gage to the other centers to see if they coincide with the first. It may be necessary in order to set these three centers in the same horizontal plane to move the two centers *e* toward each other slightly. It is better that each center be moved in order that the finished hole will be as nearly concentric with the outside of the bosses as possible. When the casting is thus set, the surface gage is used to draw the center line *a-a* on each side and across the end of the cross-head. This is done by holding the scriber against the casting while the base of the gage is moved along the surface of the plate; obviously a line drawn in this way will be parallel with this surface. Ascertain from the drawing in which direction the wrist-pin is to enter the cross-head in order to find out from which side the hole for this pin will be bored, and then, with point *e* as a center, scribe a circle equal in diameter to the small end of the wrist-pin hole. This circle will be used to set the casting by when boring the hole in the lathe or boring mill. Another circle, the diameter of the small end of the piston rod hole, should be scribed with point *c* as a center. With a pair of trammels, a line *f* should be located a distance *x*, as given on the drawing, from the center *c*. We shall assume that the dimension *y* is given, and that the taper of the inclined surfaces *A* and *B* is in inches per foot. Then to lay out lines for these tapering surfaces, locate points *h* and *h* equi-distant from the center line *a-a* and a distance *y* apart. With a square draw a line *i-i* 12 inches from the face *K*. With the surface gage transfer the points *h* to the line *i-i*, as shown, and then locate centers above and below these points a distance *w* equal to the taper per foot. Lines which are then drawn through these centers and the points *h* will have the

* With Shop Operation Sheet Supplement.

taper required. If the casting is not large enough to permit line *i-l* being drawn 12 inches from the face *K*, of course the same result would be obtained if this distance were a fractional part of a foot, providing the distance *w* were laid off to the same fractional part of the taper per foot. When locating the centers of the bolts *D* distances *u* above and below the center line *a-a*, the pointer of the surface gage should first be set to coincide with center *c*. The pointer may then be placed against scale of a combination square, and the scale moved vertically until the pointer coincides with one of the divisions, as shown in Fig. 2. If the dimension *u* then be added to the inches and parts of an inch indicated on the scale opposite the pointer, the sum thus obtained will be the division on the scale to which the pointer should be set when scribing the horizontal center lines for the bolts *D*. For example, if the gage pointer showed that the center line *a-a* was the same height as the 5¾-inch division on the scale, and if the dimension *y* on the drawing was 5¼ inches, the gage pointer would, when scribing the center line for the upper bolt, be set to 5¾ + 5¼ = 11 inches. The center for the lower bolt would, of course, be obtained by subtracting 5¼ from 5¾. In this way the scale of the combination square can often be used for accurately setting the gage pointer to vertical distances between points not in the same plane. A parallel block placed in a vertical position may also be used for this purpose. A center line *c*, coincident with the center in the work, would first be scribed and then arcs central with this line and the required distance apart would be struck with a pair of dividers or trammels.

One method of machining this cross-head would be to first bore and ream the wrist-pin hole concentric with the circle drawn for it, and at right angles with the rough surface *E*; the boss for this pin should also be faced. This finished boss can then be clamped against an angle plate (preferably on a vertical boring mill) when setting the casting for boring the piston rod hole. In this way the axes of the holes for the piston rod and wrist-pin will be at right angles, and if the center line *a-a* on the casting is set square with the table or face-plate, the axis of the two holes will also be in the same plane. By bolting the finished face *F* against an angle plate on the planer, the planes in which the finished surfaces *A* and *B* lie, will also be parallel to the wrist-pin axis, and the finished sides *H* for the shoe fittings will be parallel to the axis of the hole for the piston rod.

* * *

IMPROVEMENT VS. HUMANITY

An American and German were traveling by rail in Germany through one of the forests for which the country is noted. The wooded expanse on either hand showed the care of the trained forester. The trees were free from dead branches, and on the ground there was little or no debris. The roads were laid out with mathematical exactness; the sides were free from weeds and the gutters carefully graded and clear of obstructions. In short, the whole appearance of this great forest was that of a well-kept park, although miles and miles in extent. The German waxed enthusiastic and was constantly calling the attention of the American to the various features that attracted his admiration. He could not say enough for the beauty of the scene, for the well-kept appearance of the trees, the fine roads and the evidences of a mastery of nature and a carefully planned conservation of a valuable resource.

The American at last grew somewhat impatient and said: "You see one phase of this scene only, and that is the woods and the roads, while I am more concerned about another phase, which is the human side. Behold those men and women peasants broken down with toil before their time, stumbling along in wooden shoes, without hope, without courage and destitute of ambition! That is the other side of the scene not so fine. To me this scene is very depressing, for I see in it nothing for humanity. Of what good are all these roads, the well-kept forest, these water courses, when the men and women whose unremitting labor is required to do this work, have no joy in the prospect? Human happiness is worth more than all the improved roads and forests together, for without it all else is worthless."

GERMAN BENDING AND STRAIGHTENING MACHINE

A machine for bending cold iron and steel of round, square, T, I, channel and other sections is shown in Figs. 1 and 2. This machine which is built by Brüder Boye, Neue Friedrichstrasse 59, Berlin, Germany, is designed for bending and straightening small quantities of work of a special nature, which would not warrant the employment of special machines with expensive tools, such as bulldozers. The need of such a machine has long been felt by bridge and crane building establishments, shipyards, railway shops, machine

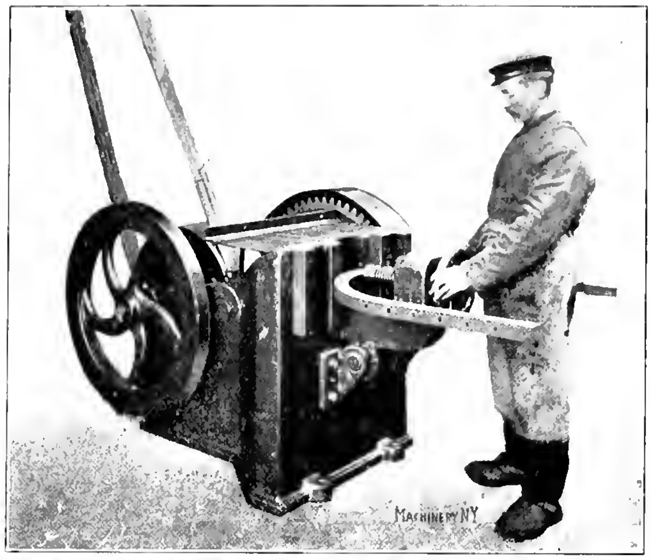

Fig. 1. The Power-driven Bending and Straightening Machine forming an Angle-iron

shops, etc. Although tools performing this work are in use, they are generally hand-operated and the results have been more or less unsatisfactory, both in regard to the output and the quality of the work produced.

As may be seen in the line engraving Fig. 2, the machine consists of a strong frame in the center of which is a massive steel ram *A*. This ram is connected at one end by an eccentric, which actuates it, and it is supported at the other by a roller *D*. In the end of the ram there is an adjustable spindle *C* which comes directly into contact with the work. By varying the position of this spindle, the piece being bent will

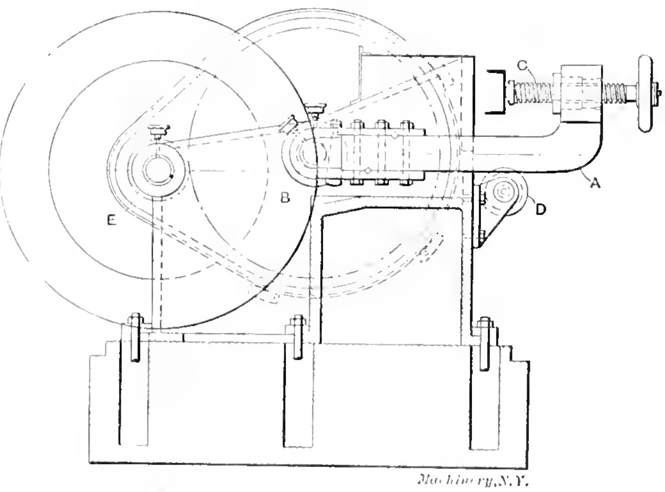

Fig. 2. Vertical Section through the Bending and Straightening Machine

be subjected to a greater or less pressure and the radius of the bend will be varied accordingly. The shaft upon which eccentric *B* is mounted is connected to the driving shaft *E* by reduction gearing. The speed of the driving shaft is 110 revolutions per minute, and the resulting speed of the ram is 25 strokes per minute. While the stroke of the ram, which is approximately 1 inch, is not changeable, the distance between its working end, that is the end of *C*, and the frame can be changed, as before stated, by simply moving *C* in or out by the hand-wheel shown, thus subjecting the work to a greater or less amount of pressure on each individual stroke. Obviously, this machine can be used either to bend

straight bars to any desired form or to straighten crooked bars. These bars may be round, square or any desired shape and the iron can be bent at any point by turning the work to the desired position. The various pieces in Fig. 3 show what uniform results can be obtained with this simple machine. Pieces having the same section throughout can easily and quickly be bent to approximately a true circle, providing the spindle C is not adjusted after a bend is started and the work is fed practically the same amount for each stroke. It is said that this machine bends the various

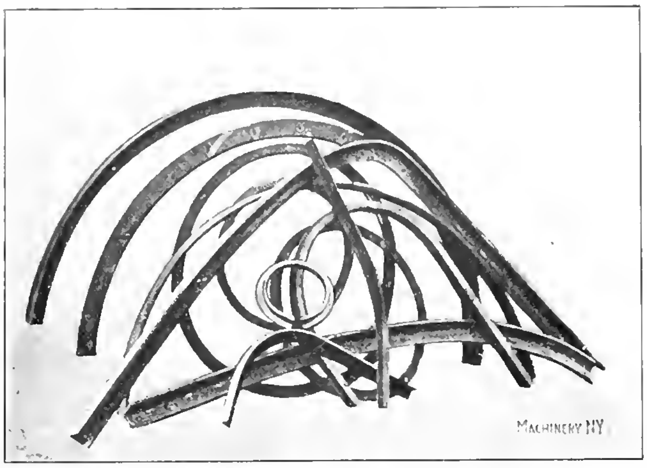

Fig. 3. Some of the Work done by the German Bending Machine

sections without any appreciable amount of buckling, which, considering the simplicity of its construction, is quite remarkable. When bending long pieces, the ends are supported by tables or horses which are arranged on both sides of the plunger or ram. Angle iron 2 by 2 inches in size can be bent to a minimum radius of 8 inches, while 4 by 4-inch angle iron can be formed to any radius greater than 2 feet 6 inches. The smallest radius to which an 8 by 3-inch channel can be bent is 4 feet 9 inches. The radius to which any material can be bent is, of course, dependent on its stiffness. About 3 horse-power is needed to drive this machine, and its weight, when ready for shipment, is approximately 2 tons.

* * *

THE LARGEST CRANE IN THE WORLD

The accompanying illustration shows what is stated to be the largest crane in the world and is the crane that was referred to in a short item in the August issue of MACHINERY,

Crane Capable of Lifting 240 Tons at a 95-foot Radius

engineering edition. As there stated, the crane will lift 160 tons at a 95-foot radius, and when tested it lifted a load of 240 tons. The illustration shows the crane while being tested ready to lift the load mentioned. The crane is erected at Devonport Dockyard in England. Its total height is 166 feet, its length over all 230 feet, and its weight 950 tons. It was built by Messrs. Cowans, Sheldon & Co., of Carlisle, and was designed by Mr. J. W. Branston.

THAT NEW APPRENTICE BOY

A. B. SAW

Terry, the new apprentice, came into the pattern-shop about three months ago, bringing his dinner wrapped up in his apron and towel and looking for all the world like a raw recruit from the Emerald Isle; but after he had been there three or four days, he was one of the most welcomed boys that ever got his trademarks in the shop.

He was, as one of the journeymen expressed it, "always keeping us in good spirits by doing funny stunts and asking innocent questions about his work."

The second day that he was in the shop, the boss came to him, where he was sorting screws, and said: "Terry, you can have that bench up there by the band saw for a while, it's kind of old but it will hold you for a time." "All right, sor," says he. So hurriedly finishing his work, he went up to the bench and started to tidy up a bit, feeling as big as life to think that he had a bench all his own.

When he had it fixed up nice and clean, he noticed with dismay that the top of his bench was full of small holes and knife cuts, while the tops of the adjoining benches were smooth and shiny. However, this down-cast mood soon gave way to one of delight because he had an "idea" that would remedy the unsightly appearance of his bench. "Why not fill up those holes with beeswax?"

For two hours he dug and worked at the old bench filling the holes with beeswax. This made the men jolly him a

"Begorra, I'll give it a good draft"

good deal, and they dubbed him "Beesy," a name he went by for the rest of his apprentice days.

Not long after this little incident, he was given a flange to make, twelve inches outside diameter, six inches inside diameter, and about two inches thick. He turned it up in the lathe and, as he thought, "made a pretty foine job." He took it up to the boss, who, after measuring it up, tried a small square to the edges. "There's no draft on it, Terry, give it a little draft and it will be all right."

Terry went back to his bench with a perplexed look on his face, until the meaning of the word "draft" dawned on him. "Begorra, I'll give it a good draft," said he, and at that he put the flange upon the window ledge and opened the window about three or four inches, letting the cool breezes from the water blow on his pattern.

About half an hour afterwards he came over to my bench and said, "Do youse think there's enough draft on me pattern, Mr. Saw? It's been there thirthy minutes."

Well, I explained to him, with a straight face, what the meaning of "draft" was, when applied to a pattern; but I must confess that after he had gone I had to give way to my suppressed mirth, and when the story was repeated to some of the others, they joined in with me.

* * *

The minute a man begins to consider himself indispensable he ceases to be.—*The Silent Partner.*

CASTING NEW FACES ON WORN VALVE SEATS

The accompanying view shows the operation of casting a new face on an old valve seat of a locomotive cylinder, as it is performed at the Firenze (Florence) repair shops of the Italian State Railways. The illustration shows the cylinder with the mold clamped to it ready for the pouring of the metal from the adjoining cupolas. Briefly described, the process consists of removing the worn or damaged part that is to be renewed, and fixing in its place the mold of the new part. Before running the metal, the cylinder is highly heated and then the pouring is performed in such manner that the metal runs freely over that surface of the cylinder which is to be fused and welded, and then passes out through a hole such as is shown in the side of the mold in the photograph. After running from 200 to 500 pounds of metal, the old metal softens and melts; the escape hole is then plugged and the mold filled up to the top of the runner head.

Unless a cylinder has been rebored so many times as to approach its final limits for thickness, this process is found to be cheaper than casting new cylinders and then machining them. The new gas "welding" processes would not be so economical in Italy considering the thickness to be melted for a weld joint; this too is the experience in French railway shops where autogenous welding (*soudure*) has been practiced for some time with considerable success up to a certain thickness, past which ordinary methods become cheaper.

Casting a New Valve Face on an Old Cylinder—Italian State Railway Shops at Florence

C. R. K.

A VARIABLE LINEAL SPEED DRIVE

Fig. 1 shows a general view of a slide *A* which moves back and forth in a straight line with a variable speed by means of a common rack *B* securely mounted on the slide, and a spiral spur gear *C* keyed on the shaft *D* running at a constant speed. From the drawing it can easily be understood that this spiral gear can only make a part of a turn or possibly a little over a turn before reversal, in order to move the slide in the desired direction. The reversing of the shaft *D*, on which the spiral is fastened, is done by a jaw clutch body *E* sliding on a feather on shaft *F*, and engaging automatically with either one of the two pulleys *G* and *H*. These pulleys, located one on each side of the clutch body *E*, run continuously in opposite directions, thus changing the direction of the rotation of shaft *F*. On this shaft there is a worm fastened which meshes with a worm-wheel fastened to the spiral gear *C*. The rack is mounted on the slide at a certain angle depending upon the required variation in speed, which is in direct proportion to any line *m*—*m'* or *n*—*n'* drawn from the pitch line of the rack perpendicular to the center line *I*—*J*. It would not be advisable to mount the rack on the slide at a steeper angle than 30 degrees. If the angle be more than this a greater resistance to the movement of the slide will occur.

The diagram, Fig. 2, shows how to construct the spiral gear when the pitch and the angle to which the rack is set are given.

The center line of the spiral gear is located as near as possible to the lower end of the rack, just enough space being left to get a good size hub around shaft *D*. In this way the smallest possible spiral gear required for the movement will be obtained, providing that the movement of the slide is not too great, in which case the size of the spiral gear may have to be increased in order to get the right number of teeth. First, space off one-half of the pitch *a*, *b*, *c*, *d*, *e*, etc., on the proper length of rack and then project lines to the center line *I*—*J* from each one of these divisions. With *A* as a center and *aa'*, *bb'*, *cc'*, *dd'*, *ee'*, *ff'*, *gg'* as radii, strike small arcs as shown at *b"*, *c"*, etc. Space off half of the pitch on these arcs, going from one to another to get the intersecting points for the pitch lines of the spiral gear. By rights the pitch should be measured on the spiral, but for a small pitch the difference is so slight that it need not be taken into consideration. When all the intersecting points are found, find the centers *B*, *C*, and *D* needed for forming the spiral. Lines drawn from these centers through the intersecting points *b"*, *c"*, etc., will give the center lines for the teeth and spaces in the spiral gear.

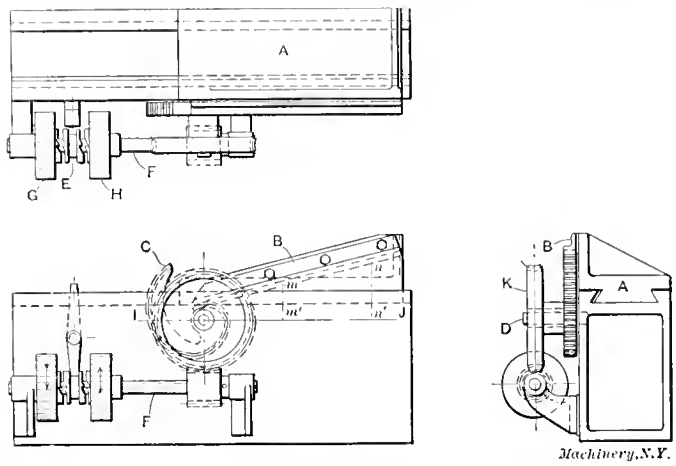

Fig. 1. Mechanism with a Spiral Spur Gear for Imparting a Variable Lineal Speed to a Slide

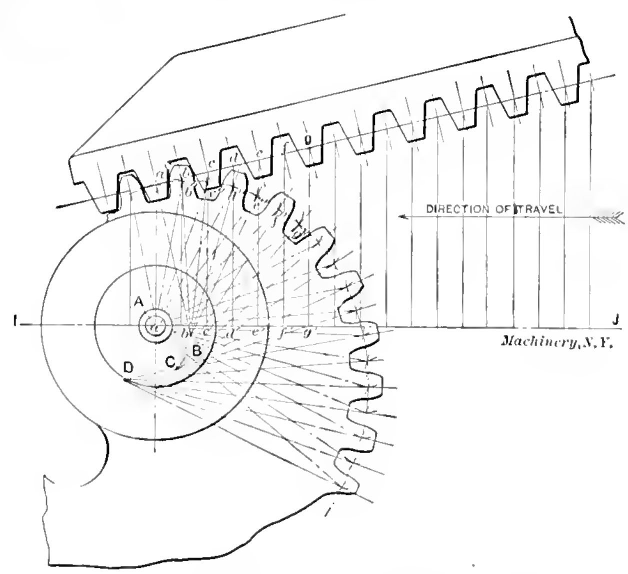

Fig. 2. Method of laying out the Spiral Spur Gear

For cutting the spiral gear, a templet was made having the correct shape of the teeth according to the various radii in the spiral. This templet was fastened on the blank and the spiral was cut in the regular way, only that it could not be cut with one cutter as the shape of the tooth changes with the spiral. [The paradoxical name of spiral spur gear given the gear illustrated in connection with this article.

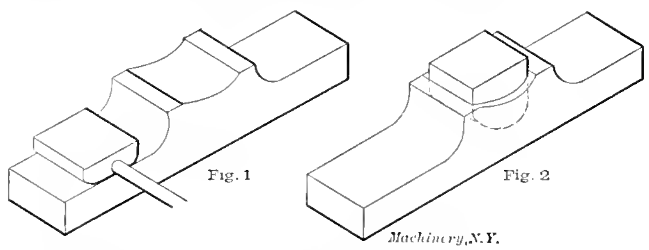
illustrates the folly of naming what is really a helical gear a spiral gear, as the gear here shown is truly spiral in form. —Editor.] Edward Person.

Brooklyn, N. Y.

FORGING DRIVING BOXES

Forged driving-boxes are preferred to steel castings by many European railway works. On account of their great height there are some difficulties in the way of forging them direct in the press. The accompanying sketches show how this work has been simplified at the Epernay shops of the French Eastern railways.

The billet for the driving-box forging is first rough-dressed as shown in Fig. 1, and then, with the aid of a die, the hollow is shaped in the crown as at Fig. 2. The third operation is to channel the sides as shown in Fig. 3, and then swage the middle portion on the block, or matrix, as in Fig. 4. The forging is then passed to the press in which it is given a truer form by a die and matrix. The sixth operation is to close up the sides or cheeks of the box by straightening out the curved ends according to the manner shown in Fig. 5, and the seventh and final operation is to square up the forging on the form or die as in Fig. 6.

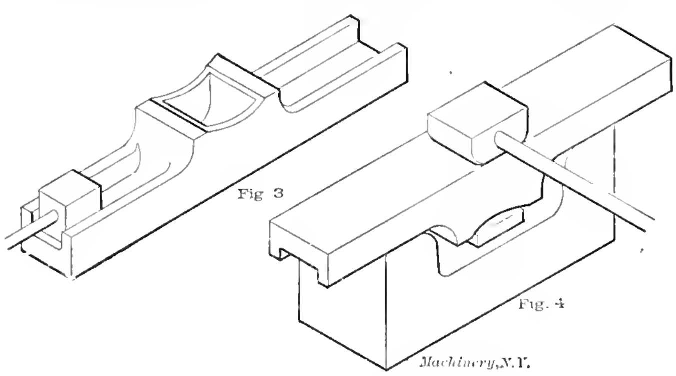


Figs. 1 and 2. Rough Dressing and Shaping the Crown of the Box

The weight of the billet being 264 pounds, the forging thus far completed will weigh 172 pounds, and, after machining, the finished driving box will weigh 105 pounds. For heavier finished boxes the weight of the billet and forging are correspondingly heavier. C. R. K.

BLIND ACCEPTANCE OF AUTHORITIES

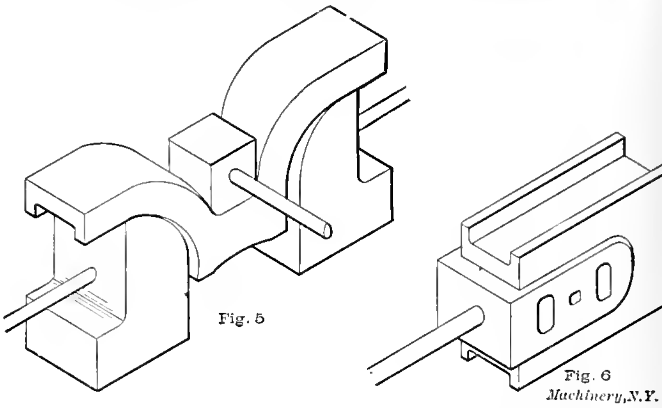
In the June number of Machinery, in an editorial, some space is devoted to what is perhaps the greatest fault of the young college-bred engineer—that of adhering blindly to rules laid down by the authorities. No text-book, or college professor, however, can overcome the handicap of a poor memory or lack of good common sense; neither should such authorities be credited with mistakes resulting from such inability, nor should ridicule emanating from it reflect on them.



Figs. 3 and 4. Channeling the Sides and Swaging the Middle

Incidents concerning the deeds of college engineers are plentiful, and two old, familiar ones may bear repeating. One young man while employed in a drafting-room was given the task of making the necessary drawings for a certain mechanism. When completed he turned the "drawing" over to the chief along with twelve closely written sheets which he said were directions for the drawing. The other engineer in writing of a new locomotive stated that it weighed 160,000 pounds, though the actual weight was slightly in excess of this, for the boiler carried 200 pounds of steam!

Just how some students manage to graduate is hard to conceive. Quite recently a graduate of the engineering school of a large university was unable to tell what part of a dynamo was the commutator. It is impossible to believe that any part of a college training is responsible for such glaring ignorance and errors. Happily for him, the college engineer may sometimes link arms with the practical man and share the "knocking" that his co-workers are only too ready to administer. Witness the following: The mechanical superintendent of a certain factory, a man of 35 years experience in various positions from apprentice to machine shop owner, was telling with a show of pride how he had forestalled a move to put 12 presses on the fourth floor of one of their buildings. The machines were hydraulic presses weighing 1,500 pounds and capable of exerting 35 tons on any article placed between the platen and bed. "Why," said he, "those floor beams are only 2 × 12, set 2 inches into the brick, and with all 12 presses working there would be 400 tons on that floor; I'd resign my position before risking lives that way."



Figs. 5 and 6. Closing in the Sides and Squaring the Forging

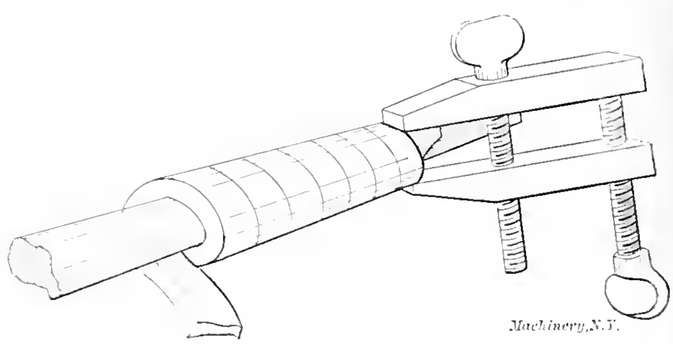
Let us have all the training obtainable; that, tempered with good common sense and coupled with broad, practical experience will give us the engineer par excellence.

Middletown, N. Y. Donald A. Hampson.

A CHEAP BUILT-UP LAP

A great deal of machine work would be considerably improved by having the holes which require accuracy, lapped smooth and true, but the equipment of the average machine shop does not include laps of all sizes, and if a few are carried the chances are all in favor of their being of the wrong size for the work in hand.

It does not take very long to make a lead lap of the ordinary kind, but molds must be provided for casting them, and, as the variety of work to be lapped is infinite, it is practically impossible to have a complete set of molds. Casting laps upon a tapered arbor, as is customary, also requires that the holes in the mold must fit the arbor to be used, at the place where the lap is desired on the arbor, and as that place may vary or



Forming a Lap by winding Narrow Strips of Sheet Lead around a Taper Arbor

one may wish two separate laps on one arbor for lapping journals some distance apart, variations of hole size must be compensated for by the use of clay or some similar expedient. Another fault of the cast lead lap is its tendency to run dry and bind in the hole, unless carefully scored to provide oil channels over most of its surface. It also must be split if of any considerable size as compared to the arbor, or it will require too much of a blow on the arbor to expand it, if this be possible at all.

To reduce the work required to make a lap, and provide material which can always be worked up into a lap on short notice without casting and without the use of molds, keep a piece of sheet lead about 3/16 or 1/4 inch thick, or even thicker, on hand. Use the same taper arbor as for the cast lap, and place it between the centers in the lathe. Cut a strip from the sheet lead about ½ inch wide with the tin shears and fasten it to the arbor a little nearer to the small end than you wish the end of the lap to be, with a clamp or lathe dog, as shown in the illustration. Now wind the lead strip as tightly as possible upon the arbor in the same way that a helical spring would be wound, tapping the lead with a hammer to produce an impression of the spline, if a splined arbor is used. If one layer of the lead does not give a lap large enough to turn to the desired size, another layer can be wound over the first in the same direction, but beginning at the opposite end. This operation may be repeated until the desired diameter is obtained, after which it is often well to fuse the ends together with a soldering iron if the lap is very large. The whole can now be driven firmly onto the arbor and turned true and round in the lathe. The helical grooves left between the various convolutions of the strip serve admirably as channels for the proper distribution of the oil and emery, and this construction will be found more elastic and easily expanded than the conventional cast lap.

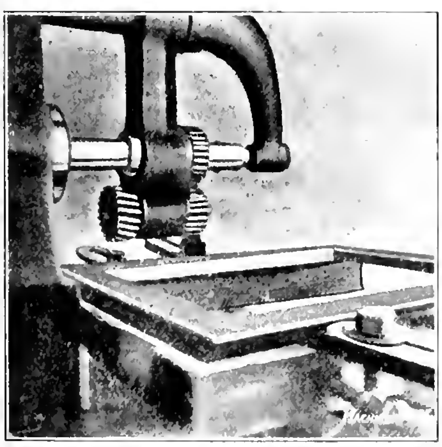
Needless to say, the lap must be run so that friction with the piece to be lapped will tend to wind the lead strip more tightly around the arbor; this proves quite an advantage rather than a disadvantage as it makes it possible to use an unsplined arbor without the constant danger of the lap slipping on it. On laps having but a single layer of lead it will be found desirable to reduce the diameter for an inch or so at the small end to prevent friction with the piece to be lapped, which would tend to unwind it. On laps of two or more layers this will not be necessary. HERBERT L. THOMPSON.

Elgin, Ill.

CORNERING TOOL FOR THE MILLING MACHINE

During periods of industrial depression a struggle for existing business is very naturally induced, which results in prices trimmed so close that there is little or no profit in handling the work. Business of this class, however, serves to keep together for future increase a force of men trained in some particular line of work, and for such purpose is self-justifying.

In an ambitious attempt to transfer some of this competition type of work into profitable business the "square cornering" tool, shown in the engraving, was evolved. We had a large number of flat castings 3/4 inch thick, with a rectangular opening 12 x 15 inches, the sides of which had to be machined straight and square with each other. As the speed of the cutters limited the time consumed in milling the sides, any reduction in manufacturing cost had to be made by cutting the time between, or rather after, these cuts had been taken. Therefore it was desirable to remove the sections left in the corners by the straddle mills as quickly as possible. The device by which this was done was simply an auxiliary arbor suspended below the regular arbor and driven by spur gearing. The castings were clamped on parallels, as in slotter work, and passed across the cutter by the elevating screw. This was a lighter task than would at first appear, for the weight of the knee formed a hold-back that permitted the work to be fed *into* the cutter, which, in turn, materially assisted in lifting the weight by its upward movement. This device turned out ten complete castings, or forty corners, in one hour, using a carbon steel cutter. DONALD A. HAMPSON.

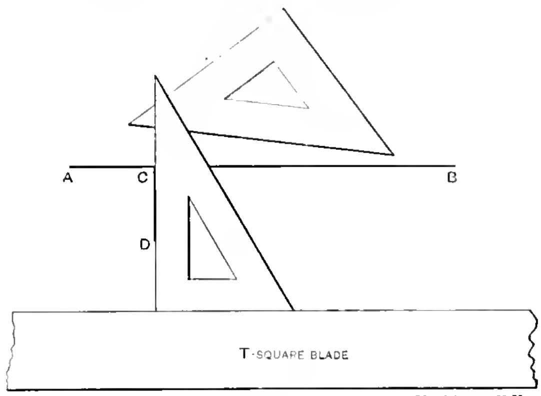


Cornering Tool attached to the Milling Machine and Example of its Work

Middletown, N. Y.

TO AVOID BLOTTING FRESH INK LINES

It sometimes becomes necessary for the draftsman to draw short vertical lines before the horizontal ink lines are dry, and it is impossible to lay the triangle on them without causing a blot. The lines can often be drawn by laying one triangle over the other, to lift it off the paper, as shown in the sketch, where the line $A—B$ is supposed to be a freshly inked line, and it is desired to draw the line $C—D$ without waiting for $A—B$ to dry. One triangle can be laid on the board just above $A—B$ with one edge approximately parallel to it. Then the upper end of another triangle can be laid over the first, its lower edge being guided by the T-square blade in the usual way. This lifts it clear of the line $A—B$, and $C—D$ can be drawn just about as well as though the triangle were flat on the paper. WALTER GRIBBEN.

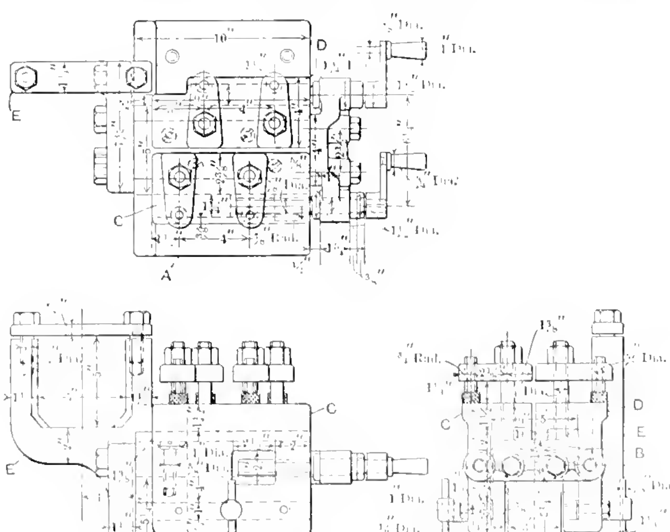


Method of using Triangles to avoid Blotting Fresh Ink Lines

Brooklyn, N. Y.

A SHAFT TURNING ATTACHMENT

We recently had to supply a three-tool rest for shaft turning which had to fit onto a lathe which was used for practically any job that came along, and as shafting seemed to come along pretty often, it was thought advisable to provide some means whereby this kind of work could be more economically dealt with. It was desired that the attachment be so designed that little time would be required in changing from shaft turning to ordinary work and *vice versa*. The device consists of a base A, which in operation is securely clamped to the cross-slide of the lathe; a slide B on which tool-holders C and D work, and a stay E which carries either metal or hard wood steadies for supporting the work. The slide B is made separate from the main casting



Shaft Turning Attachment for the Lathe

A so that the bearing surfaces may be more easily machined and scraped to fit. It will be seen that the tools come quite close together and yet plenty of room is left for the handles which work the screws for adjusting each tool.

In operation the ordinary tool rest of the lathe is moved to the back of the carriage and the two-tool rest mounted on the front. The back rest carries the roughing tool which is, of course, clamped with the cutting edge downward. The left-hand tool-holder of the attachment carries the first finishing tool, while the right-hand one carries the finishing tool proper. All three tools are under perfect control from the operator's working position in front of the lathe (the back tool is, of course, adjusted by the regular cross feed screw) and when the lathe is needed for work other than shaft turning, five minutes, at the most, is all that is required to dismount the shafting attachment.

I might say, in conclusion, that with this arrangement a feed of 1/32 inch per revolution of spindle leaves a fairly good finish which only needs polishing to meet ordinary requirements. A good stream of lubricant is required on the tools, particularly if high speed tools are used. RACQUET.

SWINGING INK-BOTTLE HOLDER FOR DRAWING TABLE

Experienced draftsmen know the risk in keeping the ink bottle on the drawing board, especially if it be a sloping board. Even when the bottle is fastened in a heavy base to avoid tipping over, it may slide off the board, or ink may be dropped on the surrounding board or paper when filling the pen, and anyway it is in the way and takes up space on the board. To avoid these difficulties, I designed and had applied to several drawing-tables the device shown in Fig. 1, which has been found very satisfactory and convenient. The line illustrations, Figs. 2 and 3, show the construction with certain improvements over the original design shown in the half-tone.

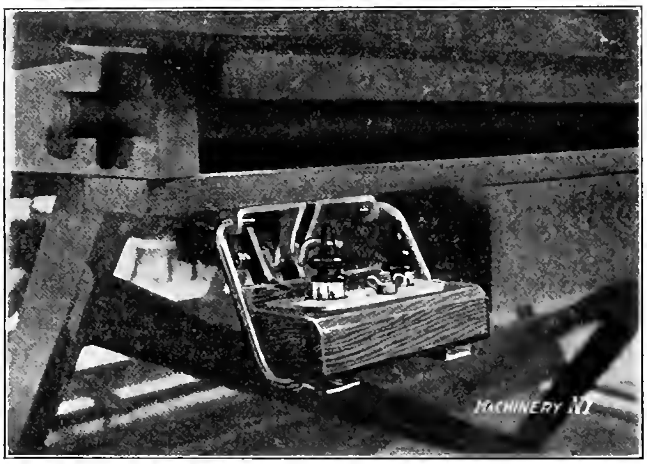


Fig. 1. Holder for Two Ink Bottles, which is easily swung out of the Way

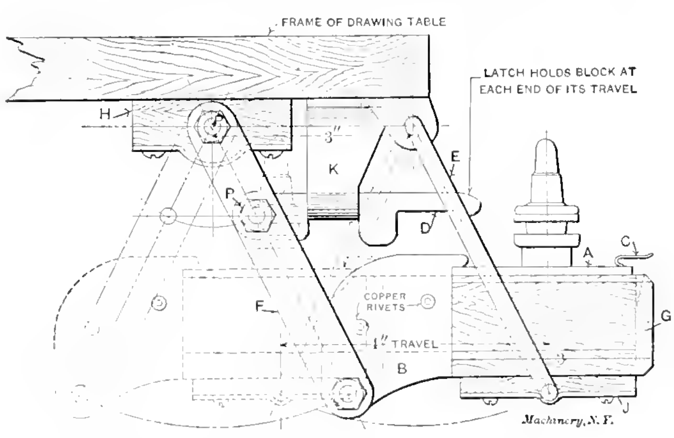

Fig. 2. Side Elevation of the Holder, showing the Inner and Outer Positions

The device illustrated may seem to have a great many parts, as compared, for instance, with a drawer, which is the first thing one would think of for the purpose; but a drawer on this folding drawing table would have been in the way, and a slide of ample length would have required more depth than was here available. This holder is located next to the left side of the draftsman, and in the half-tone it is shown pulled out, affording ready access to either of the two ink bottles which are locked fast in it, and requiring one hand only for removing the filling quill. The bottles may be quickly removed for changing or renewing, by unscrewing the one thumb-nut and removing the brass retaining-plate *A* (Fig. 2), the back edge of which slips into the recess in the wooden strip at the back. In the improved design this wooden strip is done away with, as is evident in the line drawing, ears being formed on the plates *B*, instead; also the thumb-nut and screw have been superseded by a spring clip, *C*, making it still easier to remove the bottles.

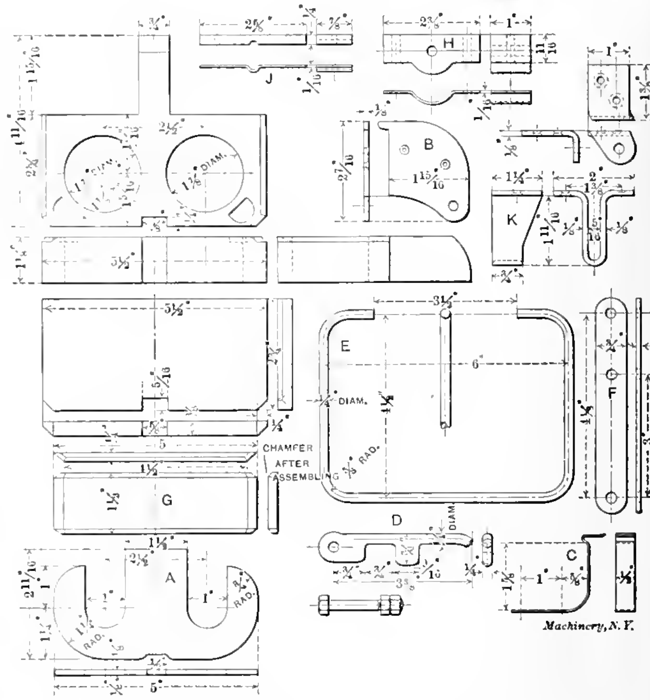

Fig. 3. Details of the Swinging Holder

After inking the pen, lifting the latch *D* with the tip of the finger enables the holder to be instantly pushed back out of the way; at the back end of the stroke the latch drops into place again and the swinging holder is retained there, entirely underneath the table and out of the way. The construction should be clear from the drawings, the marks or symbols used being the same in Figs. 2 and 3. The wooden parts of the holder are glued together, other fastening being afforded by the wood screws and the rivets indicated in the assembly drawing, Fig. 2. The portion of the drawing table to which the holder was attached is permanently horizontal, the drawing board, of variable slope, being pivoted above. Attachment was made by 8 wood screws; of course, if desired it could be all attached to a separate block, permitting, in the event of shipment, removal without disassembling.

Berkeley, Cal. H. J. KENNEDY.

HOSE COUPLING AND CLAMP

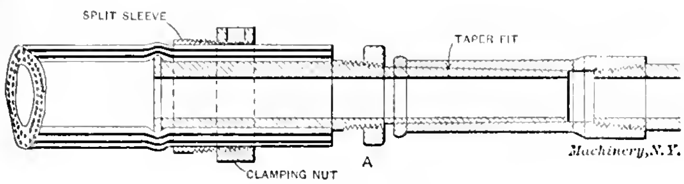
There are a great many different styles of hose couplings on the market, but still there seems to be room for improvement. No matter how careful the operators of pneumatic tools are, there is always a certain amount of time lost because couplings slip out of their hose or because the quick-adjusting types become disconnected. This trouble may be caused by poor construction and partly by rough handling.

The accompanying engraving shows a quick-adjusting hose coupling and also a hose clamp, that are giving satisfaction.

This coupling has a taper of 1/32 of an inch in 3 inches, which is very gradual, and when the parts are connected with a quick jar the taper "bites" so that they seldom come apart. When the coupling is to be disconnected, the parts are twisted by placing a wrench on the nut *A* provided for

that purpose. This takes time, but it is well spent as most couplings that can be taken apart by hand are generally leaky or very liable to come apart with the pressure on, and possibly cause an accident.

The hose clamp shown, is made of brass tubing. It has a 16-pitch taper thread cut on it and is split with a hack-saw in about six places. A knurled nut is also provided which is drilled for a round spanner, for tightening. As the nut is screwed on the taper thread, the tube takes a firm grip on the hose, which, in turn, is compressed against the inside connection or coupling.



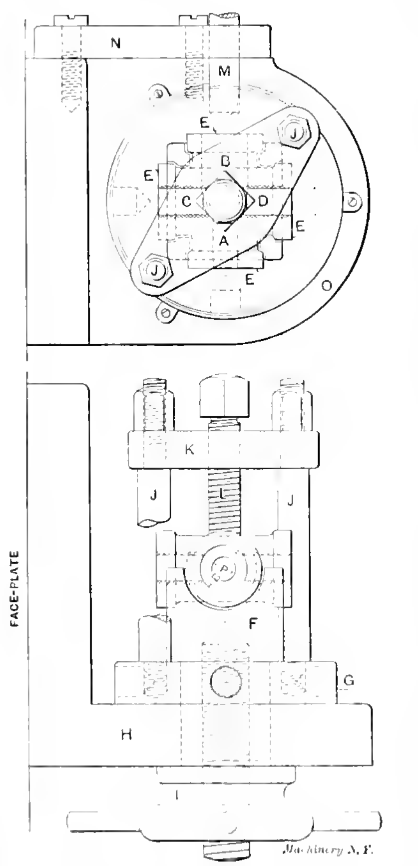
Simple Form of Hose Coupling for the Air Hose

This clamp has no extending parts such as screws, bolts or lugs which are usually found in hose clamps, to catch, as the operator pulls or drags the hose along the floor or ground. The hose couplings on one end are either made to screw on a nipple or be clamped in a hose. It will be found quite profitable in a large works to have patterns made and then cast the parts of brass as the occasion demands, rather than to buy and experiment with couplings of various kinds.

R. S. F.

TURRET LATHE FIXTURE WITH INDEXING ATTACHMENT

In the accompanying engraving is shown a fixture for facing, drilling and tapping the knuckle in a universal joint. This fixture, when in use, is mounted on the face-plate of a turret lathe, and with it the several operations are done very rapidly and at one setting of the work. These knuckles must be interchangeable, as they are used for repairs. They are made of malleable iron, and it is necessary to face the four sides *E*, drill holes 3/8 and 9/16 inch in diameter at *A* and *B*, respectively, and drill and tap the holes *C* and *D*. The castings are located in the fixture in the correct position by the holder *F*, the top surface of which is made to conform to the four flanges, there being clearance for the body of the casting. The holder *F* is made a press fit in the steel ring *G*, and the protruding end is made a sliding fit in the angle-iron *H*. Tapped into *F* is a stud on which the clamping-wheel *I* is mounted. Two tie-rods *J* are screwed into the plate *G*, and at the ends of these rods there is a strap *K* through which passes the clamping screw *L*. In the ring *G* four holes are drilled to receive the index pin *M* which is mounted in the arm *N*. This pin is held in place by a spring not shown. In the illustration the fixture is shown with the work in place, machined and ready to be taken out, which is done by simply releasing the clamping screw *L*. The changes are made for the different holes by releasing the clamp-nut *I* and withdrawing the index pin, after which the work can be turned to the desired position, the index pin locating the chuck while it is being clamped by the nut *I*. To prevent any dirt or chips from working into the index holes, a band of brass *O*, having a hole for the index pin, is placed around the ring *G* and fastened to the angle-iron. This fixture can be used for more than one class of work, as the holder *F* can be removed and replaced with one of a different shape and size.



Fixture for Universal Joint Knuckles

C. A.

OBTAINING DIAMETERS WITH A BEVEL AND SCALE

That diameters may be obtained by the use of an ordinary bevel and scale, is perhaps not as well known as the advantage of this method merits. Of course, these tools are only used when it is impossible to caliper the piece, as would be the case were it necessary to determine the radius of the cylindrical surface shown in Fig. 1. In order to obtain a diameter with the above tools, the bevel must be set to a certain angle previously determined, which corresponds to the graduations on the scale; then the diameter can be read directly from the scale. For example, if the bevel is set to an included angle of 125½ degrees, as illustrated in Fig. 2, and the distance x from the surface to the apex of the angle is measured with a scale, as shown in Fig. 1, the diameter may be readily determined, for it will contain as many inches as there are sixteenths of an inch in the distance x. Thus, if x equals ¼ inch, which is equivalent to four sixteenths, the diameter would equal 4 inches. When the bevel is set to 140½ degrees, each 1/32 inch represents an inch of diameter; 142¾ degrees, each 1/10 inch; 106¼ degrees, each ⅛ inch; 83⅝ degrees, each ¼ inch; 60 degrees, each ½ inch.

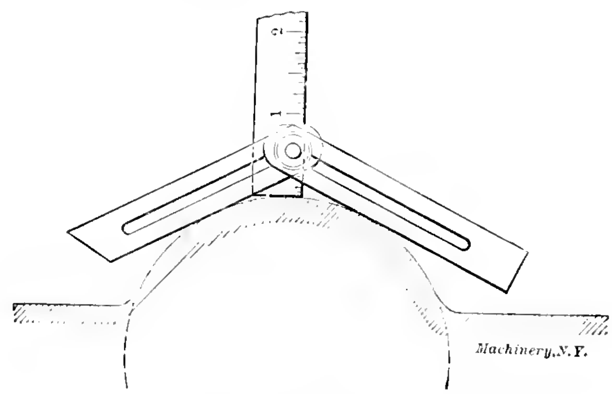


Fig. 1. Method of applying Bevel and Scale to Work which cannot be Calipered

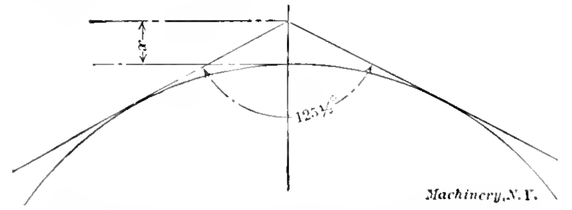

Fig. 2. When the Bevel is set to the Angle shown, each 1-16 inch in the Dimension x is equivalent to 1 inch of Diameter

It will be noticed that the less the angle the greater the distance representing inches becomes, and consequently the smaller the range of diameters which can be obtained. Thus, if the angle is set at 60 degrees, each half inch on the scale will represent an inch of diameter, and accurate fractional diameters can be obtained; but with this angle a large diameter could not be measured, and it would be necessary to use the bevel set at a greater angle.

A carpenter's square can also be used to obtain the same results, but a little calculation is necessary to get the diameter. After measuring the distance x with a scale, as explained, it must be multiplied by 4.83 in each case where an included angle of 90 degrees is used. Thus, if the distance measured 4 13/16 inches, the decimal equivalent to 13/16 should first be found, and the number 4.812 multiplied by the constant 4.83. The result would be 23.242 inches, which represents the diameter. As before stated, this method is

intended to be applied to inaccessible diameters, but it can often be used to advantage for measuring pulleys, etc., which are too large to permit the use of calipers.

C. E. J.

LARGE COMPACT DRAWING-BOARD

At the present time many shops are figuring on propositions which require large layouts, and the ordinary drawing-boards are far too small; yet conditions do not warrant the purchase of a large outfit or perhaps there is no room avail-

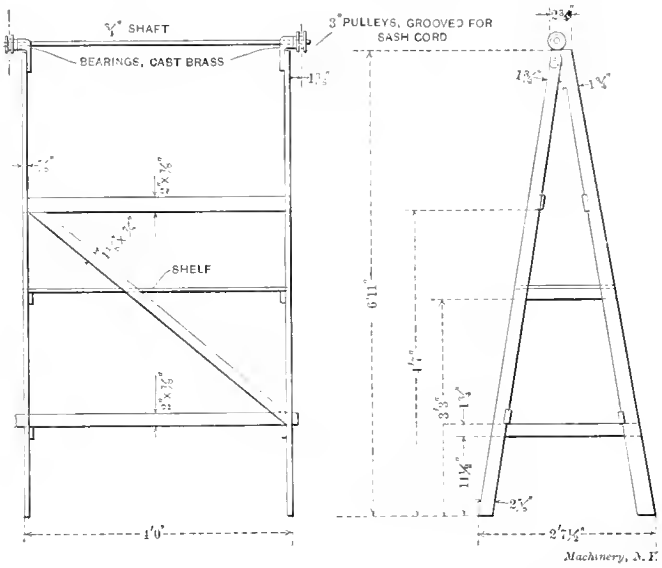

Fig. 1. Elevations of the Drawing-board Frame or Easel

able, and to meet the conditions requiring large capacity and minimum floor space, the board here shown has been built. It proved so useful that a second one was asked for and both are now in constant use. The frame, or easel, as artists would term it, is shown in Fig. 1. Only general dimensions are given, for such details as placing screws and making joints can be decided by the workman. The shaft, pulleys, and bearings, shown at the top, carry the counterweights needed to balance the drawing-board. Fig. 2 shows the general dimensions of the board and straight-edge. The board is built of 7/8-inch stock in the usual manner, with a brace at each end and one in the middle. The end braces also act as

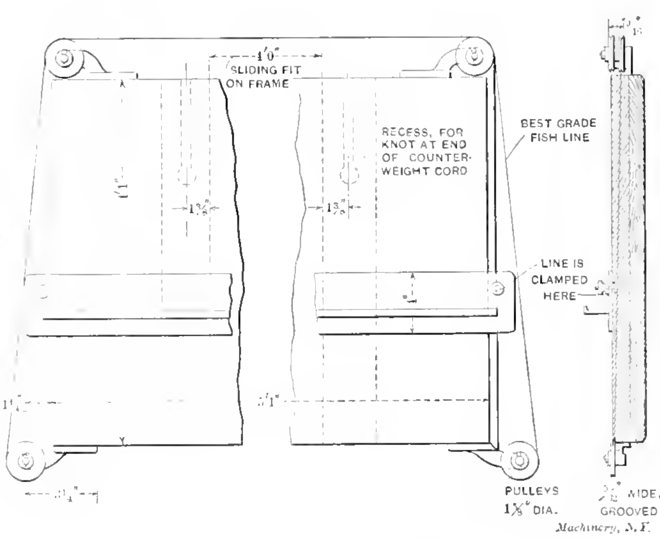

Fig. 2. Detail of the Drawing-board and Straight-edge

guides, their centers coming in line with the center line of the pulleys on the shaft shown in Fig. 1. A 25-pound window-weight at each end serves as a counter-balance for the board which is thus easily raised or lowered.

The straight-edge requires care in making, as both the upper and lower edges should be parallel. The projecting shelf is intended primarily as a brace but it is also very handy for holding tools. By means of the line and small pulleys, shown in Figs. 2 and 3, the straight-edge is moved and kept in a parallel position at every point, the line being clamped at each end of the straight-edge by a brass screw and nut. The straight-edge is counterbalanced by a weight of cold-rolled steel hung from a cord attached just above the brass clamping nut.

The material used was as follows: 25 feet of pine, 15 feet of white wood, 2 pounds of brass used in the small pulleys and bearings, 53 pounds of cast iron in the drawing-board counter-weights and large pulleys, 4 pounds of cold-rolled steel 1 inch in diameter for the straight-edge counter-weights, 7 pounds of cold-rolled steel 3/4 inch in diameter for the shaft at the top of the frame, 25 feet of window cord, 35 feet of best quality fish line, and 3 dozen wood screws.

The time required to build this board depends, of course, on the skill of the workman. About 25 hours seems to be a good average time, a large part of which is spent in gluing the board. Foreign engineers say that this type of board is very generally used in Europe, and while at first sight a designer will usually disapprove of a vertical board, a few hours trial will prove its merits.

RALPH W. DAVIS.

Rochester, N. Y.

TOOL-ROOM CHECK SYSTEMS

I have read with considerable interest the articles dealing with checking systems for tool-rooms which appeared in the numbers of March, May and July. The various systems which were mentioned each has its merits and its defects as will any system, for keeping account of tools or supplies of any kind, which depends upon human care and intelligence for its operation. The efficiency of the system will also vary directly with the quality of the care and intelligence employed.

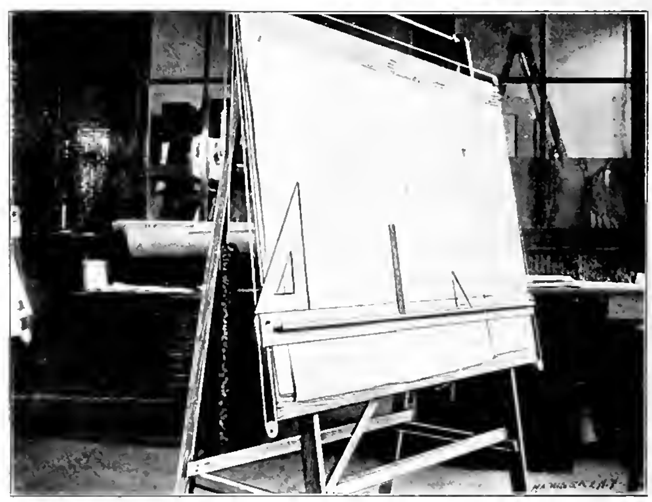

Fig. 3. Compact Drawing Board having Independent Vertical Adjustments for Board and Straight-edge

It is not my intention to put forth a better method of checking tools taken from the tool-rooms, but merely to call attention to another method which has recently come to my notice and is in operation and giving satisfaction in a large railroad shop in the East. This system consists of giving the checks to the tools instead of to the men, and it is operated as follows: A board large enough to accommodate the names of all the men who are to be served with tools, is placed in the tool-room in a location convenient to the man in charge of the distribution of the tools. Opposite each name is a hook upon which the checks are hung. The tools are numbered and the checks are also numbered to correspond. When, for example, John Jones calls for a 1-inch reamer which is number 27, the reamer is taken from its case and the check number 27, which is on a hook at the side of the case, is hung on the hook opposite John Jones' name on the board. Upon the return of the reamer the operation is reversed. The shop in which this system is in use, adopted it to overcome the trouble that was being experienced by the men losing checks and to put the prosperous check-borrow sharks out of business.

I am of the opinion that the system could be improved by supplying each man with a certain number of checks, keeping them upon a hook opposite his name on the board and exchanging one of these checks with the tool check when a tool

was taken out. This would be practically a debit and credit system of checking. Another road which uses the system of giving the checks to the men, provides for their loss by placing a value of 25 cents upon each check and deducting this amount from the man's wages for each check that is lost.

Chicago, Ill. G. E. RYDER.

The following system for keeping a record of the tools which the workmen use and which are regularly kept in the tool-room, will be found to give entire satisfaction, both to the workmen and management. It consists of two boards, each with a number of hooks equal to the number of workmen to be served. The hooks are numbered in consecutive order. On one board which is the *in* board, a number of tool checks are hung on each hook; in this case ten. The other board is the *out* board. The system operates as follows:

Every workman, when employed, receives an identification number corresponding to his number on the time recorder. Every tool kept in the tool-room is identified by a small pasteboard check, which is kept with the respective tool. Now if a workman desires a tool he presents his identification number at the receiving window. The tool-keeper hands out the tool, transfers the tool check corresponding to the number of the workman from the *in* board to the *out* board, and on the same hook hangs the check identifying the tool. It is very obvious that, through this simple system the tool-keeper is always able to tell what tools are out, and who is using them. By keeping the tool checks in the tool-room none are lost, or carried away. When a man quits, or is discharged, he must present a receipt from the tool-keeper to the timekeeper, showing that his account with the former department is in order, before he can receive his pay. This system is very easy to install and requires but little effort to operate.

Peoria, Ill. JOHN M. KUPEL.

SIMPLE FIXTURES FOR MAKING WORMS AND WORM GEARS

In Figs. 1 and 2, at *A* and *B*, respectively, are shown a single thread brass worm and a worm gear which were made in the fixtures also shown in these illustrations. As the requirements did not demand great accuracy, the worms were turned in a screw machine and the threads cut on a hand milling machine, while the gears were punched out of flat stock and then hobbed.

The thread milling fixture (Fig. 1) has a plain block of machine steel through which a hole is bored which will just admit the worms. A part of the top of the block is removed, so that the periphery of the worm is exposed, as shown. The end view shows that the worm is held true from all sides by the walls of this block. The mandrel *E* is fitted so that it

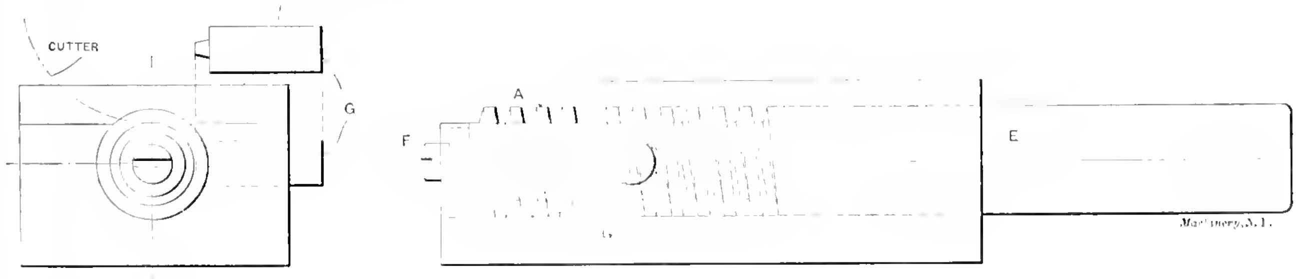

Fig. 1. Fixture for Milling Small Worms

turns snugly in the hole already mentioned. In one end of the mandrel a hole is tapped to receive the screw *F*, which holds the worm firmly against the end of the mandrel. On the mandrel a thread is cut, as shown, with the same pitch as that required for the worm. Instead of the nut ordinarily used on such fixtures, a plain key *G* is used. One end of this key is filed to fit into the thread on the mandrel, the sides of the tongue being left flat. It is hardened and driven into position in the block. In the illustration the pin is seen to extend from the block. This exposed end can be gripped in a vise if necessary to adjust the tongue properly into the thread on the mandrel.

An ordinary lathe dog is used to turn the mandrel in the block and feed the worm against the cutter. If, when the cutter comes into contact with the work, the worm tends to turn, such tendency is checked by the screw in the end of the mandrel, which tightens.

The cutter is ground to the standard 29-degree angle for the job. As the milling machine with which this fixture is used, has a hand lever to move the table, it is easy to bring the work up to the cutter. The table is held against a stop while the thread is being milled.

Before hobbing, the gears are gashed on the milling machine already mentioned, in lots on a special mandrel. The hob-

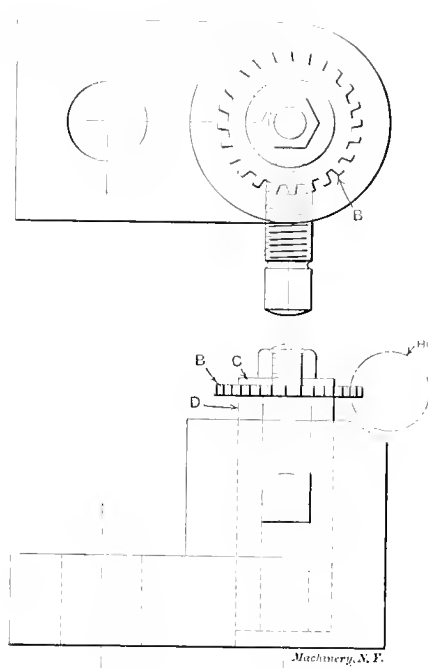

Fig. 2. Fixture for Hobbing Small Worm Wheels in the Lathe

bing fixture is shown in Fig. 2. The body is of cast iron and is made of a discarded punch holder. Into this body is fitted a post, *D*. This post has a vertical adjustment, and it is held by the set-screw shown. On the top of the post there is a shoulder on which the gear is placed for hobbing. The washer *C* is held tight against a second shoulder by the nut shown. Just enough clearance is allowed to permit the gear to turn when it is driven by the hob. The hob is used on the centers of a small lathe and is driven by an ordinary lathe dog. The hobbing fixture is mounted on the cross-slide from which the tool-post has been removed.

It was found necessary to aid the hob by turning the gear with the thumb when beginning the cut, but after the gear had made one turn, the hob finished the work without further assistance. The gear was advanced toward the cutter by turning the cross-slide feed-screw. HERBERT C. BARNES.

Brooklyn, N. Y.

* * *

A side light on methods of computing charges for job work that may be useful is the practice followed by a country printer: For composition he charges two times the labor cost; for press work two times the labor cost plus 25 per cent; for illustrations, paper, etc., the charge is the cost plus 10 per cent; and all other work involving labor is charged two times the cost and 10 per cent.

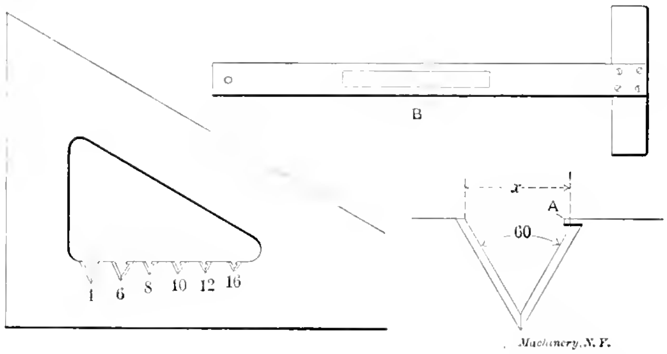
SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary

DRAWING OF V-THREADS

I found the drawing of V-threads to be very trying until I thought of the following scheme which makes this work much easier. The idea is as follows: File a number of 60-degree notches in the inner edge of the triangle, as shown in the illustration, for different thread pitches. Make the top width x equal to 1 divided by the number of threads per inch, and leave a small point A to stop the pencil. To use the triangle,

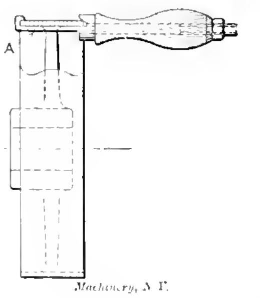


place the pencil against the left side of the notch and run it down that side and up the other to the stop; then move the triangle to the right until the pencil is again against the left side. By repeating this operation as many times as is required, a uniform thread can be rapidly drawn. Another suggestion for draftsmen is to have a 12-inch scale fastened to the T-square as shown at B. This is also a time-saver, as the scale is in a position where it is always ready for use.

Plainfield, N. J. JOSEPH WEANER.

REMOVABLE PULLEY HANDLE

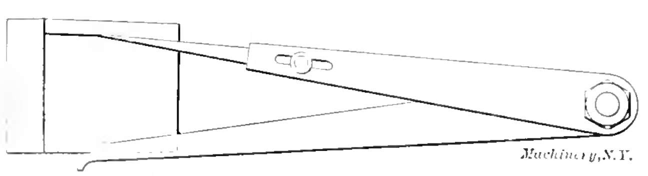
When a new machine is being built it is often necessary to revolve the feed or other pulleys by hand in order to observe the working of the machine. The removable handle shown in the engraving is extremely useful, as it may be attached to the rim of the pulley which is to be turned, thereby making the operation easy. The hook-bolt A passes under or over the pulley rim and through the handle, and is secured by a nut, as shown. The bolt is made long enough to suit various widths of rims and the ferrule is notched to grip different thicknesses. For pulleys with flanges another type of handle may be used in which a hoop-iron strap passes around the rim of the pulley, the handle being attached to the hoop iron.



BRUM.

NEW STYLE OF HERMAPHRODITE CALIPERS

The illustration shows a pair of hermaphrodite calipers, which seems to me to be an improvement, at least for a large class of work, over the style generally used. As will be seen the notch in the end of the caliper leg makes it much

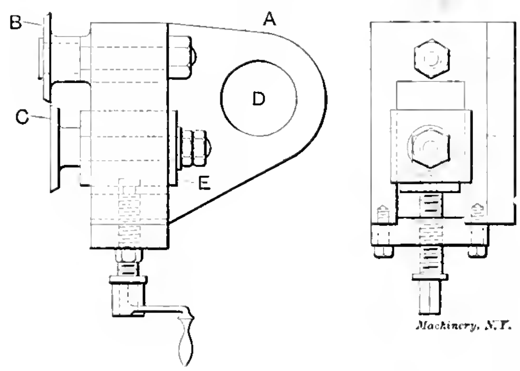


easier to scribe a line parallel with a finished edge, since the point of contact which this leg makes with the finished surface as the calipers are drawn along, is kept the same. The curved extension will also be found useful in laying out work.

Dayton, Ohio. J. L. MARSHALL.

TOOL FOR TRIMMING THIN TUBING

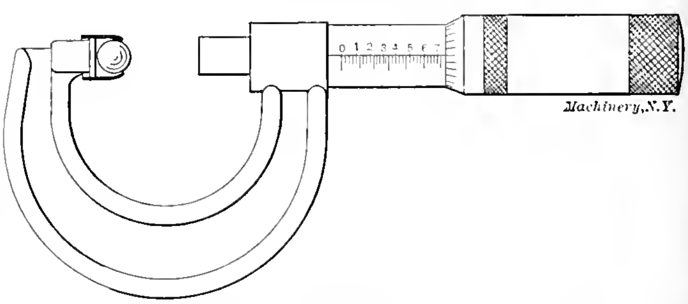
We had a number of large, drawn steel shells of about 26 gage, that had to have the ends trimmed. The metal was too thin to permit the use of a single cutting tool in the lathe, so a tool similar to the one illustrated herewith was made. It consists of a cast iron frame A, and two cylindrical cutters



B and C. The hole D through the casting A fits the tool-post of the lathe, and the fixture is clamped by passing a piece of steel through the tool-post and tightening it against the casting. Cutter B is free to revolve on a fixed stud, while cutter C is carried in a sliding box E, thus permitting it to be fed in toward B by the handle shown. When trimming the end of a tube the tool is set so that the cutter B just touches the inner side of the shell. Cutter C is then fed against the outside, and the tool makes a clean smooth cut. W. ALTON.

A MICROMETER ATTACHMENT

The engraving shows an ordinary micrometer with an attachment for measuring the thickness of metal shells or other irregular pieces of metal. A piece of brass tubing is reamed out to make a sliding fit on the anvil of the micrometer.

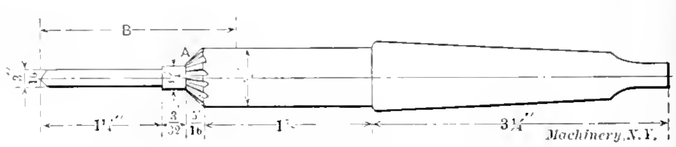


This tubing holds loosely a 1/4-inch bicycle ball, which extends beyond the end of the tube, the latter being bent over to prevent the ball from falling out. The reading, of course, will be taken from the 0.250 inch graduation as zero. Bicycle balls of this size are true to 0.0001 of an inch.

Candiac, Canada S. A. McDONALD.

HARDENING A SMALL DRILL AND COUNTER-SINK

The combination drill, counterbore, and counter-sink shown in the illustration had, of course, to be hardened. This was rather a ticklish job as the drill is so much smaller than the counter-sink, that hardening it in the usual way would mean that the drill would be at a white heat before the large part would be cherry red. To overcome this difficulty, I obtained



a fair-sized raw potato and pressed it onto the drill up to the part marked A. The tool was then placed in a slow fire and the 5/8-inch part heated, the water in the potato keeping the small part cool. When the counter-sink was heated sufficiently, the potato was removed, thus allowing the heat to run from the large part to the drill. When all was an even cherry red, the tool was cooled and the hardening was accomplished without any difficulty. JOSEPH WEANER.

Plainfield, N. J.

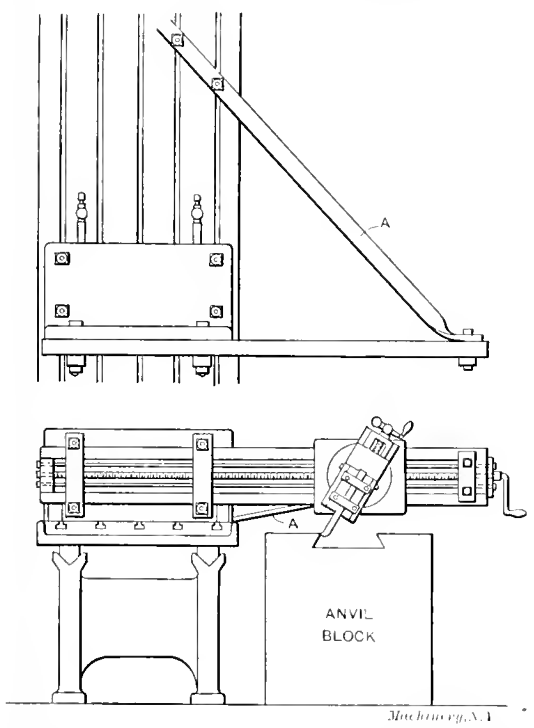
TO OBTAIN THE LENGTH OF STOCK FOR BANDS

A machinist was trying to shrink a band around the hub of a cracked pulley. He first measured the diameter of the hub and multiplied it by 3.1416 to get the circumference. The blacksmith was then told to cut off a piece of 1/4-inch steel stock equal to the length of the circumference of the hub. When the band was formed to the diameter of the hub, the ends were 3/4 inch apart; that is to say, they did not come together by that amount. The machinist could not understand how he had made the mistake. By the use of the following rule, trouble of this kind will be avoided: Multiply the diameter of the hub by 3.1416 and to the product add 3 times the thickness of the metal used for the band. JOSEPH WEANER.

Plainfield, N. J.

PLANING WORK THAT IS TOO LARGE FOR THE PLANER

The accompanying line engraving shows how a steam-hammer anvil-block that was too large to go on the planer, was machined. The block was first leveled up on the floor beside the planer, so that the top of the casting was a little below the top of the planer platen. For safety the casting was clamped to the floor, although its weight was such that there was no great danger of its moving under the thrust of the cut. The cross-rail with the attached head was then removed and clamped securely to a heavy angle-plate, which was bolted to the platen. A substantial diagonal brace A was then fastened to the cross-rail and platen as shown. The tool was fed, of course, by hand, and the dove-tail for the dies was planed by the use of the adjustable head in the usual manner. The job was satisfactory in every way and caused considerable comment in the shop. FREDERICK SEABURY.



Chicago, Ill.

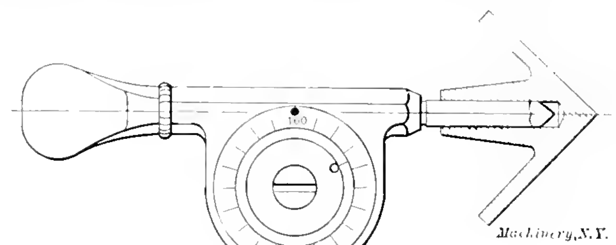
SUBSTITUTE FOR METAL WHEN MAKING ACCURATE LAY-OUTS

When making accurate lay-outs on metals, such as brass or zinc, to avoid troublesome and time-consuming calculations, I find the following objections: The needles of the drawing instruments become dull; the lines cannot be erased, and they are not very plain, especially if the metal is not coated or prepared in some manner; and the metal cannot be fastened or worked upon as easily as paper. To overcome these objections I have used as a substitute for metal what is known as filler board. This is a kind of heavy paper which looks somewhat like leather and has a mottled surface. It is often used for covers on cheap memorandum books, and is about 1/32 of an inch thick. Before lines are drawn on the surface of this board, the gloss should be removed with an eraser. The board has a good, firm body, and therefore a fine center can be made in it from which several circles can be drawn without appreciably enlarging or injuring it. Like other materials in the paper line, filler board will change slightly on account of variations in the temperature and atmosphere, and for this reason the measurements should be marked on the drawing as soon as it is made to avoid any possibility of slight errors due to changes. Where extreme accuracy is required and the nature of the lay-out is such that measurements cannot be marked to advantage, metal is advisable, especially if the drawing is to be kept for a considerable length of time as a record or for reference. H. R. ASH.

Chicago, Ill.

SPEED INDICATOR ATTACHMENT FOR SCREW MACHINE

It was necessary to determine the spindle speeds of a large number of screw machines which were operating on a wide variety of work, ranging from 1/4 to 1 3/4 inch in diameter, and it was desired to get the speeds more accurate than would be possible by simple measuring pulleys and calculating the speeds from the speed of the line-shaft. The following method

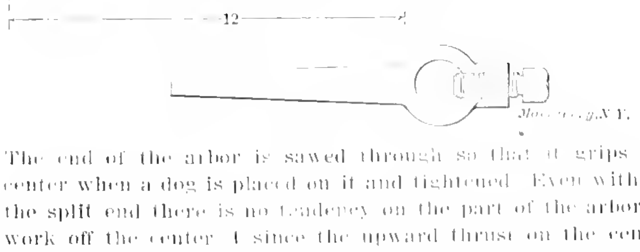


was tried with satisfactory results. An ordinary speed indicator was fitted with a brass conical tip 2 inches in diameter, as shown in the illustration. This tip was made a tight fit on the indicator spindle and was turned out to reduce the weight. To keep the indicator from slipping, three grooves 1/16-inch deep were cut radially in the conical surface and pieces of rubber peened in. In order to secure satisfactory results the indicator should be used when the feed tube is nearly empty, or just after the stock has fed into the tube; then the tip of the indicator will center in the tube and the correct spindle speed is easily taken. In this way accurate results are obtained, because there is no error due to slip of belt or variation in size of pulleys. By watching a group of machines and taking the speeds as the stock runs out, the time consumed is not as great as with the usual method of measuring pulleys and figuring from the line-shaft speed.

Indianapolis, Ind. C. C. MYERS.

ARBOR FOR SHELL REAMER

The engraving shows an arbor for a shell reamer, which is so designed that it will not creep off of the tail center and crowd into the work, as is the case when the arbor is held directly against a cone center. This arbor has a hole drilled in the end about 1 1/4 inch deep in which is fitted a special tail center A, having a straight portion about 1 inch long.



The end of the arbor is sawed through so that it grips the center when a dog is placed on it and tightened. Even without the split end there is no tendency on the part of the arbor to work off the center A since the upward thrust on the center (equal to the downward thrust on tail of the dog) has no horizontal component. There is also a special straight tailed dog to go with the arbor, but this is not really necessary. The diameters of the holes in ends of all arbors are made the same. Since adopting this form I have had no difficulty with bent arbors, broken centers, broken shell reamers and inaccurate holes. W. A. KNIGHT.

Columbus, O.

HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

DESIGN OF MACHINE LEGS

C. E. F.—Is the design of machine legs based on empirical rules or theoretical assumptions? I have given the matter considerable thought and have been unable to arrive at any definite conclusion from a study of existing designs.

A.—It is generally conceded that design of machine legs which shall have a pleasing appearance and fulfill their purpose is one of the most difficult parts of machine design. There are no empirical rules of general application or theory of design that provides for grace of outline as well as proper support. The function of the legs should be that of supporting the machine and transmitting its vibrations to the foundation, especially in the case of machine tools. The tendency of modern design is to eliminate the legs entirely and carry the frame to the floor or foundation. This form avoids the troublesome feature of proper leg design and increases the solidity and rigidity of the frame by deepening it and more closely associating it with the foundation.

ANNEALING AIR-HARDENING STEEL

F. T. M.—I would like a reliable method of annealing air-hardening steel so that I can drill holes about 3/32 inch diameter 2½ inches deep, and tap same to a depth of about ½ inch. The brands of steel that I have tried are refractory, and it has been found impossible to anneal them so that the drills will stand up. I have tried a certain brand of high-speed steel drill but the results are about the same as with regular drills.

A.—We are unable to suggest any but the well-known method of annealing air-hardening steel by using air-tight receptacles in which the steel is packed with lime, sand, ashes or other neutral material; and heating the box and contents to a full red heat for a number of hours, depending on the size of the box and stock, and allowing the whole to cool down slowly. The question is referred to the readers for answers and suggestions. Many, no doubt, will highly appreciate a description of a method of annealing air-hardening and high-speed steel that is superior to the common method in use.

CUTTING SPEEDS

F. W.—Please state the proper cutting speeds for both carbon and high-speed steel tools, cutting tool steel, machine steel, cast iron and brass, in different machines.

A.—The proper cutting speed depends on several factors besides the kind of material to be cut and the kind of steel used for the cutting tool. The depth of the cut, the feed, and whether roughing or finishing, also influence the cutting speed. For general purposes the table above, however, referring to regular carbon tool steels, will be found to give figures representing good average practice. For high-speed steel tools these speeds may be at least doubled. The Cleveland Twist Drill Co. recommends for high-speed steel drills a cutting speed of 50 to 70 feet per minute for machine steel; 60 to 80 feet per minute for cast iron; and 100 to 140 feet per minute for brass, when starting the drill. When a few holes have been drilled at these speeds, still higher speeds may be employed, as the drill point is then heated and high-speed steel tools have a higher cutting capacity when heated than when cold. At the W. G. Armstrong, Whitworth & Co. works of Manchester, Eng., a cutting speed as high as 160 feet per minute for turning machine steel and 150 feet per minute for milling machine steel with high-speed steel tools and cutters, has been employed successfully.

TABLE OF CUTTING SPEEDS IN FEET PER MINUTE

Carbon Steel Tools

Machine	Material			
	Tool Steel, Annealed	Wrought Iron and Mch. Steel	Cast Iron	Brass
Lathe, planer and shaper...	18 to 25	30 to 40	40 to 50	80 to 125
Milling machine..........	25 to 35	35 to 45	40 to 60	80 to 120
Drill press..............	20	30	35	60

A PROBLEM INVOLVING MOMENTS OF FORCES

B. R. E.—A window cleaner sets an eight-foot ladder weighing twenty pounds against a plate glass window with the foot of the ladder two feet from the plane of the window glass, and climbs to a height of three-fourths of the ladder's height. If he weighs 150 pounds, what is the horizontal pressure against the glass window when he stands erect without touching the glass?

A.—In the accompanying illustration, AB represents the ladder, the length of which is 8 feet; BC is the plate glass window; the lower end A of the ladder is placed 2 feet from the plane of the window. Four forces act on the ladder, *viz.:* the reaction P at the upper end, at right angles to the window plane; the weight W of the window cleaner, acting vertically downward at a point three-fourths of the ladder's height from the ground; the weight W_1 of the ladder, concentrated at its center and acting vertically downward; and the reaction R at the foot of the ladder acting vertically upward.

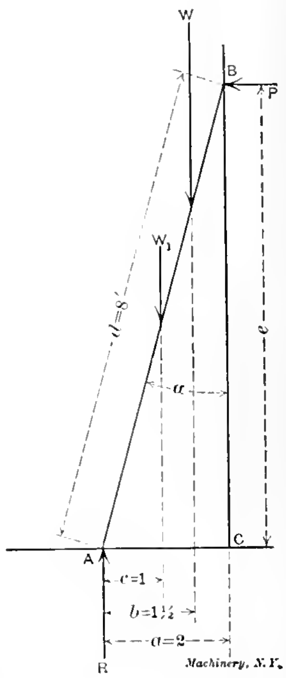


Diagram showing Forces Acting on Ladder

In order to arrive at a universal formula, let the various dimensions be represented by a, b, c and d, as shown in the illustration. To find P, find the moments of the forces relative to point A. The moment of force R relative to this point $= 0$. Hence, the moments of W and W_1 must balance or equal the moment of P. Therefore:

$$Wb + W_1c = Pe.$$

But $e = a \cot \alpha$; consequently

$$Wb + W_1c = Pa \cot \alpha,$$

or

$$P = \frac{Wb + W_1c}{a \cot \alpha} = \frac{Wb + W_1c}{a} \tan \alpha.$$

If we now insert the given values for the various quantities, we have:

$$P = \frac{150 \times 1\frac{1}{2} + 20 \times 1}{2} \tan \alpha = 122.5 \tan \alpha.$$

As $\sin \alpha = \frac{2}{8} = 0.25$, $\alpha = 14° 29'$. Tan α, then, is 0.25831, and

$$P = 122.5 \times 0.25831 = 31.64 \text{ pounds}.$$

This is the pressure due to the combined weight of the window cleaner and ladder, tending to break the glass.

* * *

It frequently happens that a babbitt-metal is required intermediate between the well-known genuine mixture and the cheapest grade in which nothing but lead and antimony is used. As the market price of tin is always high, genuine babbitt is often too expensive for many consumers to employ. The following mixture, given in the *Brass World*, will serve in instances where an intermediate grade is desired:

Lead	50 pounds
Tin	35 pounds
Antimony	15 pounds

This mixture has the advantage of containing no copper, and, therefore, is easily made in an iron kettle. It is not only intermediate in quality but in price as well. It is better than the lead and antimony mixtures, and is only slightly inferior to genuine babbitt. Many large machine builders now use it with good results where genuine babbitt was formerly employed.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

LE BLOND HEAVY-DUTY ENGINE LATHE

The accompanying illustrations show a general view and details of a 20-inch heavy-duty engine lathe recently placed on the market by the R. K. LeBlond Machine Tool Co., 4609 Eastern Ave., Cincinnati, Ohio. This is one size of a line of lathes of the same type, including 16-inch, 20-inch, 24-inch and 30-inch lathes. The principle on which these machines have been designed has been to furnish a tool capable of taking a given cut and removing a given number of cubic inches of metal per minute. The 20-inch lathe shown in Fig 1, for example, is capable of taking a cut ¼ inch deep with a feed of 1/6 inch at a cutting speed of 65 feet per minute, in 50-point carbon steel. This is equal to removing 32 cubic inches of metal per minute. While the new ideas incorporated in the design of this new line of lathes do not involve radical departures from the company's previous designs, an effort has been made to increase the productive capacity of the machine in all respects. At the same time, the manufacturers have aimed to produce a machine without complicated detail arrangements, so that it would be easily operated, and remain rigid even under heavy stress.

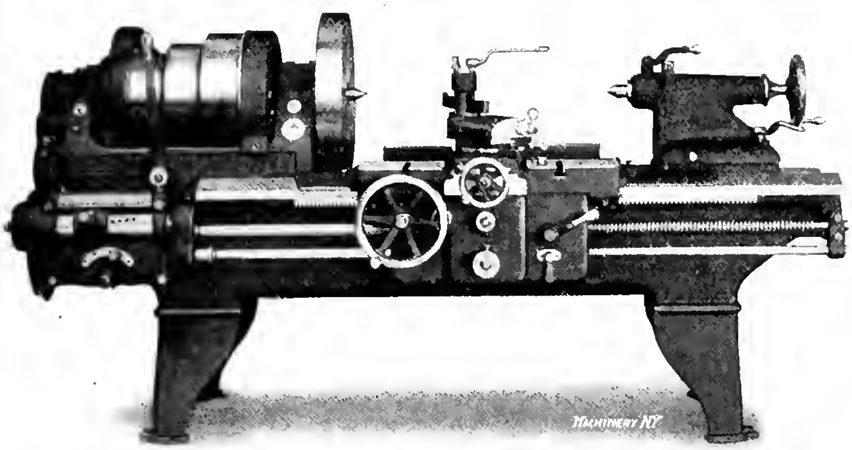

Fig. 1. R. K. Le Blond Machine Tool Co.'s 20-inch Heavy-duty Engine Lathe

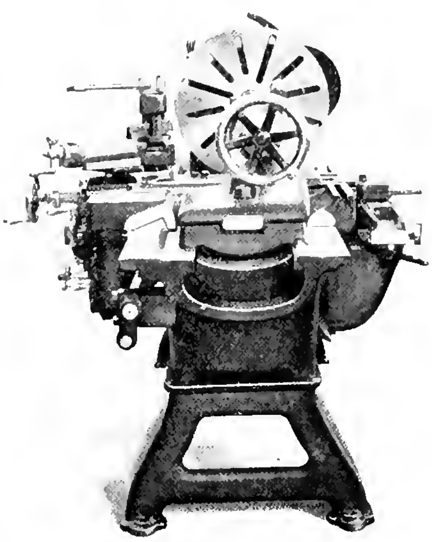

Fig. 2. End View of Lathe

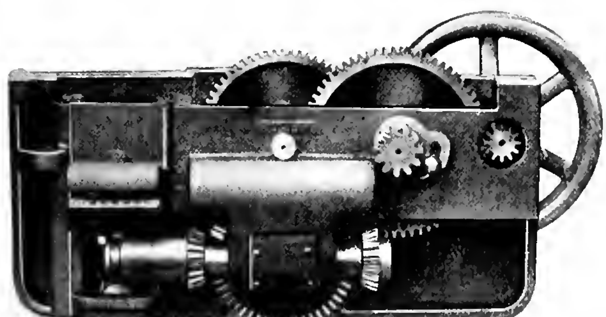

Fig. 3. View of Apron, showing Construction

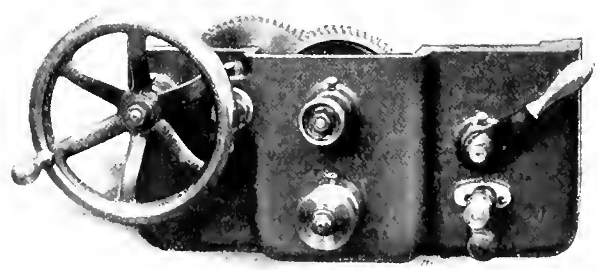

Fig. 4. Front View of Apron

The Head-stock and Tail-stock

The head-stock is of the LeBlond improved drop braced pattern and is securely fastened to the bed with bolts of large size. The three-step cone pulley in conjunction with the double friction back-gears and a two-speed countershaft, provide, in all, eighteen changes of spindle speeds, covering a range carefully selected for the purpose of the machine. The spindle is hollow and made of high carbon hammered steel, and is hardened and ground at the front and rear journals. These latter are carried in cast iron boxes scraped to a good bearing fit. This type of bearing the builders consider preferable, because it does not require intricate oiling devices with continual attention on the part of the operator; yet the lubrication is well taken care of. The bearing standards are cored out to form large oil chambers which are filled from the front of the lathe; from these the oil is fed to the bearings by means of felt pads. This construction eliminates all possibility of grit and dirt entering the bearings, and reduces the attention required to filling the oil receptacle once a week.

The tail-stock is of massive design with a bearing of ample length on the bed. The tail-spindle barrel is designed in such manner as to give the maximum length of bearing combined with long travel. Screws are provided for setting over the tail-stock for taper work, the base being graduated so that this setting can be easily accomplished.

The Bed

In the end view of the lathe, Fig. 2, the form of bed, which is a new departure, is clearly indicated. The tail-stock slides on a V of the usual proportions on the rear way, and on a flat surface in the front. The carriage travels on a flat surface in the back, as shown, and is held down in the back by a flat gib. The front of the carriage slides on a guide of different shape from that usually found in engine lathes. This guide, as shown, is V-shaped, but is machined at an angle of 15 degrees on the front side, and 70 degrees on the back, making the total included angle 95 degrees. The force exerted downward on the carriage of an engine lathe is many times greater than the upward pressure, and in designing the lathe bed this fact has been given due consideration, the wearing surfaces, therefore, having been proportioned accordingly, as shown.

The bed, in addition to having an unusually deep section, is reinforced and braced by a transverse rib of an I-beam section directly under the front bearing; this rib extends up to the extreme top of the bed. In addition to this, the metal around the holding-down bolts for the head has been reinforced to about three times the thickness usually found at this place.

The Carriage and Apron

The carriage is held in alignment on a scraped surface on the front of the bed by taper gibs at both end bearings. This

construction, together with the 70-degree angle on the back of the V overcomes any tendency of the carriage to climb the ways when the lathe is engaged on heavy work. The gibs are tongued in position in the carriage, and in combination with the special construction of the V, they automatically compensate for the wear; this makes it unnecessary to give any attention to the adjustment of the gibs. Wipers are provided, fitted with felt pads, which in addition to wiping off chips and grit from the sliding surfaces also provide for automatic oiling of the ways.

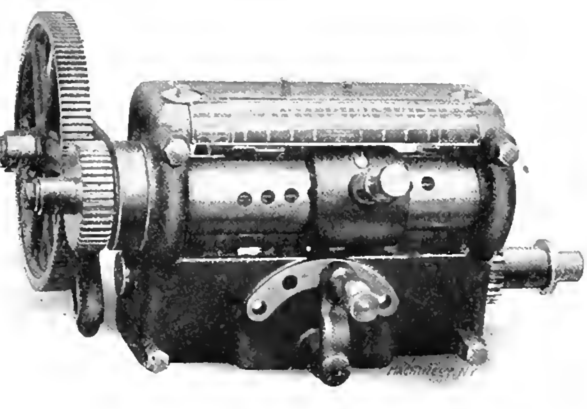

Fig. 5. Gear Box, complete, ready to be Applied to Machine

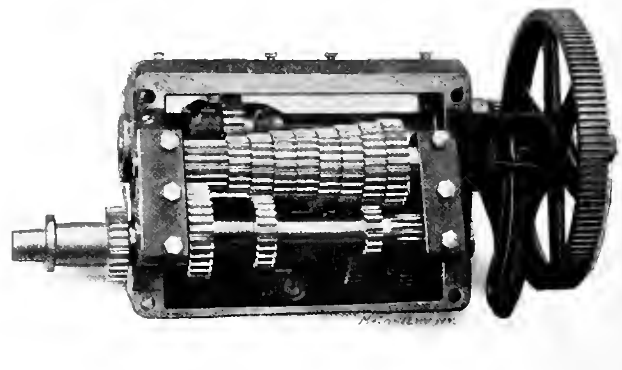

Fig. 6. Arrangement of Gearing in Gear Box

The line engraving, Fig. 7, shows a cross-section through the bed, carriage, apron and taper attachment. This engraving indicates clearly the proportions of the shears, and shows also the relative position of the lathe spindle to the bed. The spindle, as will be noted, is set back a certain distance (in this size of lathe two inches) from the center of the shears, which construction not only provides for an increased swing over the carriage, but at the same time permits the machine to be used at full swing without the tool overhanging the bed, a construction which adds greatly to the rigidity of the machine when turning work of large diameters.

Figs. 3 and 4 show a front and rear view of the apron. From these illustrations it will be seen that the apron is constructed of a one-piece box section casting, with all gears and studs supported at both ends. The apron has a wide bearing on the carriage, is held in position by four bolts, and is fitted to the carriage by means of a tongue. The single box section form of the apron, it is stated by the manufacturers, does away with the necessity of an auxiliary support at the lower end of the apron, and overcomes the difficulty of uneven wear between the lower slides and the V on the top of the bed.

The longitudinal and cross feeds are operated by a single friction which, in addition to being of large diameter, is so placed in regard to the gearing that it has but a light duty to perform. The feeds are engaged by an inward or outward movement of the knob of the lever shown on the front of the apron in Fig. 4. This lever has a central position, which disconnects all gearing when the lathe is used for screw cutting. The apron is further provided with a device which makes it impossible to engage the feed rod and lead-screw at the same time.

Change Gear Box

The quick change gear box supplied with these lathes is shown in Figs. 5 and 6, the former showing the gear box ready to be assembled to the lathe, while the latter shows the gearing, the front cover having been removed. The entire mechanism is completely self-contained. Nine changes of speed for the lead-screw are obtained by means of the cone of gears shown and the tumbler. The tumbler gear, as will be seen, is supported on a cylindrical bearing, and is securely locked in position by the plunger in the change handle. This construction is the same as has been used on the LeBlond lathes for some time. The nine changes mentioned above are quadrupled by the addition of a sliding gear transmission, which is illustrated in Fig. 6. The gears of this sliding transmission are operated by the lower lever shown in Fig. 5. This construction permits of the use of a speed or index plate which reads directly, and from which the operator can see at a glance the position of the levers required for any desired speed. The changes can be made while the lathe is running under the heaviest cut. The gears in the gear box as well as all other feed gears are made from drop-forged steel blanks. The feed rod is driven by the same mechanism by means of gears connecting it with the lead-screw, the range of feed being from 8 to 120 per inch. The changes for the lead-screw provided by the gear box are thirty-six in number, ranging from 2 to 30 threads per inch.

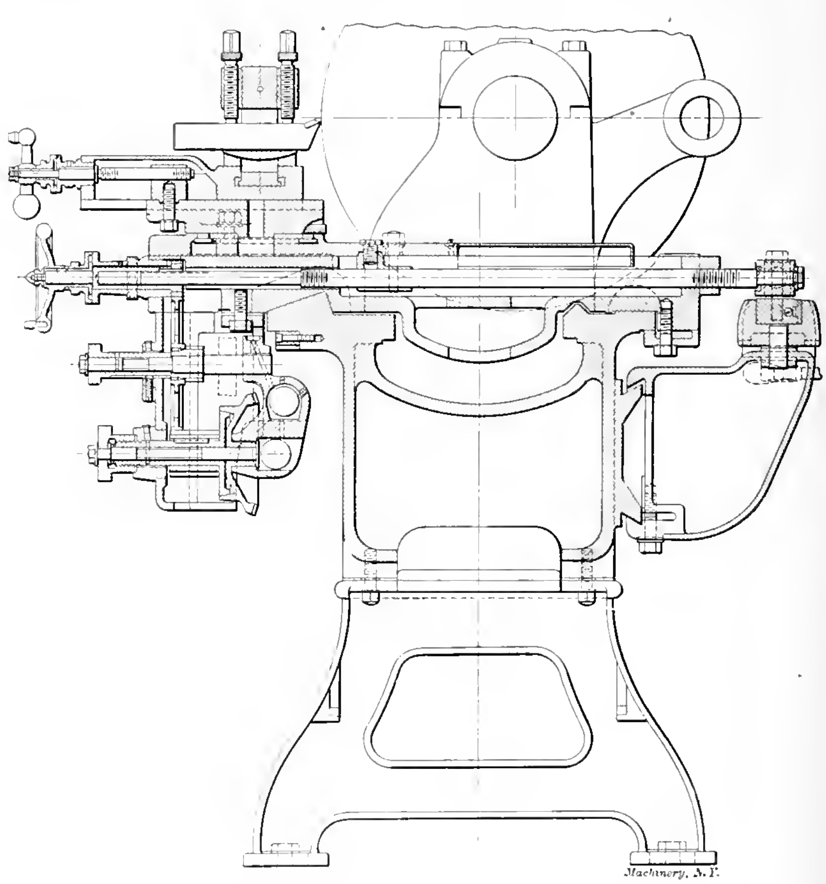

Fig. 7. Cross-section through Bed, Carriage and Apron of Le Blond Lathe

The feed box is connected to the spindle by means of gears, the intermediate one of which is mounted on a quadrant, which permits the use of compound gearing at this point if required for cutting special or metric threads with a standard English pitch lead-screw. A metric pitch lead-screw can also be supplied, in which case the gearing arrangement permits of cutting English pitch threads with this screw, by using compound gearing in the same manner.

UNIVERSAL HORIZONTAL BORING MACHINE

A universal horizontal boring machine has recently been placed on the market by the Universal Boring Machine Co., of Hudson, Mass. This machine has been built with a special view to accuracy and permanence of alignment, and is known as the No. 2½ universal horizontal boring machine with extra long bed; this latter feature facilitates the machining of large castings. The machine is especially adapted to jig work and similar operations where it is necessary to do very accurate boring, milling and drilling, the machine itself being used for obtaining the various distances between the centers of the holes.

A general view of the machine is shown in Fig. 1. As will be seen from this illustration, the machine is of the constant

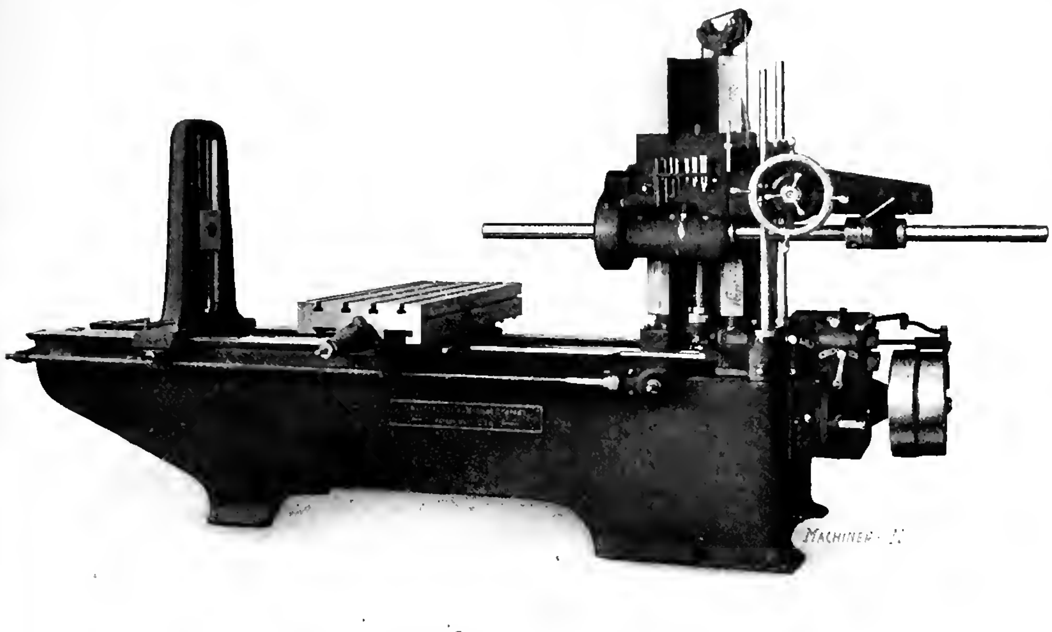

Fig. 1. Univereal Boring Machine Co.'s Horizontal Boring Machine

belt speed gear-driven type. The bed of the machine is of a deep box construction, and is heavily ribbed on the inside to insure rigidity, which is one of the most essential features in machines of this type when accurate results are required. A heavy bed also gives a solid foundation to all the different parts mounted on it, keeping them in accurate relation to each other in all positions, and eliminating the necessity of building a foundation under the machine. Due to the fact that a foundation is not necessary, the location of the machine is not confined to the ground floor. The bed rests on three

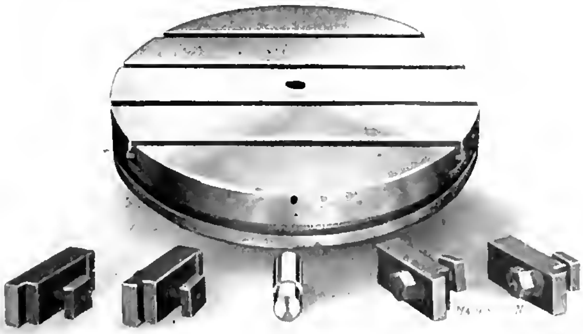

Fig. 2. Rotary Table used on the Horizontal Boring Machine

points, making it very easy to level up on uneven floors; at the same time undue strain on the bed, due to imperfect support, is eliminated.

Head and Driving Mechanism

One of the prominent features of the machine is embodied in the placing of the head at the right-hand end of the machine. This arrangement permits the spindle to run in the same direction when milling as when boring and drilling. The hand-wheel for the rapid adjustment of the spindle is placed on the head conveniently in relation to the spindle where the cutter is mounted, thus allowing the operator to see the milling cutter and to make adjustments at the same time. In the line engraving, Fig. 4, is shown a cross-section of the head and the feed and speed gear box. It will be noted that the machine is provided with a power vertical feed to the head, employed when milling, which for many classes of work is a very valuable feature. Aside from the regular vertical milling feed, the head has a power feed raising and lowering device. A hand feed for fine adjustment of the head by a micrometer dial graduated to thousandths of an inch is also furnished. The head is counter-balanced by a weight attached to a wire rope, as shown, and it is moved by a large screw of coarse pitch. Suitable arrangement has been made to oil the sliding surfaces in order to minimize the wear.

The gear box, the arrangement of which is shown in Fig. 4, is strong and compact and contains both the feed and speed change gears, which are all made of steel and run in a bath of oil to provide quiet running and long wear. Eight speed changes are secured in the gear box, and these are doubled by the back gearing in the head. There are nine feed changes in either direction for the head, one lever reversing or stopping all the feeds.

The spindle is driven at a point near to the work, and thus torsional stresses are practically eliminated. This manner of driving the spindle is of special advantage when using large milling cutters, because the chatter usually present when taking heavy milling cuts on machines where the application of the drive is some distance from the cutter, is eliminated. The driving gear has a long hub in which the spindle is inserted and held by two sliding keys. The spindle itself runs in self-oiling bearings, these bearings having an individual oil compartment containing enough oil for about twenty months running. The bronze bearings, which are fitted into the bearing proper, have a groove cut the entire length, and in this groove is laid a wick having its ends submerged in the oil compartment below. The bearing proper is also split and provided with clamp screws for taking up the wear.

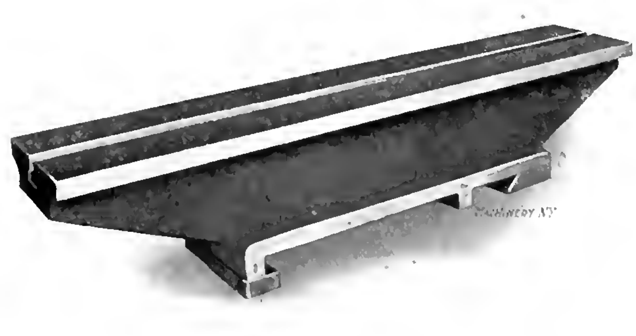

Fig. 3. Auxiliary Table used for Work which would Overhang the Regular Table

Fig. 4 also shows a cross-section of the tight and loose pulleys on the driving shaft. It will be noted that the loose pulley is slightly smaller in diameter than the tight pulley, so there is practically no tension on the belt when it is on the loose pulley, consequently there is but slight wear. The loose pulley is made in one piece and has an oil reservoir cored out around the bearing. This reservoir is filled with cotton waste and oil, and a wick is laid in a groove cut in the bearing, the ends of the wick extending downward into the oil reservoir below.

Table and Table Feed Motions

The platen or table of the machine is made especially heavy in order to avoid springing when clamping the work upon it. It is provided with power feed in either direction, and with automatic stops. The screw which imparts motion to the platen, carries a dial graduated to thousandths of an inch. The gears which drive the feed-screw are encased and run in oil. The top of the table is provided with four milled T-slots running the entire length.

The feed motion of the machine is taken from the driving shaft which runs at a higher speed than the main spindle. This arrangement, shown in Fig. 4, makes it possible to obtain nine feeds without increasing the ratio of the gearing, thus avoiding excessive stresses on the feed gears and bearings. The fine feeds are obtained by reduction gearing. Besides the table shown in place in Fig. 1, the machine is provided with a rotary table, shown in Fig. 2. This table is 24 inches in diameter and is graduated on the outside periphery to one-half degrees. The feed in both directions to the table, together with the rotary table arrangement, permit of finishing at one setting many classes of work, which would otherwise require re-setting and finishing in other machines. Holes, for instance, may be bored and drilled and surfaces milled at various angles without re-setting, thereby saving considerable time and expense in handling. In Fig. 3 is shown an auxiliary table which is used for work which would overhang the regular table. This auxiliary table has a T-slot milled its entire length as shown, and is a very essential feature in the rapid and accurate machining of large castings.

Miscellaneous Features

The outer support bearing for the boring-bars, shown in position on the bed in Fig. 1, is gibbed to the internal guiding surfaces of the support. The raising and lowering of the bearing in the support is accomplished by means of a screw connected by spiral gearing and splined shafts to the elevating screw of the spindle head, so that the two bearings for the bar move simultaneously. Provision has also been made for re-aligning the bearings in case of wear. The outer support bearing is moved longitudinally on the bed of the machine by a hand-crank. It can easily be removed from the machine, if required, by removing the bracket at the end of the bed and pulling off the supporting post, and it can be replaced in exact alignment without difficulty.

The machine is provided with extension boring-bars, and bushings to fit in the outer support bearing, and with one roughing and finishing cutter for each boring-bar. The extension boring-bars are provided with No. 4 Morse taper shanks, fitting the socket in the spindle. The spindle is provided with a slot for driving the extension boring-bars by means of two keys in addition to the usual driving tang. Two face milling cutters are also furnished with the machine, if required, one being 2 inches and the other 10 inches in diameter. The hub of the driving gear forms a face-plate to which the 10-inch face milling cutter, provided with holes for clamping screws, may be fastened. This arrangement makes the most rigid connection possible between the drive and the cutter. The smaller face milling cutter is attached to an arbor fitting the taper hole in the end of the spindle. The 10-inch cutter is provided with a center hole large enough to permit a spindle, when carrying the 2-inch cutter, to pass through it, so that either of these two cutters may be used without the necessity of removing the other.

The machine will take pieces 94 inches long between the face-plate and the outer support of the boring-bars. The greatest distance from the top of the platen to the center of the spindle is $22\frac{3}{4}$ inches. The table or platen is 20 inches wide by 42 inches long and has a cross-feed of 34 inches.

Messrs. Hill, Clarke & Co., Inc., 14 So. Canal St., Chicago, Ill., are the selling agents for this machine, and it may be seen in operation in their demonstration shops.

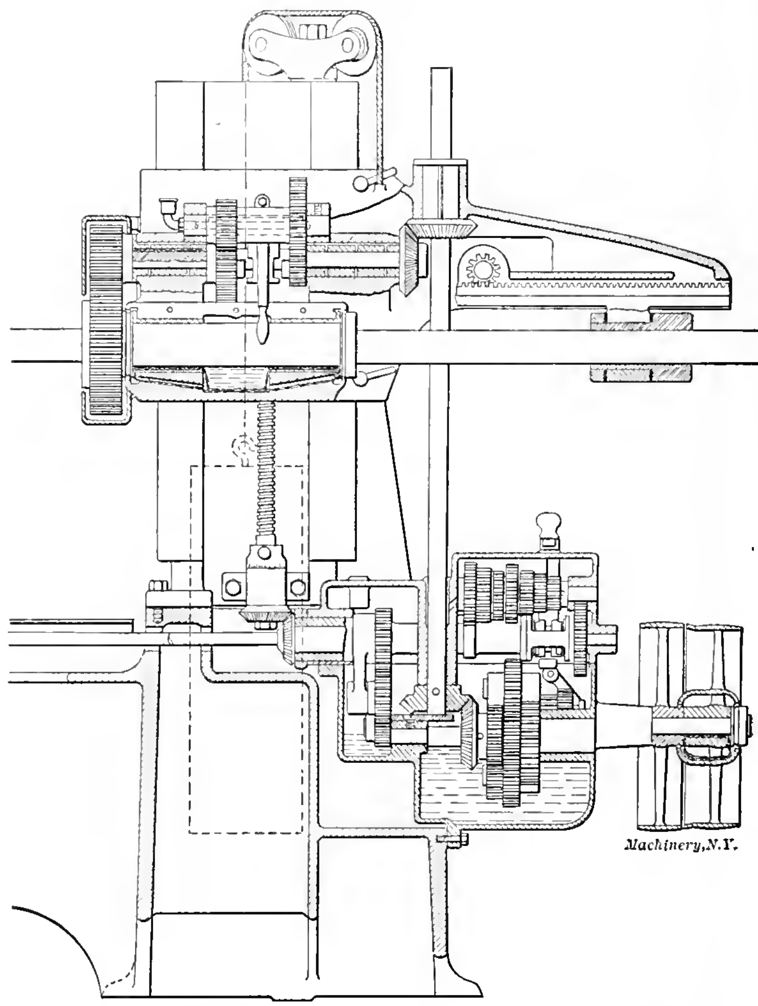

Fig. 4. Section through Head and Gear Box of Universal Boring Machine

---

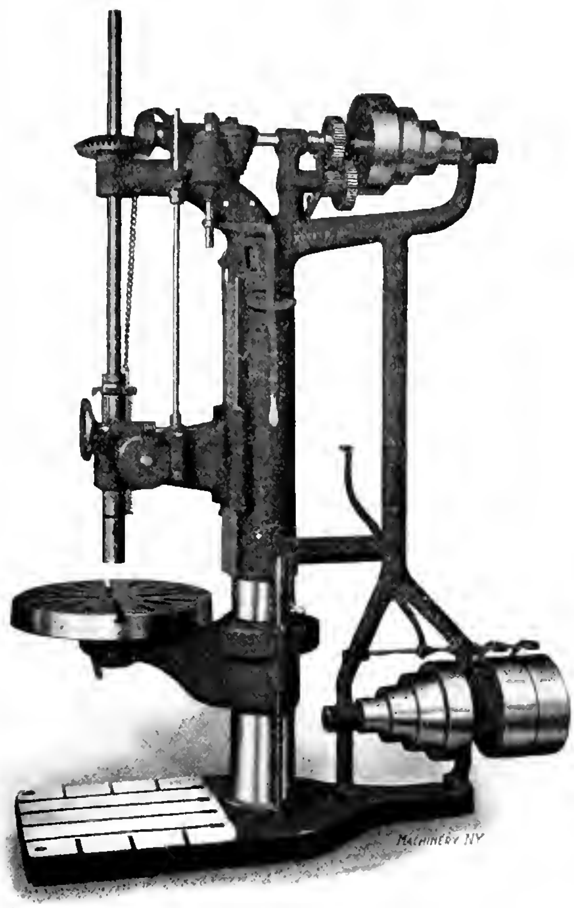
HOEFER DRILL PRESS WITH POSITIVE GEARED FEED

The accompanying illustration shows an improved drill press recently brought out by the Hoefer Mfg. Co., 120 Jackson St., Freeport, Ill. The most important feature in this new machine is the positive power feed and the method of changing the feed. An improvement has also been introduced in the mechanism used for raising and lowering the table arm.

As will be seen from the illustration, the drill spindle is fed downward by means of a series of gears enclosed inside of a gear box at the top of the machine, which transmit motion from the main driving shaft through a worm and worm-gear to a pinion engaging a rack on the drill press spindle sleeve. Described in detail, the motion is transmitted as follows: The horizontal driving shaft at the top of the machine carries a worm which engages with a worm-wheel keyed to a short vertical shaft. To this shaft are also keyed five gears of different sizes each engaging with a corresponding gear on a second vertical shaft. The gears in the second set run loosely on the shaft on which they are mounted, except that any one can be engaged with the shaft by means of a key sliding in a spline in the shaft and the gears. By shifting this sliding key up and down, any one of the gears in the second set can be engaged to transmit motion from the first vertical shaft to the vertical feed spindle. The motion between the second vertical shaft and the feed spindle is transmitted by means of a gear keyed permanently to the lower part of the second vertical shaft, driving a gear on the feed spindle, the latter, of course, being splined so that, while its driving gear is keyed to it, it can yet slide freely. The feed spindle carries at its lower end a worm engaging with a worm-gear keyed permanently to the short horizontal shaft

which carries the pinion engaging with the rack on the spindle sleeve.

By shifting the sliding key up or down to engage with the different gears in the gear box, as already mentioned, the amount of feed per revolution of the main spindle can be adjusted as desired, five feeds of 0.006, 0.015, 0.023, 0.032 and 0.041 inch per revolution, respectively, being obtainable. The feed can be changed while drilling, by merely moving the lever operating the sliding key. The lower end of the key is attached to a collar on the second vertical shaft, previously mentioned, and the horizontal arms of the bell crank lever engages with this collar. The handle of the vertical arm of the lever is within easy reach of the operator, as shown in the



Hoefer Improved Drill Press with Positive Geared Feed

engraving, and by shifting it to various notches on the projecting boss on the side of the column of the machine, the feed is easily adjusted to any predetermined amount. The design prevents the key from engaging with two gears at once, as this would obviously cause damage to the mechanism. For this reason, a hardened tool steel ring is placed in a recess on one side of each gear, and as the key slides past this ring, it is forced back into the keyway in the shaft and out of engagement with both the gear that is being disengaged and the gear that is to be engaged. Continued movement of the sliding key will bring it into engagement with the next gear. In order to obviate any unnecessary loss of time, three keyways are provided in each gear so that the engagement is practically instantaneous.

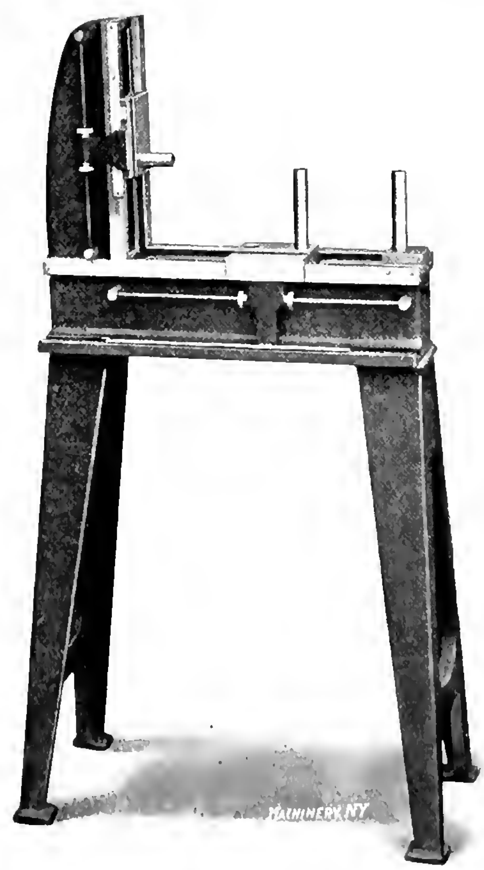
Returning to the feed mechanism on the sliding head of the machine, it should be noted that the drill or tool used can be fed by three methods, viz.: by a hand lever, by the hand worm feed, or by the power feed just described. The hand worm feed is thrown into engagement with the worm-wheel by an eccentric, while the power feed is thrown into engagement by a cam, the cam lever and eccentric being so interlocked that the engagement of both worms with the worm-wheel at one time is impossible. When passing into or out of engagement, the vertical power feed spindle swings through a small arc, but is in true alignment when in the driving position so that there is perfect mesh between the small gear by which it is driven and the driving gear on the second change gear shaft. A stop is provided by means of which the feed can be thrown out of mesh automatically at any desired point.

The improved feature for raising or lowering the table arm consists of a screw passing through a nut so arranged that it bears equally against both sides of a circular slot in the table bracket. When manufactured each machine bores the hole in its own table arm and the circular table is turned to fit the socket in the arm exactly, so that an accurate and rigid bearing is provided and, at the same time, perfect alignment of the spindle and table is assured.

The horizontal driving shaft at the top is fitted with back gears having a ratio of 4 to 1, the back gears being thrown into and out of engagement by an eccentric, as usual. The machine can be either belt or motor driven, but in either case, the driving speed can be changed, in addition to the speed change by the back gears, by means of a pair of four-step cone pulleys. The brace support at the outer end of the pulley shaft gives additional rigidity to the machine. The greatest distance from the spindle head to the base is 56 inches, and the greatest distance from the top of the table to the spindle head, 45 inches. The distance between the column and the center of the spindle is 16¼ inches. The vertical feed of the spindle is 16 inches, and the vertical motion of the spindle head 27 inches. The diameter of the spindle is 2 1/16 inches.

GEAR TESTING MACHINE

The accompanying illustration shows a gear testing machine built by the Cincinnati-Bickford Tool Co., Cincinnati, O. This machine was originally designed for the company's own use without any intention of placing it on the market; but as many of the company's customers intimated that such



Gear Testing Machine built by the Cincinnati-Bickford Tool Co

a machine would undoubtedly meet with favor if made on a commercial basis, it has finally been decided to manufacture it for the trade. The machine is intended for testing the running of both spur and bevel gears. The gears are mounted on the removable studs shown, which are held in adjustable slides, moving freely. Provision is made for clamping these slides at any point. Each slide is capable of a fine adjustment by means of a screw and knurled nuts, the screws being seen in the illustration, one running horizontally and one vertically on the side of the machine. A vernier scale is also provided, reading to thousandths of an inch, so that

the correct center distances between the gears when mounted on the studs can be determined. The shortest distance from center to center of the two studs for testing spur gears is 2 inches and the greatest is 19½ inches. This permits of testing a pair of gears where the sum of the pitch diameters of the gears is 4 inches as a minimum and 39 inches as a maximum. The two studs for bevel gears permit of testing miter gears from the smallest made up to 18 inches in diameter, and of a combination of bevel gears where one is 4 inches and one 32 inches in pitch diameter. Each machine is furnished with two studs one inch in diameter, and 4 inches long above the slide. Extra studs can be furnished if required.

The slightest imperfections in the gear teeth are readily detected by this testing device and the cause can be analyzed with comparative ease. By remedying the defects, it is possible to produce gears that have a perfect bearing on the surfaces in contact, and that will run smoothly and noiselessly when in service. The net weight of the machine is 325 pounds and the floor space required, 16 by 34 inches.

QUEEN CITY DOUBLE-ACTING PRESS

A new double-acting press has recently been placed on the market by the Queen City Punch & Shear Co., 208 Lawrence St., Cincinnati, O. The machine has been designed for forming and pressing operations of various kinds in sheet metal, and is of especial value where a large quantity of duplicate work is to be done. The main feature of the machine is the oscillating table, presenting a feature whereby the operator is safeguarded from personal injury. Patents have been applied for, for such features as are new departures in this design. The general construction and operation of the machine will be more easily understood by referring to the accompanying two half-tone engravings, Figs. 1 and 2, one of which shows the front view and the other the rear view of the machine.

Two operators are required for the machine, to feed and remove the work, one standing in front of the machine and the other in the rear. In the illustration, Fig. 1, the plunger or ram is shown down and the front die projects out in the front of the machine. This is the proper position of the die when the work is removed, and the die remains in this position sufficiently long without motion so that the operator in the front can remove the finished work and replace it with a blank, meanwhile being entirely out of the range of the plunger and without any danger of injury. The plunger then raises up and the die moves in under the ram for pressing or forming the blank just inserted. While this is being done the rear die projects outward in front of the operator in the rear, see Fig. 2, who then removes the finished work from this die and replaces it with a blank. It is evident that there is no occasion for the operators to place their hands or fingers under the press plunger, and the danger thereby avoided is of equal importance to employe and employer, for while the former, of course, is the one who suffers most directly through the bodily injury in case of accident, it is also a very important feature to the manufacturer, who is continually liable for damages sustained to operators when working with machines where the operation presents a constant danger to the workman.

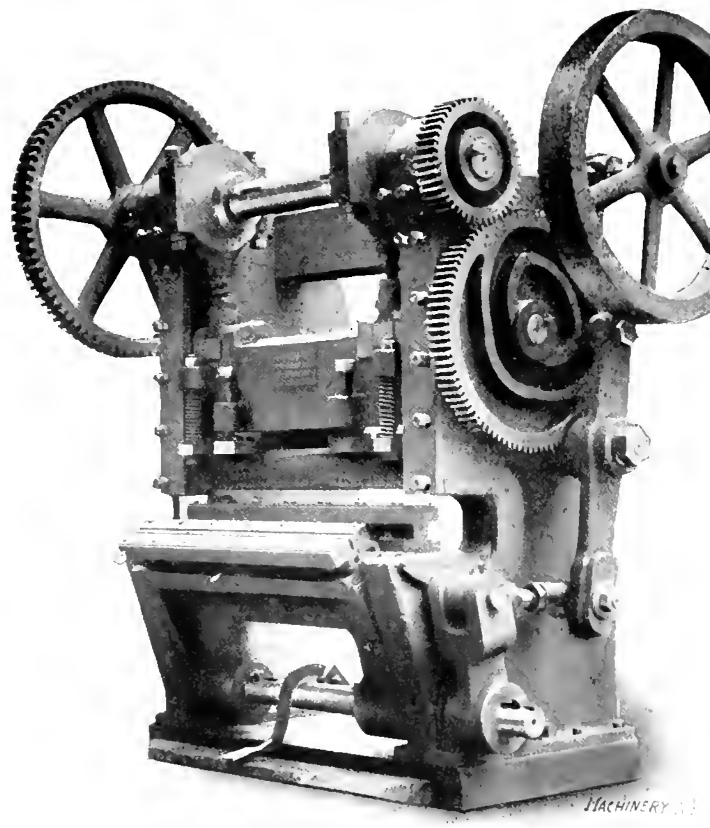


Fig. 1. Front View of the Queen City Double-acting Press

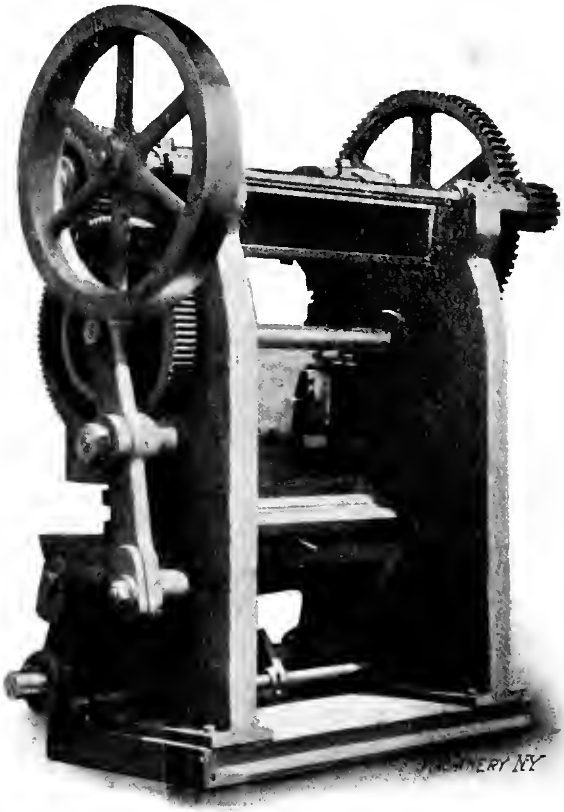

Fig. 2. Rear View of Double-acting Press

The machine runs continually, the movements being divided in two equal periods of time, as follows: One-half of the revolution of the cam-shaft is devoted to pressing the work in the die, removing it when finished and replacing it with a new blank; the other half of the stroke allows the filled die to enter the pressing ram; this is repeated for each of the two tables or dies, thereby making it possible to press a piece of work for every revolution of the cam shaft. There is no necessity of stopping the machine except in a case of emergency, but the machine is provided with an automatic safety clutch by which either of the operators can stop the machine at will. The speed of the machine can be regulated and is governed by the character of the work to be done and by the rapidity with which the operators can handle the finished work and the blanks.

The machines of this type are equipped with machine-cut gears and can be either belt or motor driven, as required. The machine illustrated in Figs. 1 and 2 is 36 inches between the housings and weighs 7,300 pounds. It can be built in any size required and adapted to any class of forming or pressing. The novel features introduced in the design of this machine should make it a valuable tool in the sheet metal trades, both on account of its productive capacity and the safety of operation.

COLBURN 30-INCH VERTICAL BORING MILL

A new 30-inch vertical boring mill embodying a number of interesting improvements has recently been brought out by the Colburn Machine Tool Co. of Franklin, Pa. The most prominent feature of the new design is embodied in the main

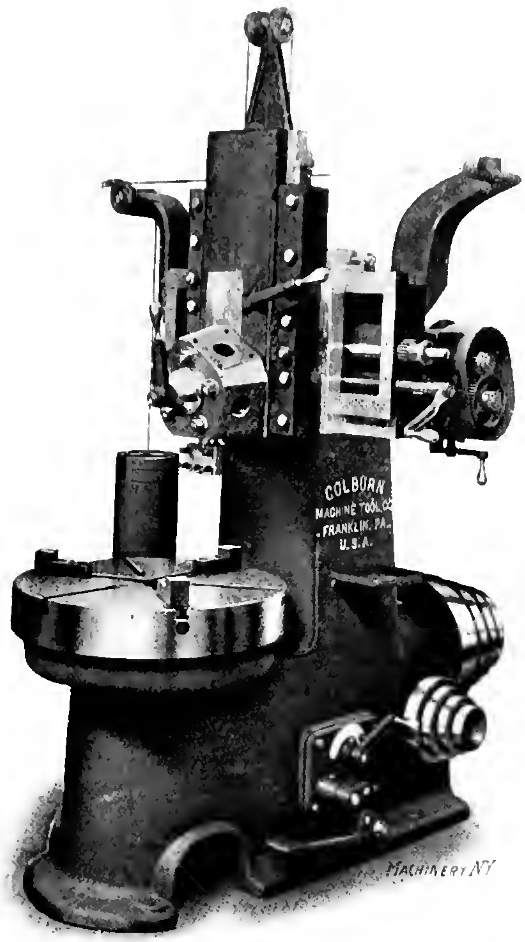

Fig. 1. Thirty-inch Vertical Boring Mill, built by the Colburn Machine Tool Co.

drive or head-stock, which is enclosed in a separate box or frame, and which can be quickly detached from the main frame of the machine and removed if required. This construction makes the assembling of the machine very convenient, and enables the proper fitting of the various parts to be done with greater accuracy. This feature is also of advantage in case of repairs, as all the parts are easily accessible and can be handled without difficulty. Another feature of special interest in the machine is the addition of a foot brake for quickly stopping the machine with the table in any desired position; this feature is not generally found on small boring mills. A general view of the machine is shown in Fig. 1, and in Fig. 2 is shown a view of the head-stock detached from the machine. In Figs. 3 and 4 are shown sectional views which give a clear idea of the construction of the machine.

As will be seen from Fig. 1, the turret is five-sided. It is set on an angle of 8 degrees with a vertical line which gives sufficient clearance for large tools when swung over the slide. The turret slide can be swiveled to any angle up to 30 degrees to either side of the vertical center line. A graduated scale with a pointer is provided which makes it convenient to measure the depth of the cut taken. The boring mill is

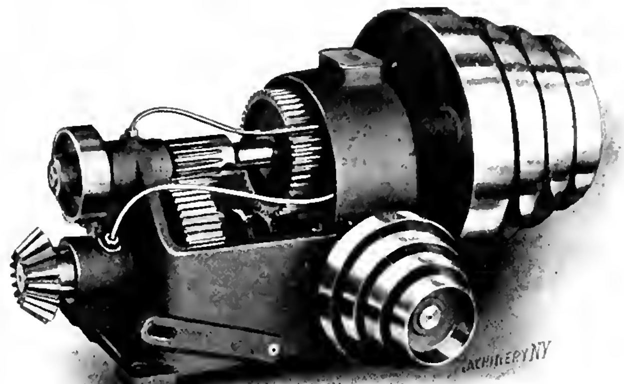

Fig. 2. Driving Head of Colburn Boring Mill

provided with a plain table having three or four chuck jaws, as required. The main spindle has sixteen speed changes, and provision is made for eight feeds vertically, and the same number horizontally. The machine is furnished with a two-speed counter-shaft.

Construction of Driving Mechanism

In Fig. 3 is shown a cross-section of the head of the machine, the table, the lower part of the frame and the driving mechanism. The motion from the cone pulley *E* to the table is transmitted through shaft *F* to which are keyed a gear *G* and a pinion *H*, which in turn drive the gears *K* and *L*. These latter two gears revolve loosely on the shaft *M*. A clutch operated by the handle on the outside of the frame directly above the foot treadle, as shown in Fig. 1, is provided with teeth on the face on both ends, and can engage with the clutch teeth on the sides of either gear *K* or *L*. By this arrangement two speeds are provided for, and by means of the four-step cone pulley eight speeds are obtained. The two-speed counter-shaft increases this to sixteen speeds.

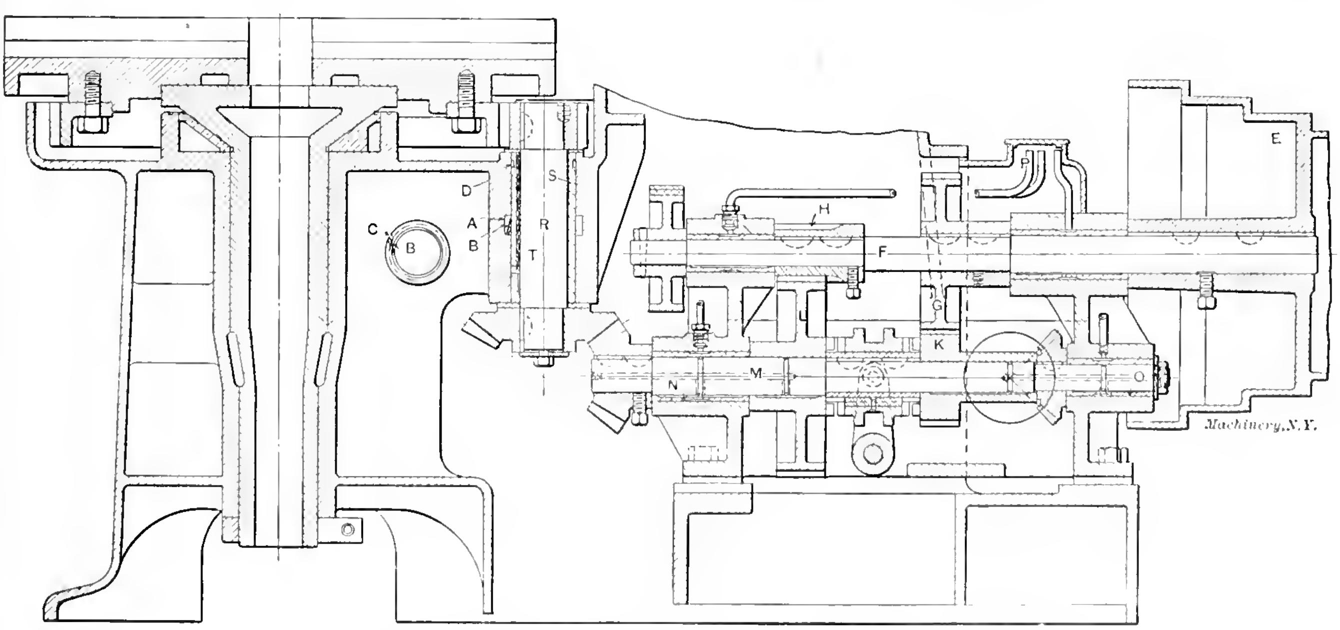

Fig. 3. Section through Driving Mechanism of Colburn Vertical Boring Mill

From shaft M the motion is transmitted in the usual manner by bevel and spur gearing to the table.

Method of Lubrication

Special attention should be called to the manner in which all running bearings are lubricated. The two gears K and L

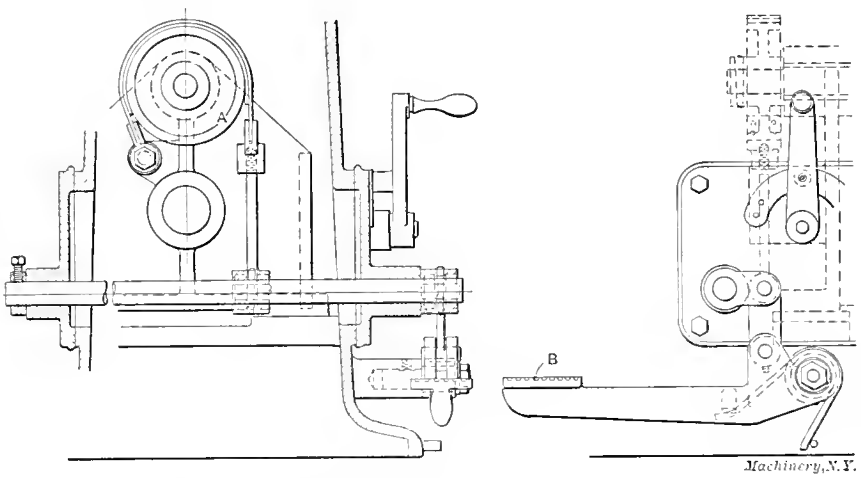

Fig. 4. Foot Brake Mechanism for Stopping the Table at any Point

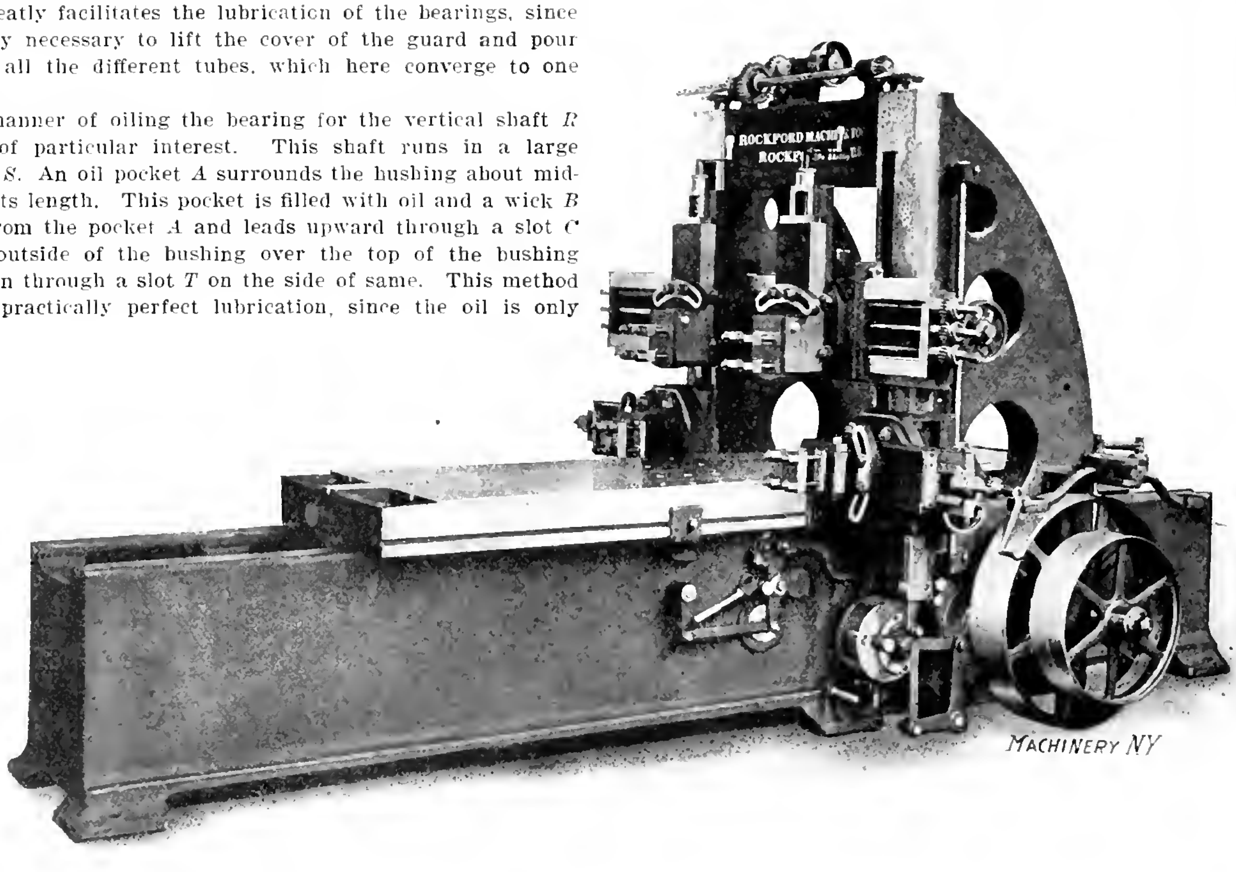
which run freely on shaft M are oiled through holes drilled through the center of the shaft M, as shown, the oil being carried to the gears from the bearings N and O. Brass tubes which all end at the common location P, under a cover provided at the top of the gear guard enclosing the head-stock gears, lead to every bearing in the head-stock. These tubes are indicated in Fig. 3 and some of them are visible in the half-tone illustration of the head-stock Fig. 2. This arrangement greatly facilitates the lubrication of the bearings, since it is only necessary to lift the cover of the guard and pour oil into all the different tubes, which here converge to one point.

The manner of oiling the bearing for the vertical shaft R is also of particular interest. This shaft runs in a large bushing S. An oil pocket A surrounds the bushing about midway of its length. This pocket is filled with oil and a wick B starts from the pocket A and leads upward through a slot C on the outside of the bushing over the top of the bushing and down through a slot T on the side of same. This method insures practically perfect lubrication, since the oil is only



Rockford 32-inch x 32-inch x 8-foot Heavy Duty Planer

fed through the wick in the required quantities and in an amount determined by the amount used, on the same principle as that of an oil lamp. As long as there is any oil left in the reservoir, the wick will feed it to the bearing. Should the supply in the reservoir run out, there will always be a sufficient amount in the wick to insure the bearing running reasonably well lubricated for a long time without causing any difficulties. Oil is supplied to the reservoir A from the outside by means of the pipe shown directly in front of the tool-pan in Fig. 1. This pipe leads to annular groove D cut in the bushing S, whence it flows downward to the reservoir A. Thus, in fact, two supplies of oil are maintained, one at D and one at A, making it practically impossible for the bearing to ever become dry.

Brake Mechanism

The line engraving Fig. 4 shows the brake mechanism. The band-wheel A, which is also shown in Fig. 2 directly above the bevel gear at the left-hand end of the head-stock, is used in connection with the foot brake B for stopping the machine at any desired point. The details of the mechanism are simple in their construction, and the working of the brake can be studied without difficulty from the illustration. The leverages of the foot treadle arm are of such a ratio that considerable power is exerted at the hand-wheel by even a comparatively light pressure on the treadle at B.

The new features embodied in this boring mill make it a very convenient tool, and its distinctive points will undoubtedly be appreciated by mechanics.

ROCKFORD HEAVY DUTY PLANER

The accompanying illustration shows a planer manufactured by the Rockford Machine Tool Co., of Rockford, Ill., and is known as the 32-inch by 32-inch by 8-foot heavy duty planer. This company has been for some time manufacturing planers in smaller sizes, in addition to its line of shapers, and have recently developed a full line of planers, the feature of the design of which is, in the first place, rigidity and power, while at the same time efforts have been made to maintain the smooth running qualities and the ease of operation required of modern machine tools.

As seen in the illustration, the planer is equipped with four heads of which two are placed on the cross-rail and one on each side of the machine on the housing. All the heads are provided with horizontal, vertical and angular feeds. The down feed for the heads on the cross-rail is 12 inches.

The gearing of the main drive is located inside of the planer bed between the bearings. These latter are provided with long straight bushings fitted into holes bored directly into the bed casting. The belt shifting device is of a very simple construction and reverses the table smoothly. Ample means are provided for lubrication.

The feed friction is of the combination releasing type and will carry the heaviest feeds without slipping or running warm. The feeds are changed by moving the knob shown in the illustration on the front of the friction device, a pointer indicating the feed obtained at different settings of the lever.

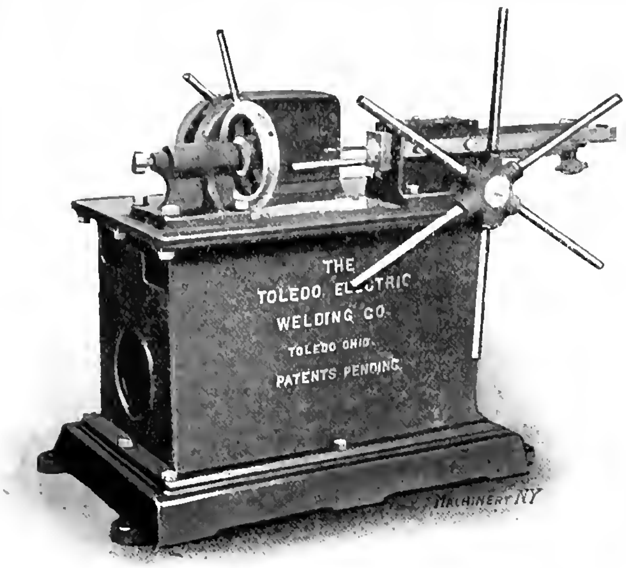


Fig. 1. Machine for Electrically Welding Small Drills to their Shanks

By means of this device the feed can be changed for the finishing cut after having rough planed a piece of work, and the lever can be instantly returned to the position for the roughing feed for the next casting. Besides the time thus gained, an additional advantage is obtained in that the operator knows exactly what feed he is using, and can get the feed he wants without making several adjustments.

All running bearings are provided with means for adjustment for wear and taper gibs are used in the slides throughout the machine so that any wear may easily be taken up in these parts. Bevel gears, pinions and feed racks are made from open-hearth bar steel. The machines are built on the interchangeable plan, and side heads can be furnished at any time to fit the machines, if not originally so equipped.

TOLEDO ELECTRIC WELDING MACHINES

The Toledo Electric Welding Co., Toledo, O., has brought out a line of electric welding machines for various purposes, three of which are shown in the accompanying illustrations. The machine shown in Fig. 1 is intended for welding small drills to their shanks, one of the drills being shown in place in the machine. The head on the left-hand end is provided with a chuck for holding the drill. Sockets are provided for different sizes of drills, and the varying lengths are taken care of by means of the adjusting bolt with a knurled head, shown at the left-hand end of the head. By this arrangement every drill projects the same distance from the clamping jaws. The shanks of the drills are held in the chuck shown at the right-hand end of the machine. The two heads are brought together by turning the spider on the right-hand head; the pieces, when brought together, are in practically perfect alignment.

The automatic switch shown at the back of the machine is adjustable and can be set to open the circuit at any predetermined point. This enables the operator to set the machine so as to make the welds with a great degree of accuracy. After the weld is made, the drill is automatically thrown out, and the chucking jaws are in a position ready to receive another drill. The operation of this machine is simple and no expert operator is required.

Fig. 2 shows a larger machine designed for welding tubing, such as automobile steering rods, etc., or solid bars up to and including $1\frac{1}{8}$-inch round iron or steel. The stock is clamped between the copper jaws by means of the hand wheels shown at the top of the machine. The right-hand head slides back and forth in ways on top of the machine bed, and is actuated by the spider shown at the right-hand end of the machine. The current is turned off and on by means of a foot switch shown on the floor at the side of the machine.

The clamping dies project far enough above the top of the table to permit bars or tubes of any length to be conveniently handled and welded without in any way interfering with

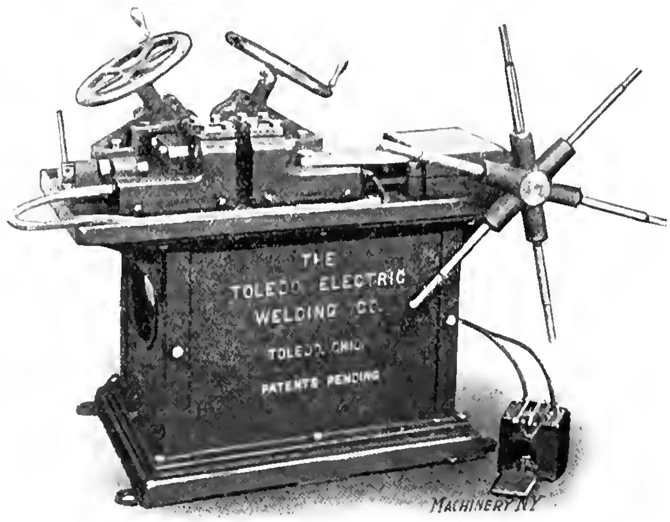

Fig. 2. Machine for Welding Tubing and Solid Stock of Large Sizes

the working mechanism. The line of thrust is in the center of the work-holding jaws, thus insuring alignment of the parts when welded. The copper jaws are water cooled in all of these machines.

Fig. 3 shows a universal welding machine which welds solid iron or steel up to and including $\frac{3}{4}$-inch diameter. The

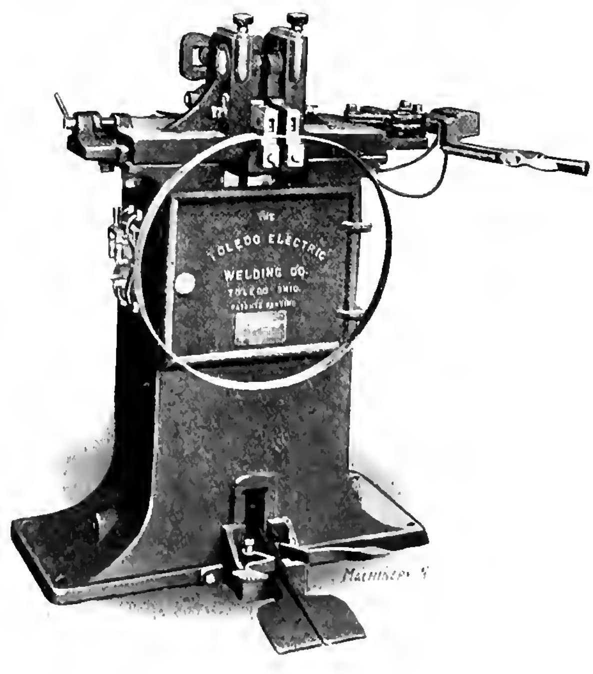

Fig. 3. Universal Welding Machine for Steel up to $\frac{3}{4}$-inch Diameter

clamping jaws are here actuated by foot treadles, and the current is turned on or off by means of a switch mounted on the lever handle shown at the right-hand end of the machine.

These welding machines are, of course, adapted to work done in quantities and are not intended for the average repair man, who has only a few pieces to weld per day. When work is done in quantities, however, the cost per weld is very small. The accompanying table gives a general idea of the time required for making a weld and the cost per

1,000 welds if the current cost is, say, 4 cents per kilo-watt hour. If the cost of current is more or less than this, the total cost will, of course, be accordingly greater or less. Figs. 4 and 5 show some examples of work which has been electrically welded on the machines shown. These illustrations also give an idea of the variety of work that can be done on these machines. On some pieces part of the metal at the weld has been cut away to the center in order to show the internal structure of the metal at the place where the weld is made.

The underlying principle of the electric welding machine is simple and is based on the fact that a poor conductor of electricity offers so much resistance to the flow of the current that heat is produced, the degree of heat depending on the amount of current and the resistance of the conductor. The process of electric welding is especially applicable to butt welding of metals having practically the same cross-section at the weld. The temperature produced by the current can be maintained at any point desired for any length of time, and any degree of heat may be obtained up to the melting point of the metal. The heat can be increased and decreased at the will of the operator by means of turning on or cutting off the current by the switch on the machine.

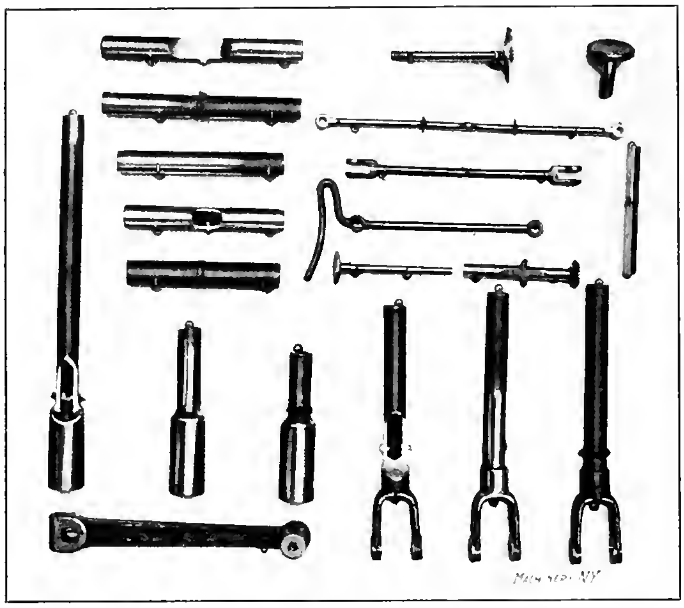

Fig. 4. Examples of Work Welded Electrically

An advantage of the electric welding process is that there is none of the disagreeable glare or blinding effect which takes place either in the arc welding process or the oxy-acetylene process of welding. No goggles or smoked glasses are, therefore, needed. No flux is required in making an ordinary weld.

For electric welding an alternating current is necessary. The current as supplied from a dynamo in the plant or from a central power station is transformed so that it has a pressure of from 4 to 5 volts, there being then absolutely no danger for the operator. The copper clamping jaws of the electric welding machine are similar to a pair of movable vise jaws, and form the terminals of the secondary current of a special transformer located in the welding machine.

TIME REQUIRED FOR MAKING WELD, AND COST OF 1000 WELDS

Diam. Round Iron or Steel, Inches	Seconds required to Make a Weld	Cost of 1000 Welds at 4 cents per Kw.-hour	Diam. Round Iron or Steel, Inches	Seconds required to Make a Weld	Cost of 1000 Welds at 4 cents per Kw.-hour
$\frac{1}{4}$	3	$0.28	$\frac{5}{8}$	10	$1.32
$\frac{3}{8}$	5	0.52	$\frac{3}{4}$	12	2.00
$\frac{1}{2}$	7	0.88	1	20	6.00

When two pieces of iron are to be welded they are clamped between the vise jaws, the ends of the metal to be worked touching each other. The current is then turned on and when the metal reaches a white heat and is in a partially molten state, the ends of the metal are forced together by means of a lever, thus producing a perfect weld. A projection or fin is raised where the ends come together, but this may be ground off or removed by any other suitable means. A weld properly made in this manner is practically as strong at the welded point as at any other place.

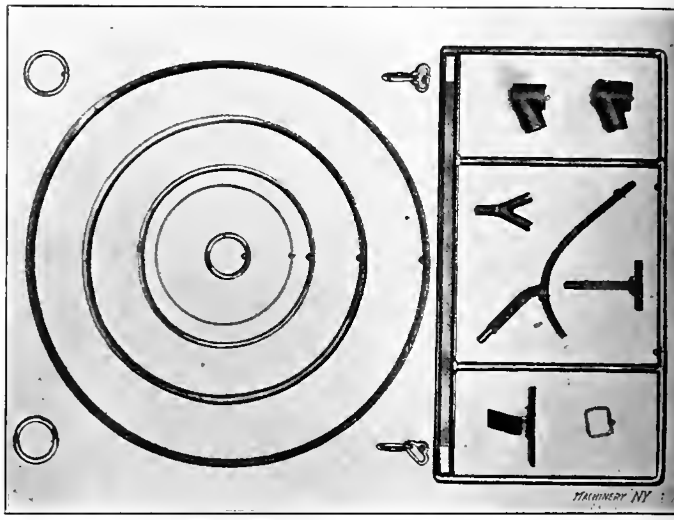

Fig. 5. Other Examples of Electric Welding

NEW MODEL "STAR" LATHE

The Seneca Falls Mfg. Co., 330 Water St., Seneca Falls, N. Y., has re-designed its line of 9- and 11-inch "Star" lathes. The accompanying illustration, Fig. 2, shows the lathe having 11-inch swing with a 5-foot bed, known as the No. 30H Star lathe. The following description of the improvements in this lathe also applies to the 9-inch size.

The bed of the machine is mounted on an oil pan as shown. In the head, guards have been provided for the back-gears, and the main spindle, which is made of 60 to 65 point carbon steel, revolves in large ring oiling bearings. The spindle nose is threaded only part of the way, and the remainder is ground cylindrical so as to insure accurate fit for chucks and face-plates. The tail-stock has been made heavier to insure greater strength, and has a longer bearing on the bed; it is provided with side adjustment and an oil-well. The carriage has been made stronger and is provided with T-slots for fastening the tool-posts. The cross-feed screw and the ways have been carefully protected from chips and dirt by a guard reaching the full length of the slide. The cross-feed screw is provided with a micrometer collar graduated to read in thousandths of an inch, and secured by a friction spring. Even when the machine is not originally provided with a taper attachment, the carriage is so designed that a taper attachment can be applied to the lathe at any time. The plain and compound rest easily interchange, and a binding device has been introduced which facilitates quick changes and rigidly binds the rest to the cross-slide. Graduations up to 180 degrees are provided for setting the compound rest.

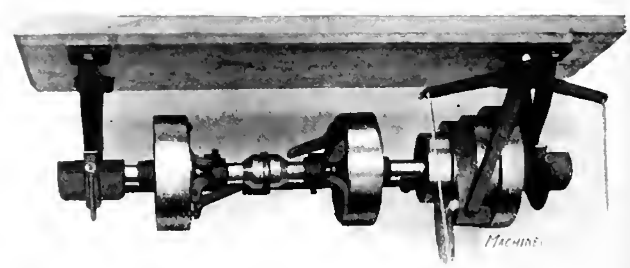

Fig. 1. Counter-shaft for the "Star" Lathe

The automatic cross and longitudinal feeds are actuated by a friction clutch and driven from the head spindle through gearing and the splined lead-screw, as usual. The range for thread cutting is very wide, it being possible to cut all standard threads from 3 to 72 per inch, including 11½ and 27. The lathe is also furnished for cutting metric threads, either by using proper translating gears with the regular lead-

screw or by using a lead-screw having threads cut with metric pitch.

The change gears have rounded edges so as to avoid injuring the hands when handled. The change gear yoke has an improved intermediate stud which is adjustable from the outer end. All the adjusting screws are provided with uniform size heads, fitting the same wrench as is used for the tool-post screw. Patented split spring washers hold the change gears in place, making convenient and rapid changing of the gears possible.

A full line of regular attachments may be used with this machine including taper attachment, draw-in chucks and collets, automatic draw-in chuck and rod feed, milling and gear cutting attachments, automatic turret on the bed, carriage turret, double tool block, and stop for the carriage. These attachments can be furnished and applied to the machine at any time without special fitting.

Fig. 1 illustrates a new counter-shaft furnished with the machine which is provided with improved friction clutch pulleys with large friction surfaces. In this counter-shaft the wear on the friction parts when the pulley is running idle, has been eliminated, and the usual counter-shaft troubles are, therefore, renduced to a minimum. The belt-shifter for the cone pulley shown in place on the counter-shaft operates quickly and will be found very convenient especially with high ceilings. The hangers are provided with large ring-oiling shaft bearings and are adjustable for alignment. The advantages of these features will undoubtedly be appreciated by the lathe operator.

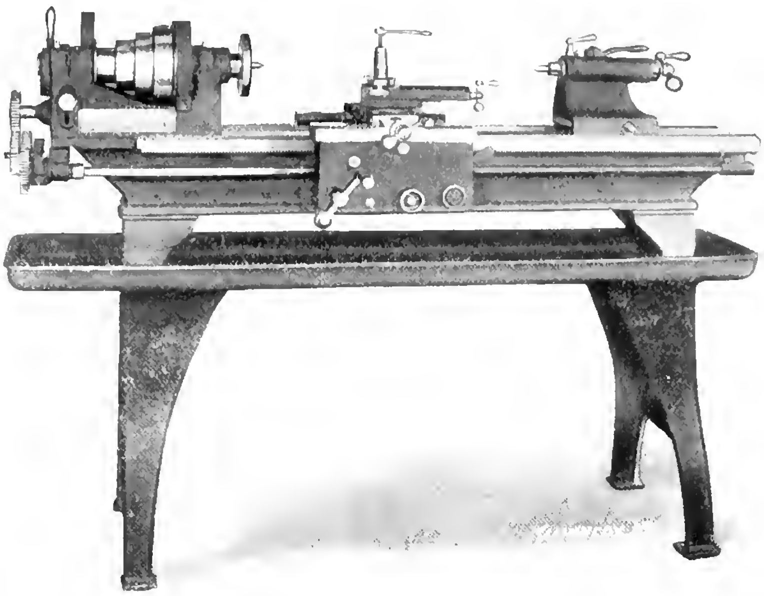

Fig. 2. New Model 11-inch "Star" Lathe, built by the Seneca Falls Mfg. Co., Seneca Falls, N. Y.

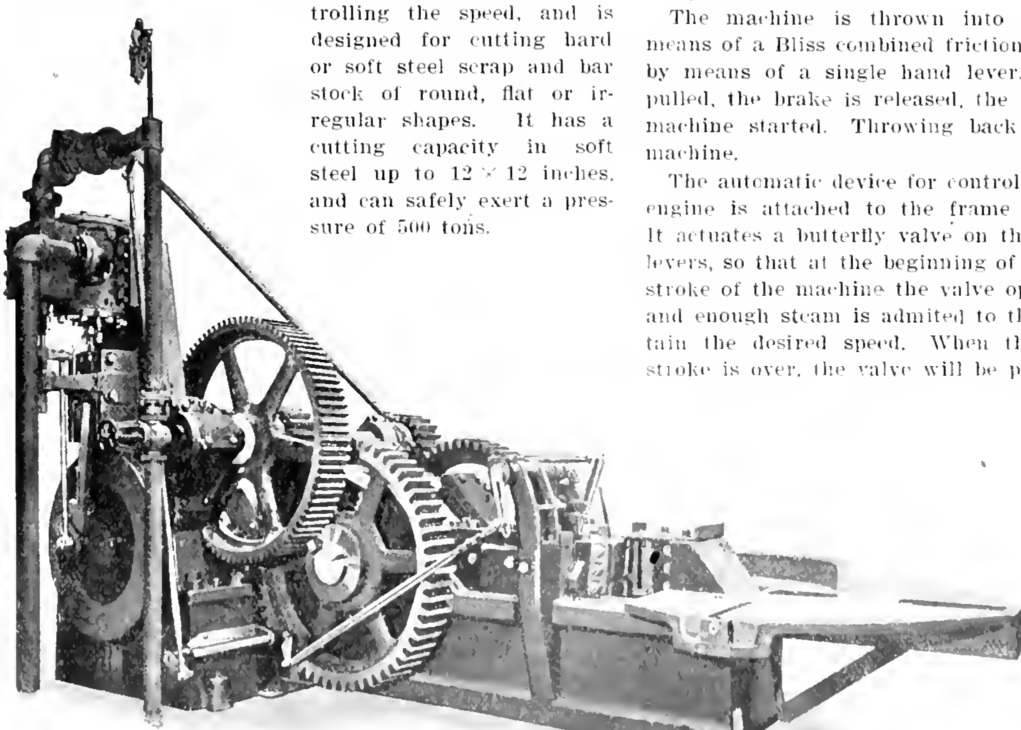
BLISS HORIZONTAL SHEARING MACHINE

The accompanying illustration shows a special horizontal shearing machine built by the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. The machine is driven by an independent steam engine, provided with an automatic device for controlling the speed, and is designed for cutting hard or soft steel scrap and bar stock of round, flat or irregular shapes. It has a cutting capacity in soft steel up to 12 × 12 inches, and can safely exert a pressure of 500 tons.



Bliss Heavy Horizontal Shearing Machine

The slide carrying the cutting knife is designed rather long for the purpose of providing proper guidance. The socket and pin for the pitman end are near the middle of the slide; in this way the downward pressure of the pitman is utilized for minimizing any lifting tendency due to the shear of the knives. The slide is held in position and guided by beveled gibs, firmly bolted both horizontally and vertically. These gibs are designed with a view of making provision for taking up the wear. The stroke of the slide is 4½ inches, which allows the moving knife to safely clear the bar or piece when it is fed in to be cut. The pitman is of cast iron, and the frame, slide and gearing are steel castings. The crank-shaft is made of 50-point carbon open-hearth steel and is 10 inches in diameter in the bearings; the eccentric portion, which serves as a crank, is 14½ inches in diameter. The shaft is driven from both ends, there being a main driving gear on each side of the press. This arrangement tends to reduce the stresses, and makes possible a more rigid and compact machine.

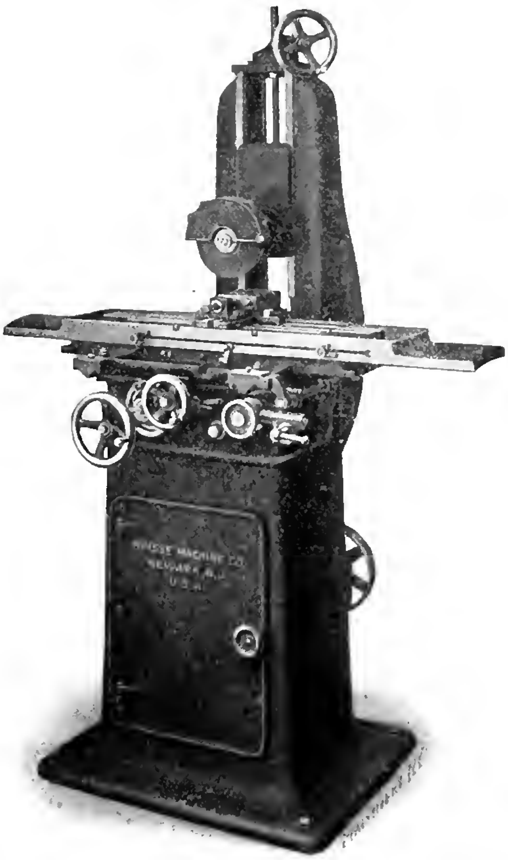
The machine is thrown into operation and stopped by means of a Bliss combined friction clutch and brake operated by means of a single hand lever. When the hand lever is pulled, the brake is released, the friction thrown in, and the machine started. Throwing back the hand lever stops the machine.

The automatic device for controlling the speed of the steam engine is attached to the frame and slide of the machine. It actuates a butterfly valve on the engine through rods and levers, so that at the beginning of the working portion of the stroke of the machine the valve opens wider than previously, and enough steam is admited to the engine cylinder to maintain the desired speed. When the working portion of the stroke is over, the valve will be partly closed, thereby reducing the amount of steam admitted to the engine, and thus preventing excessive speed. This device takes the place of the usual engine governor.

The cylinder of the steam engine is 12 inches in diameter and the stroke is 14 inches, the speed of the engine being from 200 to 250 revolutions per minute. All the gearing is machine cut, and it has a ratio of 17 to 1, which gives a speed of from 12 to 15 strokes per minute to the slide of the machine. With a steam pressure of 80 pounds, the engine will deliver from 70 to 90 H. P. at the speeds mentioned above. The total weight of the machine, including the engine, is approximately 65,000 pounds.

BINSSE SURFACE GRINDING MACHINE

An improved design of surface grinding machine, as shown in the accompanying illustration, has been brought out by the Binsse Machine Co., Newark, N. J. The most important improvements of the design are the added rigidity and the provisions for taking up wear and preserving the alignment—



Surface Grinding Machine built by the Binsse Machine Co., Newark, N. J.

the most important points in securing long life in grinding machinery. The working parts and the feed mechanism have also been efficiently protected from dirt and chips by ample covers and guards, and the arrangement of hand-wheels and levers has been taken care of in such a manner that the greatest possible ease in the manipulation of the machine is assured.

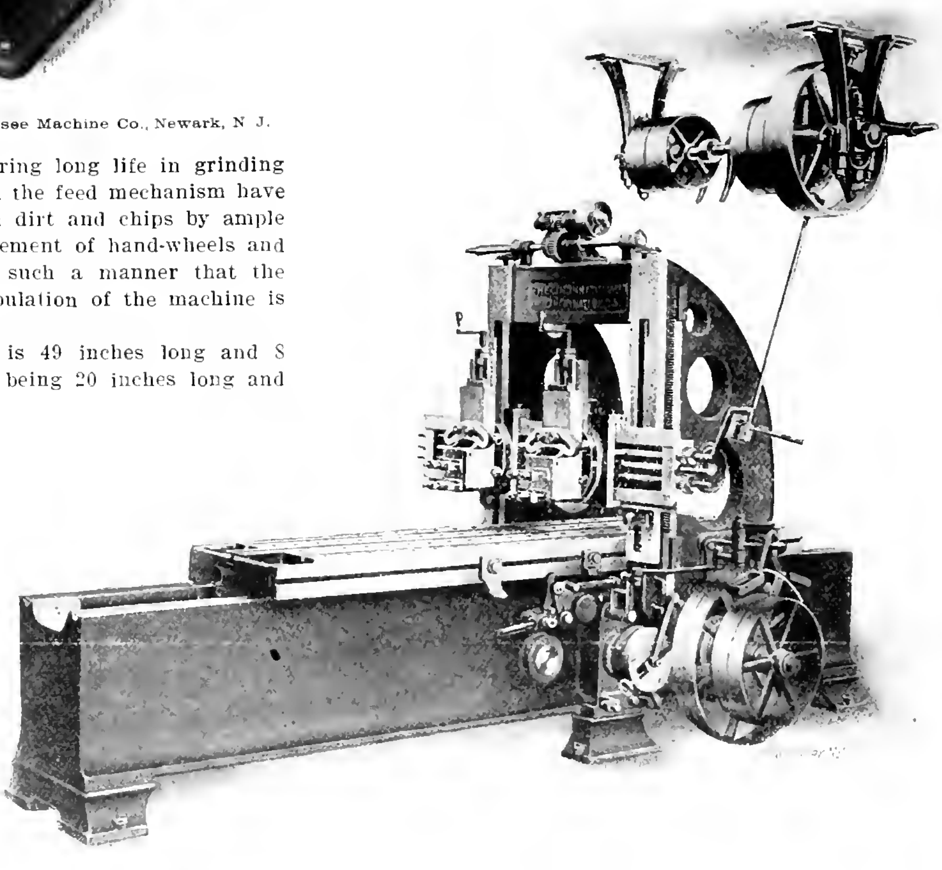
The work-table of the machine is 49 inches long and 8 inches wide, the working surfaces being 20 inches long and 6 inches wide with three slots ½ inch in width. The largest piece of work which can be ground on the machine, using a 7-inch diameter wheel, is 20 inches long, 6 inches wide and 10 inches high. The table is provided with automatic motion in the longitudinal direction, and an automatic cross feed. The length of the stroke is regulated by dogs in the usual manner. The reversing lever can be turned down so it will clear the dogs, thus enabling the table to run past the reversing position, if required, without changing the adjustment. A hand-operated movement for the table is also provided which enables the operator to move the table by hand without changing the automatic feed. The automatic cross-feed movement of the table may be worked in either direction, and it can be stopped automatically when the cut has passed over the work.

The spindle is made of tool steel and is hardened, ground and lapped, and runs in bronze boxes provided with adjustment for taking up all lost motion. The end of the spindle is tapered to receive the wheel flanges. The vertical movement of the spindle is controlled by a hand-wheel at the top of the machine, as shown, which is provided with a graduated dial reading to one-half thousandths of an inch. The shortest distance from the spindle center to the table is 3½ inches and the maximum distance 13½ inches. The maximum size wheel that can be used is 7-inch diameter by ½-inch face.

The machine is equipped with a 7-inch emery wheel, ½-inch face, 1¼-inch hole, with one pair of wheel flanges; a complete separate counter-shaft with tight and loose pulleys, 8 inches in diameter for a 3-inch belt; wrenches and spanners; and flanged vise with hardened jaws, 4⅛ inches long, 1 1/16 inch deep, opening to 2 inches. The counter-shaft should run at a speed of 360 revolutions per minute. The net weight of the machine is 1,500 pounds, and the floor space 6 feet by 3 feet.

CINCINNATI TWO-SPEED PLANER DRIVE

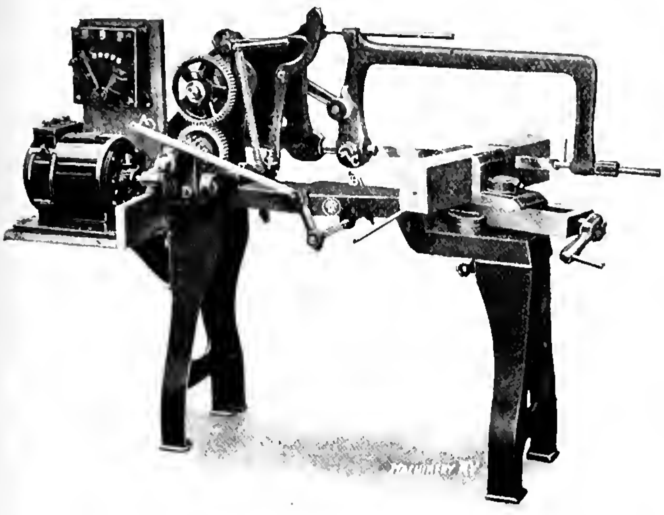
The accompanying illustration shows a planer provided with a two-speed drive brought out by the Cincinnati Planer Co., Cincinnati, O. By means of this drive two cutting speeds for the table are obtainable with a constant return speed. Either of the two cutting speeds can be obtained instantly, and change from the one speed to the other can be made while the machine is running. The speed change is accomplished by the arrangement of the pulleys in the counter-shaft, the drive consisting of two sets of pulleys, one pulley in each set being keyed to the shaft and the other pulley running loose. By operating the lever shown at the side of the housing, either speed required is obtained, the high speed by moving the belt to the right and the low speed by moving the belt to the left. The return belt remains in one position, giving a constant return speed to the table, as mentioned. The simplicity of construction and ease with which the device can be manipulated, makes it very useful for the planer drive; and it can be applied advantageously to all planers from 22 inches to 36 inches, inclusive.



Cincinnati Planer Co.'s Two-speed Planer Drive with Constant Return Speed

ROBERTSON MOTOR-DRIVEN HACK-SAW

The accompanying illustration shows a motor-driven hack-saw built by the Robertson Drill & Tool Co., Department 5, Buffalo, N. Y. The machine shown is known as the No. 3 saw, but all the sizes of the company's saws may be motor-driven by using the same attachment as applied to the present machine. The motor is mounted on a bracket secured to the rear leg of the frame of the machine and provision is made on the same bracket for mounting the rheostat or starting box. The machine is provided with an automatic stop arrangement working through the levers *A* and *B* and actuated by the pin *C*. Lever *A*, shown disconnected in the engraving, connects the switch handle with the cutting mechanism, and when the cut is completed, pin *C* will trip lever *B*, thereby throwing the switch and stopping the machine by cutting off the current.



Robertson Motor-driven Hack-saw

The machine is driven from the motor through a worm and worm-gear, the worm being placed on the motor shaft inside of the housing *D* and the worm-gear on a shaft on which a spur gear is also mounted from which in turn the power is delivered to the reciprocating saw mechanism. The worm and worm-wheel run in oil.

The machine can be conveniently mounted on a platform or truck and taken to any place inside or outside of the shops, where beams, bars or other steel parts have to be cut. It thus serves the purpose of a portable machine, and the only thing necessary is that electric power be available, so that the machine can be easily connected by wiring at any place where it is to be used.

STARRETT'S MACHINISTS' AND TOOL-MAKERS' TOOLS

A number of new machinists' and tool-makers' tools have been recently brought out by the L. S. Starrett Co., Athol, Mass. Fig. 1 shows a taper gage in which the thin leaves

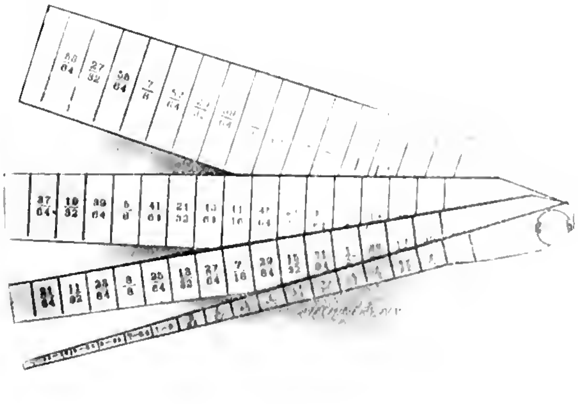


Fig. 1. Starrett Taper Gage

are tapering, the widths varying by 1/64 inch for every quarter inch of the length of the gages. The gages are graduated by lines ¼ inch apart, and on each gage is stamped the width at each division, the graduations reading by 64ths from 1/16 up to 1 1/16. The gage is designed for brass and steel tube manufacturers, for inside measurements, and is also convenient for tool-makers and machinists when measuring the width of slots and the size of holes, as well as for setting calipers to size within its capacity.

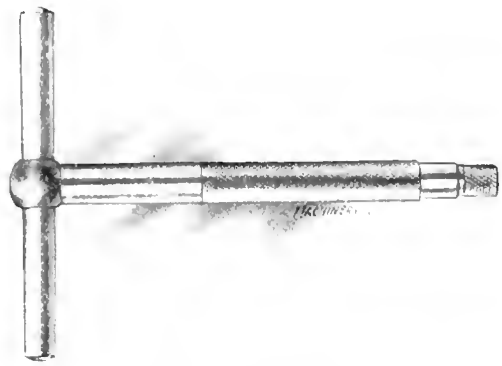

Fig. 2. Telescoping Gage used in conjunction with Outside Micrometer for Inside Measurements

Fig. 2 shows a telescoping inside gage by means of which the exact size of holes or slots can be measured by outside micrometers, so that various classes of fits, varying in thousandths of an inch or less, can be made and measured without resorting to inside micrometers. The instrument is used in the following manner: The telescoping head is compressed and the plunger locked by a slight turn of the knurled screw in the end of the handle. The head is then inserted inside of the hole to be measured, the lock is released, and the plunger allowed to expand to fit the hole. Then the plunger is again locked by a slight turn of the screw. The instrument is withdrawn and is calipered over the ends of the head with a micrometer, thus obtaining the exact size of the hole. The ends of the telescoping head are hardened and are made to a radius equal to that of the smallest hole the instrument will enter. The gages are made in five sizes, the total range of the complete set being made to enter holes from ½ inch to 6 inches.

In Fig. 3 are shown a number of tool-makers' buttons with screws and washers for jig work. The buttons are hardened

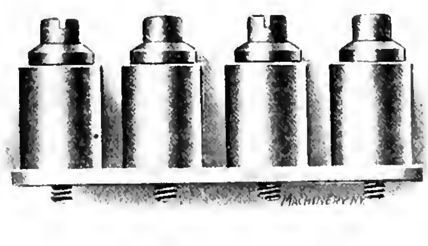

Fig. 3. Tool-makers' Buttons with Screw and Washers for Jig Work

and ground to exact standard size, the diameter being 0.400 and the length ½ inch. The use of these buttons in jig making is well-known to tool-makers, and constitutes one of the most accurate methods for laying out holes with accurate center distances in jigs. These buttons are furnished in sets of four screwed into a small plate, which makes a convenient holder for them when not in use.

MAYMONT SELF-OILING LOOSE PULLEY

The accompanying half-tone illustrations, Figs. 1 and 2, and the line engraving Fig. 3, show a new design of loose pulley brought out by the McMaster-Carr Supply Co., 176 Lake St., Chicago, Ill., and known as the Maymont self-oiling loose pulley.

As shown by the illustrations, the pulley is made in halves and bolted together, and provided with an oiling collar between the two halves. Fig. 1 shows the outside of the enlarged hub which encloses an oil reservoir. This reservoir is plainly shown in Fig. 2, where the two halves of the pulley are shown before final assembling. The two halves are bolted together with a thin oil-proof gasket between, to prevent leakage of oil. The oil distributing collar is fixed to the shaft by two set-screws, and therefore also serves the purpose of shaft collar, so that no outside collar is needed.

Fig. 3 shows the construction of the pulley. A is the collar with its two set-screws. All the rest of the pulley is free to rotate on the shaft. The collar has two curved wings or lips B, extending outward so that they nearly touch the inside walls of the oil reservoir. Close inside of these wings

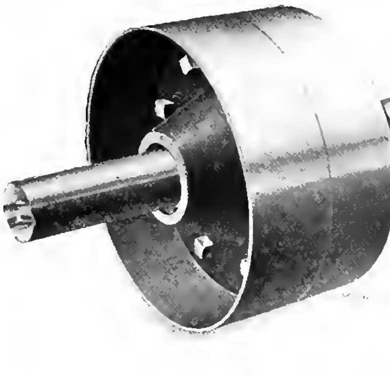

Fig. 1. The Maymont Self-oiling Loose Pulley

are inclined drilled holes C passing through the body of the collar and leading to the shaft at each side. Cored into the hubs at the outer ends are recesses D and E, the former closed and the latter open, as shown. These recesses are connected with the central reservoir by four drilled channels F. As the pulley rotates, these holes at their reservoir ends pass close to the wings of the fixed collar.

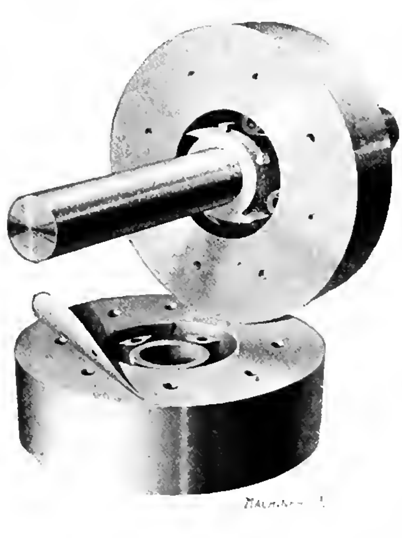

Fig. 2. View of Pulley in Halves, showing Oil Reservoir and Collar

The operation of this device is as follows: As the pulley rotates, the oil in the reservoir is carried up by the wings B of the collar, and forced into the holes C leading to the shaft, where the oil passes directly onto the surface between the hub halves and the shaft. Working along either way of the shaft, the oil reaches the end recesses D and E, where the centrifugal force carries it outward to the ports F and through them back into the reservoir. As the oil returns through the channels F, the wings B collect it and again force it into the holes C; thus continuous circulation of oil is automatically maintained.

The joint between the two halves of the pulley is made tight by a thin oil-proof gasket as shown in Fig. 2. The centrifugal force prevents oil from leaking out along the shaft when the pulley is in motion, and when it stops the

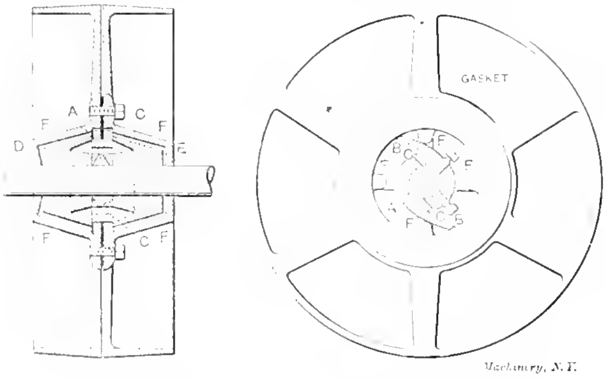

Fig. 3. Section of Self-oiling Pulley, showing Construction

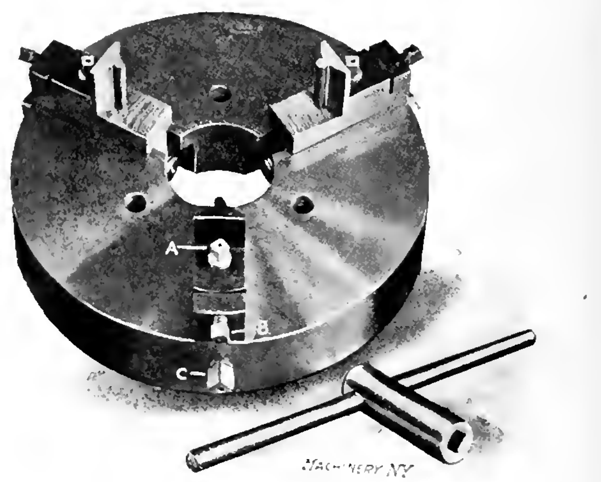
oil in the channels F above the shaft will drain to the recesses D and E, and from there down around the shaft to the bottom of the reservoir. The oil is fed in with the pulley in motion by feeding it in at the open end E of the pulley. As there is practically no loss of oil, an addition of a small amount of oil once a month usually maintains the supply.

With slight alterations the construction can be changed to suit vertical and inclined shafts. The pulley is made regularly in sizes from 6 to 30 inches diameter, and with width of face to suit conditions. Special sizes of pulleys are made to order.

SKINNER CHUCK FOR HOLDING AUTOMOBILE GEARS

The accompanying illustration shows one size of a line of special three-jaw universal chucks designed especially for holding automobile gears on the pitch line, and made by the Skinner Chuck Co., 94 No. Stanley St., New Britain, Conn. This line of chucks is especially adapted for use on grinding machines when grinding the holes of hardened gears true with their pitch circle. The chuck shown in the illustration is known as the 12-inch size and is set for a 6-pitch gear with a number of teeth which can be evenly divided by 3. Within



Skinner 12-inch Chuck for Holding Gears true with the Pitch Circle

its range it will hold the gear true at the pitch line at three points. When the number of teeth in the gears is not evenly divisible by 3, it is necessary to loosen the binding screws A on two jaws, leaving the third jaw stationary. The gear is then placed in the chuck, and the jaws are adjusted by means of the pinion screws C, each jaw being thus permitted to find its own place. The binding screws are then tightened enough to hold the top of the jaws in this position. The gear is removed and each jaw is set an equal distance from the center by means of the independent adjusting screws B, a test indicator being used for this purpose. Then the binding screws are firmly tightened and the chuck is ready for operation. Gears of any pitch can be held in these chucks by using interchangeable top jaws with rounded ends of suitable size for the required pitch.

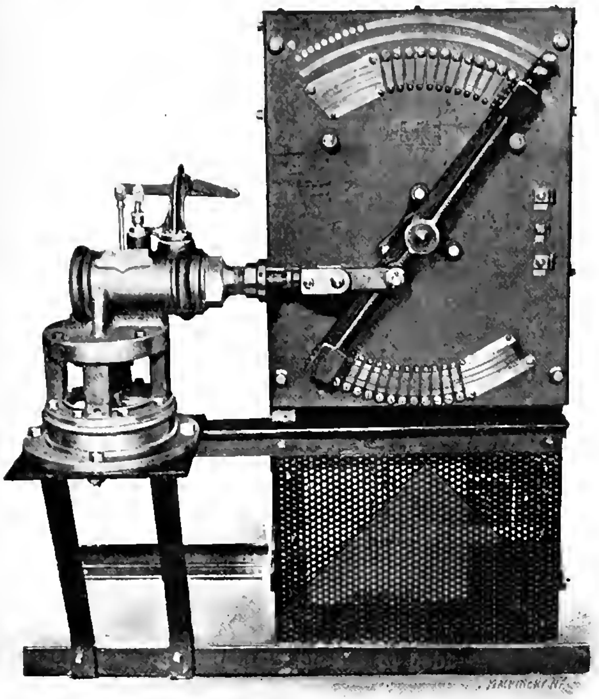
CUTLER-HAMMER PRESSURE-CONTROLLED SPEED REGULATOR

The accompanying illustration shows an interesting speed regulator built by the Cutler-Hammer Mfg. Co., Milwaukee, Wis., and intended for use in connection with electric motors operating the blower of a mechanical stoker, a boiler feed pump, a gas pressure blower, etc. It automatically regulates the speed of the motor to maintain the operating pressure practically constant.

The controlling equipment for use in connection with a direct current motor consists of a standard hand-operated starting rheostat (provided with no-voltage release) and a special speed regulator designed to vary the speed of the motor in accordance with the variations of pressure of the boiler system served by the stoker. The speed regulating part of the equipment may be designed to reduce the speed of the motor below its normal rated speed by inserting resistance in the armature circuit, or to raise the motor speed above normal by field weakening, or by a combination of these two methods.

A direct current blower regulator designed for armature and shunt field regulation is shown in the accompanying en-

graving. Another regulator is also designed for armature regulation only. The regulator consists of a slate panel mounted on the front of an angle iron cage, the panel carrying the contact segments over which a double-ended lever moves. The cage contains the necessary regulating resistance. The lever is actuated by the piston of a hydraulic cylinder, the admission and exhaust port valves of which are in turn controlled by the movement of a pressure regulator diaphragm, one side of which is subjected to the boiler



Cutler-Hammer Pressure-controlled Speed Regulator arranged for Armature and Shunt Field Regulation

pressure. The normal boiler pressure on the under side of the diaphragm is balanced by a weighted lever bearing on the top of the diaphragm in such a manner that the lever will rise or fall as the boiler pressure rises above or falls below the normal pressure for which the lever is counter-balanced. This up and down movement of the lever operates a pilot valve controlling the admission of water to the hydraulic cylinder, and due to the variations in pressure, the piston of the cylinder is moved back and forth, and in turn actuates the double-ended lever, the ends of which move over the contact segments on the slate.

The operation of cutting the resistance in and out of the circuit is not a continuous operation but proceeds step by step with pauses between each movement of the contact lever. This is accomplished by the bell crank connection shown above the cylinder. The lower end of this bell crank is connected to the piston rod of the cylinder and the upper end to the floating lever. Any upward movement of the weight lever results in an upward movement of the floating lever, admitting water to the right-hand end of the cylinder and forcing the piston to move inwardly (to the left), while any downward movement of the weight admits water at the left-hand end of the cylinder and forces the piston rod out (to the right). As soon as the piston begins to move, however, it exerts through the bell crank connection a pressure on the floating lever exactly contrary to the movement produced by the weight lever; that is, if under the influence of increasing steam pressure the weight lever moves up, the pilot valve stem and floating lever will also move up, and the piston rod of the cylinder will start to move to the left. This movement of the piston, however, is presently checked by the operation of the bell crank attached to it which pulls down on the floating lever, depresses the pilot valve stem, and shuts off the water pressure, stopping the movement of the piston and the lever on the slate actuated by it. Thus the lever proceeds step by step with a pause after each movement, resulting in a gradual cutting out of resistance and increase in motor speed.

The cylinder has been assumed to be hydraulically operated in the description above, but if water pressure is not available the same results are accomplished by connecting the inlet of the cylinder to a compressed air tank; the pressure, however, whether air or water, should not be less than 25 pounds per square inch. The system, as described, applies to direct current motors, but a regulator can also be furnished for alternating current motors, the operation being similar to the one described.

MULTIPLE TOOL-HOLDER FOR THE LATHE

A multiple tool-holder which was invented by Mr. F. J. Brewer and placed on the market by the Multiple Tool-Holder Co., 3197 West 48th St., Cleveland, O., is shown in the accompanying illustrations. As shown in Fig. 2, this tool-holder can be used for holding four tools at a time, and it is, in fact, a small temporary turret which can be applied to any engine lathe. Provision is made for indexing the upper part of the holder to different positions, so that the tool is particularly useful when a number of similar pieces are to be made and but few operations are necessary. This holder can also be used with equal advantage for chucking work, boring and turning. It is provided with a T-shaped bottom piece which fits in the slot where the usual tool-post is attached to the cross-slide of the lathe. This bottom piece, *B*, Fig. 1, is held in place by two set-screws *C* so that it will not shift when the top part of the holder is loosened for the purpose of indexing it. Indexing pins *D* for accurately locating the upper or turret part of the holder, are provided. These pins, which operate in threaded bushings screwed into the bottom piece, are pressed against the plate *E* by springs *F*, so that when the turret is turned it is easy to determine when the pins are in alignment with the holes in plate *E*. This plate has eight holes, and it is screwed and doweled to the bottom of the tool-holder proper. All indexing parts are made of hardened tool steel and the holder proper is a steel casting. The tools are adjusted vertically by the ordinary shoe or wedge, one of which is shown in Fig. 2. Each tool is held in place by two set-screws, and it can be clamped in either of two positions at right angles to each other. When the holder and the tools are properly adjusted, it is securely locked in position by turning the center clamping nut *A*. One-half a revolution of this nut releases the holder so that it may be indexed. When this nut is released the turret part of the holder is lifted by

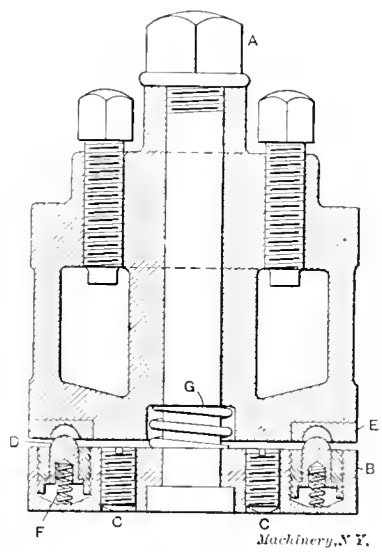


Fig. 1. Sectional View of the Brewer Multiple Tool-holder

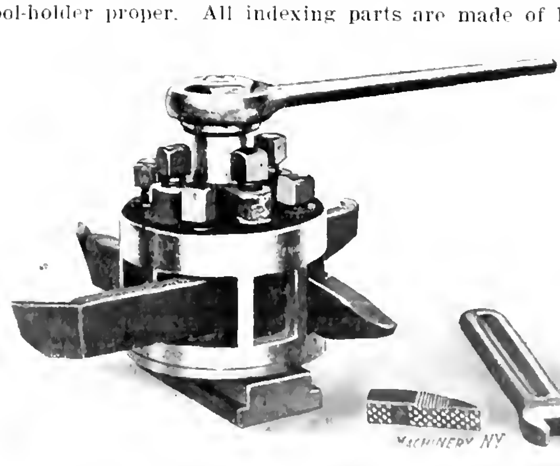

Fig. 2. Brewer Multiple Tool-holder for the Engine Lathe

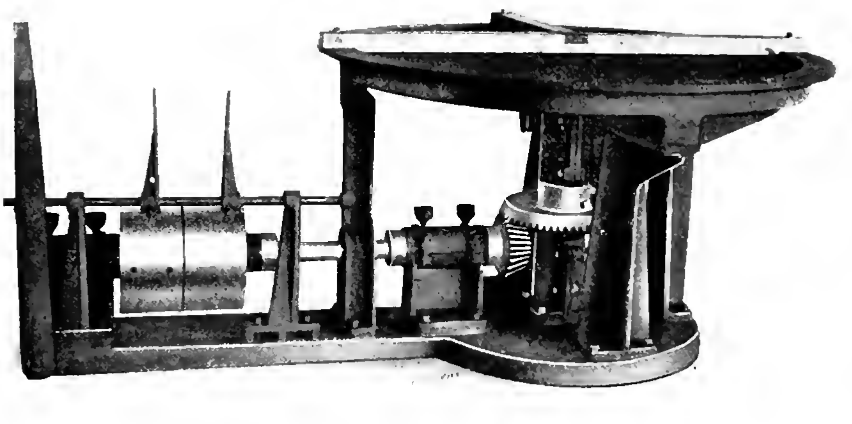
a central spring *G*. As this tool-holder practically transforms an engine lathe temporarily into a turret lathe for work where only a few operations are required, it will undoubtedly prove a useful tool in any machine shop, particularly as it can be very quickly attached and detached, and in no way interferes with the usefulness of the lathe for ordinary straight turning work.

BESLY HORIZONTAL DISK GRINDER

The accompanying illustration shows a new 48-inch horizontal disk grinder brought out by the Charles H. Besly Co., 15 So. Clinton St., Chicago, Ill. This machine is designed for grinding large surfaces such as fire doors, door jams of furnaces, stove doors, and large gear case covers for automobiles.

The method by which the machine is driven is clearly shown in the illustration. The belt used for driving is 8 inches wide and runs on a 12-inch diameter pulley from which the power is transmitted to the grinding wheel spindle by means of a 2-inch horizontal shaft and bevel gearing. The gears have planed teeth, and all gears and pulleys are keyed and held in place by set-screws directly on the keys. The vertical spindle, to which the large bevel gear is attached, is 3 inches in diameter at the bearings and 6 inches in diameter at the wheel collar, and is provided with a pilot 2 inches in diameter for holding and centering the disk wheel. The thrust is taken by two hardened tool steel blocks, one of which is secured to the lower end of the spindle and rotates



Besly No. 19. Forty-eight inch Horizontal Disk Grinder

with it, while the other is secured to the bed plate. Proper attention has been given to the lubrication of this thrust bearing.

The spindle and driving-shaft bearings are 9 inches long and are of the split type, babbitted and reamed. The disk wheel is 48 inches in diameter and provided with ribs radiating from the hub to the outer rim. The thickness at the hub is $2\frac{1}{2}$ inches, between the ribs $\frac{3}{4}$ inch, and at the rim $1\frac{1}{2}$ inch. A guard ring is provided around the disk wheel, projecting $\frac{3}{4}$ inch above the face of the wheel. This prevents the work from flying off the disk wheel while being ground. The top surface of the guard ring is machined true with the face of the disk wheel, so that bars, jigs, etc., for holding the work to be ground can be secured to it. The speed of the disk wheel is 400 revolutions per minute, and the bevel gearing being in the ratio of 1 to 2, the driving shaft should run at 800 revolutions per minute. The machine can be driven either direct from the line-shaft or from a counter-shaft as required. The operating space for the machine is 8 by 10 feet, and the height over all 32 inches. The net weight of the machine complete is 2,400 pounds.

MOTOR-DRIVEN SENSITIVE DRILL

In the June, 1908, issue of MACHINERY, a sensitive drill built by the Rockford Machine & Shuttle Co., of Rockford, Ill., was described. An improvement on this machine was illustrated in the department of New Machinery and Tools in the March, 1909, issue of MACHINERY. The improvement related particularly to the drive, the general arrangement of the machine being unchanged. The company has now brought out a motor-driven machine of the same general design as the one described in the previous issues. The driving cone, however, is eliminated, and a bracket is provided instead on the lower part of the column on which is placed the motor and starting box. The bracket for the motor is mounted on a slide which is vertically moved by means of an adjusting screw so that the tension on the driving belt can be varied. This movement permits an adjustment of 3 inches, which is sufficient to take care of the stretch of the belt for a long time without requiring that the belt itself be shortened. In all other details the machine is the same as that which has previously been described in MACHINERY.

* * *

NEW MACHINERY AND TOOLS NOTES

ANGLE BENDER: Estep & Dolan, Sandwich, Ill. This machine has a capacity for bending round or square stock cold, up to $1\frac{1}{4}$ inch in size, to a right angle, and it can be used for bending flat stock up to 4 by $\frac{1}{2}$ inch.

IMPROVED BALL BEARING UNIVERSAL JOINT: B. Frank Teal, Glenside, Pa. In this device the journal friction on the trunnions has been largely eliminated by using a ball bearing trunnion with automatic lubrication. The bearings are dust-proof. The weight and dimensions are no greater than of the ordinary type of universal joints.

HEIGHT GAGE: Louis Mastrangal, 35 Spring St., West Hoboken, N. J. This instrument is designed to provide means whereby the distance between a stationary surface and a given point outside of it may be accurately determined. It consists of a base carrying an upright, which in turn carries the gage mechanism proper.

"HIGHPOWER" TWISTED DRILL: Pratt & Whitney Co., Hartford, Conn. This is a flat twisted drill with a twisted taper shank and is practically the same as the Hackett twisted drill shown in the October, 1908, issue of MACHINERY. Another convolution has been added to the shank, however, to increase the holding power in the socket.

LINE OF POPPET DROP HAMMERS: Miner & Peck Mfg. Co., New Haven, Conn. These hammers are adapted particularly for silverware, jewelry and similar light stamping work, and are used as plain drops, controlled by the foot or hand, and operated by the maker's lifting pulley, or automatic lifter. The four-poppet drop is made in five sizes of 50, 100, 150, 200 and 300 pounds, respectively, and the six-poppet in five sizes of 300, 350, 500, 600 and 800, respectively.

GASOLINE HEATING TORCH: Volcano Torch & Mfg. Co., Erie, Pa. This torch is intended for making or releasing shrinking fits of various descriptions, extracting broken taps and drills, brazing, straightening shafts and similar work between lathe centers, annealing, hardening and tempering tools, and for repair work in general. Pieces three inches in diameter can be heated to a red heat in from ten to fifteen minutes. The torch can also be used for illuminating by changing the burner plug.

UNIVERSAL PLATE, BAR AND ANGLE SHEAR: Covington Machine Co., Covington, Va. This machine is adapted both for boiler-makers and structural shops. The location of the angle shears permits right or left angles of even or uneven legs to be cut to any angle up to 45 degrees. The clutch mechanism is positive and stops the knives at the highest point of the stroke. A table and gages are provided for the double angle shear for cutting different angles. Bars may be cut in either the angle or plate shear.

GEAR TOOTH GRINDER: G. W. Baker Machine Co., Wilmington, Del. This machine is intended for grinding the teeth of cast spur and bevel gears, as well as of racks. The grinding head carries a wheel of a shape to suit the gear tooth to be ground. The machine is adapted for spur gears up to 36 inches in diameter, and an attachment is furnished for holding bevel gears at any required angle while being ground. The work is indexed by use of a tooth rest engaging with one tooth in the gear while another tooth is being ground.

HOB GRINDING ATTACHMENT: Brown & Sharpe Mfg. Co., Providence, R. I. This attachment, used on the company's No. 13 universal and tool grinding machine, is intended for accurate sharpening of spirally fluted hobs by grinding the faces of the teeth. The mechanism for revolving the hob resembles in design that of the spiral head used on universal milling machines. Hobs with from two to twenty grooves can be ground, index plates being furnished for indexing within these limits.

SCREW DRIVER: Lynn Tool Forging Co., 260 Maple St., Lynn, Mass. This tool consists of a very substantial handle and is provided with blades specially forged and inserted by a locking arrangement so that the screw driver cannot work

loose from the handle, and the annoyance usually met with on this score is eliminated. Three blades of different lengths and widths are provided with each handle. The blades are forged from square stock so that a wrench can be used on the screw driver if necessary.

Sand Blast Nozzle: Walter Macleod & Co., Cincinnati, O. This nozzle largely overcomes the expense and annoyance in connection with the use of sand blast, due to rapid wear of the nozzles. By a special construction a film of air is interposed between the sand and the nozzle, which in an effective manner prevents undue wear. The device works by suction, and the sand reservoir may be placed at any convenient point, as the nozzle will elevate the sand to a point up to 50 feet above the sand tank.

Universal Shear: C. C. Wais Machine Co., Cincinnati, O. This machine is designed particularly for boiler makers and structural iron workers for cutting plates, bars and angles of even and uneven lengths of legs. The changes required and the loss of time incident to cutting angles or plates on an ordinary punching and shearing machine are eliminated. The machine is built in five sizes, the largest adapted for angles 6 x 6 x 1 and 7 x 7 x 3/4 inch, and to cut plates 7/8 inch thick. The smallest will take angles 3 x 3 x 1/2 and 4 x 4 x 3/8 inch, and will cut 1/4-inch plates.

Blue-print Washing Machine: Williams, Brown & Earle, Philadelphia, Pa. This machine is intended to accompany the makers' blue-printing machine mentioned in the August issue of Machinery. The machine is attached to a water pipe and takes care of the blue-prints as they come from the printing machine, washing them and passing them over a gas drying arrangement; the prints can then be delivered at the rear either separately or in a continuous roll. In connection with the electric blue-printing machine referred to, four feet of prints can be printed, washed and dried per minute.

Double Crank Press: E. W. Bliss & Co., 5 Adams St., Brooklyn, N. Y. This machine is designed for accurate cutting and punching operations extending over the entire width of large sheets which are fed through the machine from front to back. The safe working capacity of the machine is from 100 tons for operations requiring great rigidity, up to 140 tons for less particular work. The machine can be provided with an automatic feed for sheets from 6 to 10 feet wide and up to 40 inches long. It is driven by a direct connected 10 H. P. motor and makes 18 strokes per minute.

Hydraulic Beam Shear: Watson-Stillman Co., 192 Fulton St., New York City. This machine is designed for cutting I-beams, channels, flat bars, angle irons and other structural shapes, and may be used for cutting round sections in emergencies by removing the regular cutting mechanism. It can also be readily converted into a powerful hydraulic press for general work. The machine is made in two sizes to take beams and sections having the longest dimensions 15 and 24 inches, respectively. It is hydraulically operated. The weight of the smaller size shear is 12,000 pounds, and that of the larger, 16,500 pounds.

Automatic Two-jaw Chuck: Cleveland Chuck Co., 514 Garfield Bldg., Cleveland, O. This chuck is intended as a substitute for the old style box chuck. It is mechanically operated, but its action is similar to that of a pneumatic chuck, while the expense of installing and maintaining an air supply system is eliminated. The gripping action is accomplished by a rocking movement of the jaws, effected by the spreading of the rear ends by the axial movement of a conical collar. One pair of jaws is required for every 1/16 inch difference in diameter of the work, but the device is so designed that the change for different sizes is very quickly made.

Drill Press with Universal Table: Robertson Drill & Tool Co., Department 5, Buffalo, N. Y. This machine, known as the tilting table drill press, is provided with a table which can be swung to any position in the vertical plane. It is operated by worm and worm gear, and graduations up to 90 degrees are provided so that the table can be set accurately to a given angle. After the table has been swung into an angular position it can be turned on its center bearing so as to bring the work to any position under the drill. It can be tilted over to either side of the knee, and clamping bolts are provided to secure it firmly in any position.

Machine for Testing Hardness of Metals: Tinius Olsen & Co., 12th and Buttonwood Sts., Philadelphia, Pa. This machine is designed for use in every-day shop practice for testing the hardness of locomotive tires and other material entering into locomotive construction. The test is made by means of the Brinell method, using a ball which is subjected to a standard pressure for different materials. A dial is provided where the amount of penetration of the ball in the material tested may be read off directly without calculations. To make a test with this machine requires less than a minute, including the time necessary for inserting and removing the test specimen.

Transmission Devices: Carl M. Wheaton, 9 Callender St., Providence, R. I. The devices brought out include a self-oiling bearing in which the oiling device consists of a number of cork balls contained in tubes and held in contact with the shaft by their buoyancy or inclination to float on the oil; a method of hanging shafting in rooms with high ceilings, consisting of brackets holding a pipe which in turn supports the hangers; a clutch pulley where centrifugal action is made use of for throwing out a counter-weight holding the friction surfaces out of contact except when forced into position by the clutch lever; and a loose pulley with special oiling arrangement.

Hydraulic Coping Machine: Watson-Stillman Co., 192 Fulton St., New York City. This machine, designed for trimming structural shapes, small pieces of plate metal, bar iron, etc., is especially intended for use in steel mills, shipbuilding plants, and structural iron, boiler and locomotive shops. It is operated by hydraulic pressure and consists essentially of a heavy steel beam or lever actuated from the rear, and having the forward end fitted with shearing knives. The construction offers a large number of cutting combinations, the change from any one of which can be made in less than a minute's time. The machine is operated by a foot lever. The total weight of the machine is 4,700 pounds.

Testing Machine of 1,200,000 Pounds Capacity: Tinius Olsen & Co., 12th and Buttonwood Sts., Philadelphia, Pa. This testing machine has been designed for the new testing labaratory of the Rensselaer Polytechnic Institute of Troy, N. Y. The method of weighing the load is a departure from all previous methods. The pressure in the main cylinder is transmitted to a diaphragm, which is exactly 1/25 of the area of the main press cylinder. The pressure on the diaphragm is communicated to a lever system terminating in a standard dial vernier screw beam. As the transmission of pressure through the diaphragm is frictionless, the amount of pressure is thus weighed with great accuracy.

Double Seamer for Cans: Charles Leffler & Co., 49 Clymer St., Brooklyn, N. Y. This machine, known as the No. 21 double head automatic square double seamer, will simultaneously double seam the top and bottom to the body of square and irregular cans, such as cocoa cans, powder cans, etc. The machine is entirely automatic and can be operated by one man. All that is required of the operator is to put the cans on and off of the machine and press the treadle. Despite the complicated movements required, the machine works as easily as single end machines, and runs at the same speed. It will take work up to 8 inches wide and 12 inches high. It is possible to double seam more than 10,000 can ends, of certain shapes, per day.

Steam Turbine: E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. This steam turbine is the outcome of several years of experimenting; as far as possible the weaknesses of other turbines have been avoided, and structural strength is one of the main features of the design. The steam is expanded completely in the nozzles, so that there is no difference in pressure between the buckets in the wheel and the reversing chamber, and consequently no loss from leakage. This makes it possible to run with a very large clearance without the primary losses in efficiency common in most turbines and caused by steam friction and leakage. The turbine is made in types for operating both condensing and non-condensing, and also to run on exhaust steam from reciprocating engines.

Speed Reducer: Foote Bros. Gear & Machine Co., 44 No. Carpenter St., Chicago, Ill. This device is designed for driving machinery running at relatively low speeds from a source of power running at a high speed. The speed reducer known as style D is particularly adapted for high reduction ratios, and will give any reduction of speed up to 60 to 1. These reducers can be furnished in seven sizes, in capacities from 1 to 50 H. P. The reduction of speed is obtained through spur gears, but the design provides for elimination of the usual objections to a spur gear speed reducer in that sufficient central support of the shaft between the high and low speeds is provided. There are no rotating parts in the interior that can get out of balance and cause vibration.

Flame Welding Outfit: Schaap Flame Utilities Corporation, 344 Cumberland St., Brooklyn, N. Y. This apparatus is designed for the purpose of fusion welding cast iron, aluminum and other metals by the heat generated by combustion of the illuminating gas. The special novelty of the device is the torch. A mixture of gas and air under high pressure is sent through the tip in the center of the torch, thus generating the heat for melting the metal to be welded. A mixture of gas and air under low pressure is forced through openings of the torch which surround the central nozzle and this mixture protects the central jet from the outside atmosphere; for this purpose the torch is composed of five tubes, one inside of the other, with a space between each for the low-pressure gas to pass through.

Drilling and Milling Machine: W. B. Knight Machinery Co., 2019-2025 Lucas Ave., St. Louis, Mo. This machine, known as the No. 2 Knight drilling and milling machine, is designed with the object in view of furnishing a machine on which a great variety of both drill press and vertical milling machine work can be done. It is built along the same lines as the original Knight machine, but is intended for much heavier duty. The machine is particularly advantageous to use upon work which requires drilling, boring and milling op-

erations which ought to be done at a single setting of the work. In this way greater accuracy is obtainable, and a considerable saving in time is effected. The table of the machine can be tilted, and is mounted so as to permit of rapid adjustment. This permits some of the operations required to be performed at an angle with some of the other operations.

IMPROVED PIPE MACHINE: Bignall & Keeler Mfg. Co., Edwardsville, Ill. This machine is designed for cutting off and threading pipe from 2½ to 8 inches inclusive, and has been constructed with a view of eliminating rocking gears and clutches. The speeds are obtained through a gear box and a compound sliding gear on one of the shafts, a speed plate attached to the box showing how to obtain the speeds for the various sizes of pipe. A single driving pulley is used, and the belt speed, consequently, is constant. The die-head is of the "low-down" type, placing the handles and die lever within easy reach of the operator, and is equipped with a special adjusting mechanism, making it very simple to operate. The chucks are of the independent type, each having three jaws, and the jaw slides are graduated and easily set to any required size of pipe. On the rear chuck, the slides are provided with flange grippers in addition to the regular pipe grippers, so as to hold flanged work. The pipe grippers are of hardened steel, are dove-tailed into the ends of the slides, and can be removed and sharpened.

* * *

HEAVY TRAINS ON THE VIRGINIAN RAILWAY

The Virginian Railway, built by the late H. H. Rogers, is probably the most carefully engineered railway in the United States, if not in the world. It was planned with the idea of making a locomotive utilize its maximum hauling capacity from the coal fields in the Alleghanies to Tidewater. It was recently announced that 80 cars of 100,000 pounds capacity each had been hauled from Alleghany summit to Tidewater, the total weight of the cars being 4,310 long tons. This record was soon beaten by a train of ninety cars loaded with 100,000 pounds, drawn by a single Mikado type locomotive. The total weight of the train approximated 7,000 tons. The maximum adverse grade is about 0.2 per cent, compensated. The grades are such that the empty cars can be hauled back to the mines by a single locomotive in trains equivalent in length to the loaded trains. That is, a locomotive that is able to handle ninety cars to Tidewater is able to haul the empty cars back to the mines.

* * *

PERSONAL

Herbert L. Beeler has been appointed advertising manager of the R. K. Le Blond Machine Tool Co., Cincinnati, Ohio.

C. W. Wrenshall, superintendent of the Western Steel Car & Foundry Co., has been made general superintendent of the Pressed Steel Car Co., Pittsburg, Pa.

H. E. Longwell has been appointed consulting engineer with particular jurisdiction over the publicity department of the Westinghouse Machine Co., East Pittsburg, Pa.

W. A. Bole has been appointed assistant manager of the works of the Westinghouse Machine Co., East Pittsburg, Pa., with particular jurisdiction over the Trafford Works.

Otto J. Rantz, formerly in charge of the shop work at the Haverford College, Haverford, Pa., has been appointed superintendent of the Stephens Industrial School, Lancaster, Pa.

John Scott, a contributor to MACHINERY, recently was promoted to the position of factory inspector of the Tomson Co., Lowell, Mass.

H. L. Mills, president of the American Specialty Co., Chicago, has just returned from an extensive business trip through the East.

Hiram Pruim, for nearly ten years in the employ of the William Hahn Co., Chicago, makers of flexible shafts, has been made superintendent.

J. E. Stark, formerly with the Courier Koeth Mfg. Co., has accepted a position as superintendent of the Western Wire Goods Co., of Buffalo, N. Y.

R. L. D. Mackie, formerly with the Morgan Construction Co., Worcester, Mass., is now manager of the high pressure and pipeage department of the W. J. Scholl Co., Youngstown, Ohio.

W. S. Heger, of the Allis-Chalmers Co., who was formerly assistant to the president, has been placed in charge of the company's interests in southern California, with headquarters at Los Angeles.

Harold O. Rugg, a graduate of Dartmouth College, and now in the employ of the Missouri Pacific Railway, has been appointed instructor in civil engineering in the James Millikin University at Decatur, Ill.

S. H. Reck, of the Rockford Drilling & Machine Co., Rockford, Ill., sailed from New York August 26 on the *La Lorraine* for a two months trip in Europe. Mr. Reck expects to visit the various machine tool agencies in England and on the continent.

F. C. Armstead, supervising engineer of the stoker department of the Westinghouse Machine Co., who, for a number of years, has been located at East Pittsburg, Pa., has moved his headquarters to the Westinghouse Works, Attica, N. Y., where the stokers are manufactured.

Charles M. Robertson, formerly superintendent of the Colburn Machine Tool Co., Franklin, Pa., will henceforth be associated as special representative and expert with the E. L. Essley Machinery Co., 62 West Washington St., Chicago, selling agent for the Colburn Machine Tool Co. Mr. Robertson has a large and varied experience in the manufacturing and selling of vertical boring mills.

W. R. Chapin, who has been for five years connected with the Cleveland Twist Drill Co., Cleveland, Ohio, has engaged with E. C. Atkins & Co., saw manufacturer, Indianapolis, Ind. While with the Cleveland Twist Drill Co. Mr. Chapin was in charge of the chemical laboratory, heat treatment and experimental departments, and will have a similar position with E. C. Atkins & Co.

Charles T. Hawley, of Gardner, Mass., has been appointed assistant examiner in the patent office at Washington, and has, therefore, resigned from an important position with the Simplex Time Recorder Co., of Gardner, Mass. Mr. Hawley has been active as an inventor, and was formerly connected with the experimental department of the Draper Machine Co. of Hopedale, Mass. He graduated in 1898 from the Worcester Polytechnic Institute.

E. H. Fish, well known to the readers of MACHINERY as a frequent contributor to its columns, has been elected director of the new Worcester Independent Industrial School. For nine years Mr. Fish was associated with his father, Henry C. Fish, in the machine tool manufacturing business in Worcester, producing a line of engine lathes. Later he went to the Worcester Polytechnic Institute—from which he graduated in 1892—as instructor. He has been instructor in various subjects, and his experience in this work make him particularly fitted to take charge of a trade school designed primarily for the education of mechanics.

* * *

OBITUARIES

T. H. Sears, builder of machinery, Holyoke, Mass., died July 30, aged fifty-eight years.

Fred W. Ridlan, treasurer of the Superior Grate Co., of Springfield, Mass., died July 27 at the age of thirty.

Levi M. Brown, who for more than thirty years was superintendent of the Gilbert & Barker Mfg. Co., Springfield, Mass., died July 15 at the age of seventy-three.

John Moore, superintendent of the machine shops of the Carnegie Steel Co., at Bellaire, Ohio, died by accident at Wheeling, W. Va., July 26.

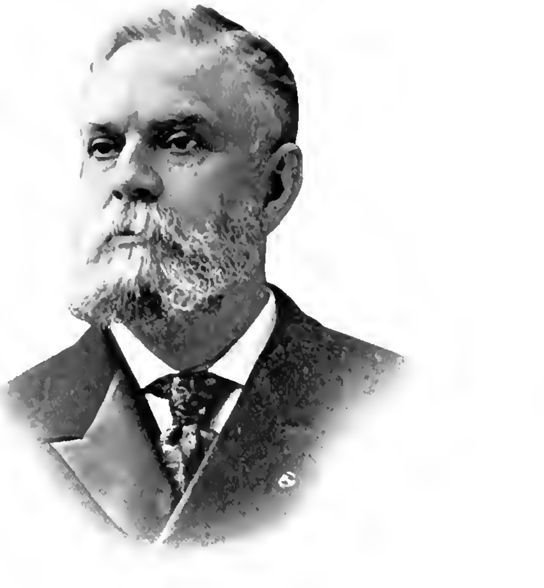
Henry Mitchell, well-known as an engraver of seals, medals and coats of arms, died at his home in Chelsea, Mass., August 1, in his seventy-fourth year. He entered the service of the United States Government as official engraver in 1868, and engraved the medals for the Centennial Exposition, 1876, before he was thirty years old.

John Morse Ordway died at his home in Saugus, Mass., July 5, at an age of eighty-six years. He was a graduate of Dartmouth College in the class of 1844, and was, up to three years ago, professor at Tulane University, New Orleans. He has also been a member of the faculty of the Massachusetts Institute of Technology.

David H. Gildersleeve, mechanical engineer, died at his mother's home, 104 Montague St., Brooklyn, July 30, aged forty-one. For five years Mr. Gildersleeve was sales manager for the C. W. Hunt Co. Early in 1909 he became vice-president of the Waters, Gildersleeve, Colver Co., in the shipbuilding and marine machinery business. He is survived by a widow and two children.

Leffert Lefferts Buck, a well-known civil engineer, who was associated with Roebling in the building of the Brooklyn bridge, and who was engineer of the Williamsburg bridge across the East River, New York, died at Hastings, N. Y., July 17. Mr. Buck also designed two steel arch bridges across the Niagara river, and had direction of many other engineering works of note both in this country and South America.

Roderick Perry Curtis, president of the Curtis & Curtis Co., Bridgeport, Conn., died at Southport, Conn., August 9, aged fifty-nine, as a result of injuries received in an automobile collision at Westerly, R. I., a few weeks previous. Mr. Curtis was born in New York, from where his family moved to Southport, Conn., in 1868. In 1882 he founded, with William D. Forbes, the firm of Forbes & Curtis, for the manufacture of the Forbes patent die stock. In 1887 the Forbes interests were taken over by Mr. Lewis B. Curtis and the firm of Curtis & Curtis formed to continue the business. In 1900 the firm was incorporated under the name of the Curtis & Curtis Co. Mr. Curtis was also director of several other manufacturing corporations.



Albert A. Pope

Albert A. Pope, pioneer bicycle manufacturer of the United States, died at his summer home in Cohasset, Mass., August 10. He was born in Boston in 1843, and at the age of nineteen he joined the volunteer force of the Union army, and was made lieutenant-colonel in 1865. In 1876, at the Centennial exposition in Philadelphia, he first saw a bicycle. Early in 1877 he organized the Pope Mfg. Co., and as soon as the company was organized he went to Europe to study the development of the bicycle and its possible manufacture in America. In 1878 he placed an order for the manufacture of bicycles with the Weed Sewing Machine Co., which concern he finally bought out, merging it with the Pope Mfg. Co. The business grew rapidly until, after twenty years, it comprised five large factories. In 1896 Col. Pope formed the Columbia Electric Vehicle Co., of Hartford, Conn. In 1899 the Pope Mfg. Co. was absorbed by the American Bicycle Co., but in 1903 the Pope Mfg. Co. was re-organized, and the factories became largely devoted to the building of automobiles. A lull in the motor car business proved unfortunate for the company, and after a period of financial readjustment, the company was again reorganized and incorporated last December under the laws of Connecticut. Col. Pope was prominent in many other industrial undertakings, and was also a director of several banks and other corporations.

Frank L. Bliss, president of the Ajax Iron Works, Corry, Pa., died in Corry, August 3. Mr. Bliss was active in the management of the company since its organization.

* * *

COMING EVENTS

September 14-16. Fourteenth annual convention of the International Association of Municipal Electricians, Atlantic City, N. J. Frank T. Foster, secretary, Corning, N. Y.

September 25-October 9.—Hudson-Fulton celebration of the three-hundredth anniversary of the discovery of the Hudson River by Hendrick Hudson in 1609, and the one-hundredth anniversary of the successful application of steam to the navigation of the Hudson River in 1807. The headquarters of the commission are in the *Tribune* building, New York City, General Stewart L. Woodford, president, and Mr. Henry W. Sackett secretary. The commission solicits the loan of collections of machinery, models, books, etc., having a bearing on the history of early steam navigation in the United States.

September 27-October 1.—Autumn meeting of the Iron and Steel Institute, London. G. C. Lloyd, secretary, 28 Victoria St., London, S. W.

October 3-9.—St. Louis Centennial Week, St. Louis, Mo. Balloon, airship and aeroplane races will be arranged under the auspices of the Aero Club of St. Louis.

October 4-8.—Annual conventions of the American Street and Interurban Railway Association, American Street and Interurban Railway Accountants Association, American Street and Interurban Railway Engineering Association, American Street and Interurban Railway Claim Agents' Association, American Street and Interurban Railway Transportation and Traffic Association, American Street and Interurban Railway Manufacturers' Association, at Denver, Col. Bernard V. Swenson, secretary and treasurer, 29 West 39th St., New York.

October 12-13. Convention of National Machine Tool Builders' Association, New York. P. E. Montanus, secretary, Springfield, Ohio.

October 14.—MACHINERY'S seventh annual outing.

April 1-June 30, 1910.—American Exposition in Berlin to stimulate trade relations with Germany and American export business generally. The exposition will be held in the Exposition Palace, having 110,000 square feet floor space. Max Viewger, American manager, 50 Church St., New York.

NEW BOOKS AND PAMPHLETS

AMERICAN SOCIETY OF ENGINEERING CONTRACTORS, Park Row Building, New York. Journal containing the constitution and list of members.

AMERICAN SOCIETY OF MECHANICAL ENGINEERS, 29 W. 39th St., New York. Pocket list of the 3,680 members, including the life members. The list appears in a new form, better adapted to the side pocket than the former shape, it being $4\frac{1}{4} \times 6\frac{1}{2}$ inches, or "standard" pocket-book size.

DICTIONARY OF CHEMICAL AND METALLURGICAL MATERIAL. 182 pages, $4\frac{1}{2} \times 7\frac{1}{2}$ inches. Published by the *Electro-Chemical and Metallurgical Industry*, 239 W. 39th St., New York City. Price $0.50.

This dictionary contains an alphabetically arranged list of chemical and metallurgical machinery appliances and material, manufactured and sold by advertisers in the *Electro-Chemical and Metallurgical Industry*. It is divided into three sections, the first or main section being a dictionary of industrial supplies, the second section giving a finding list of manufacturers of measuring instruments and laboratory supplies, while the third section is given up to a professional dictionary of metallurgical, analytical and engineering chemists, consulting engineers and patent lawyers.

WORKSHOP RECEIPTS FOR MANUFACTURERS AND SCIENTIFIC AMATEURS. VOLUME 1. 532 pages, $4\frac{3}{4} \times 7\frac{1}{4}$ inches. Published by Spon & Chamberlain, 123 Liberty St., New York. Price $1.50.

The older edition of "Workshop Receipts" has, during the past few years, grown into five bulky volumes, and the present edition therefore has been thoroughly revised and a great number of the receipts that seemed obsolete have been omitted. The remaining matter has then been carefully revised. The arrangement of the book is alphabetical, and the present volume treats of subjects from Acetylene Lighting to Drying. Outside of the alphabetical arrangement of subjects, a very complete index is given, which will be of considerable aid in finding certain subjects which have not been given a special heading in the main text.

ELEMENTARY PRINCIPLES OF INDUSTRIAL DRAWING. By George Jepson. 29 pages, 8 x 6 inches. 11 plates of illustrations. Published by the author, Roslindale, Boston, Mass.

The object of this book is to present the subject of industrial drawing by such a method that the student will master the fundamental principles without a great deal of preliminary study. Special efforts have been made to make the descriptive matter as short, simple and concise as possible, and to let the drawings largely explain the principles involved. The book should be of great value to beginners as well as to teachers of geometrical drawing, who desire to get a clear conception of the simplicity of the subject when viewed from the position of the practical user of mechanical drawing, rather than from the point of view of the mathematician or student of the theory.

A PRIMER OF THE CALCULUS. By E. Sherman Gould. 122 pages, $3\frac{3}{4} \times 6$ inches. 24 line engravings. Published by D. Van Nostrand Co., New York. Price $0.50.

This book, which is at present in its fourth edition, is No. 112 of the Van Nostrand Science Series. The work treates of calculus as far as the first differentials of algebraic functions of one independent variable, and their corresponding integrals. It is thus restricted to the first principles of the subject, but within its limits, however, it is reasonably complete and gives the beginner a clear idea of the far-reaching importance of calculus, even in its elementary steps. The book may well be recommended to students who want to acquire a general working knowledge of calculus and desire to become familiar with its fundamental principles.

STEAM POWER PLANT PIPING SYSTEMS. By William L. Morris. 490 pages, $6 \times 9\frac{1}{2}$ inches. 389 engravings. Published by the McGraw-Hill Book Co., New York. Price $5.

In this work the author has taken up the design, installation and operation of piping systems for power stations, giving a detailed and consecutive treatment of the entire subject. Only such parts of the power plant are dealt with as are directly related to the piping system. The design of boilers and engines has not been touched upon, as being outside the limits of the treatise, but their operation has been covered. All auxiliary apparatus in the pipe circuit between the boiler and engine and in the various piping systems for steam, oil, air, etc., are also described, and their general design discussed. The book embodies the personal experience of the author and is written from his own point of view. The main subjects of which the book treats are as follows: Piping diagrams and systems; condensers and heaters; live steam drips; blow-off and exhaust piping; air and oiling systems; oil and water purifying systems; details of piping arrangements for live steam, vacuum and atmospheric exhaust, boiler feed, fire pump suction, heater water supply and condensation, air and vacuum lines; city water piping; artesian water piping; fire service piping; hydraulic elevator piping; tile sewers and sundry minor piping details.

CATALOGUES AND CIRCULARS

TRENTON ENGINE CO., Trenton, N. J. Catalogue illustrating the Reeves compound and single cylinder steam engines.

PROTECTIVE VENTILATOR CO., 129-133 Fulton St., New York. Circular and leaflets advertising protective window ventilators.

AMERICAN BLOWER CO., Detroit, Mich. Card advertising the Detroit trap system for boiler feed, water lift and coil drainage.

FIRTH STERLING STEEL CO., E. S. JACKMAN & CO., agents, Chicago, Ill. Circular of Blue Chip high-speed steel.

INGERSOLL-RAND CO., 11 Broadway, New York. Catalogue describing the construction of rock drills and drill mountings.

H. W. JOHNS-MANVILLE CO., 100 Williams St., New York. Folder describing safety blow-off sectional pipe covering, giving price list and directions for applying the covering to pipes.

SUCRO FILTER CO., 12 Broadway, New York. Catalogue of Sucro water coolers and filters, and filtration plants, showing a number of interesting devices for purification of drinking water.

AMERICAN TAP & DIE CO., Greenfield, Mass. Catalogue No. 3 of "Adamantine" screw plates, "Eagle" brand taps and dies, stocks and tap wrenches; also pipe tools, comprising stocks, taps and reamers.

ABBOTT BALL CO., 14 Hicks St., Hartford, Conn. Circular describing the use of the Abbott steel balls for finishing metal goods by the burnishing and tumbling process, using the Abbott tumbling barrel.

E. W. BLISS CO., 5 Adams St., Brooklyn, N. Y. Catalogue of Bliss steam turbines, describing the construction of the Bliss turbine and calling attention to the advantages of turbines over reciprocating engines.

FULLER & JOHNSON MFG. CO., Madison, Wis. Circular illustrating and describing the Fuller & Johnson diaphragm bilge pump outfits. A general description of the engine and pump is given, and the cost of operation is stated.

JNO. HY. ANDREW & CO., Ltd., Toledo Steel Works, Sheffield, England. Booklet giving information relating to the Toledo high-speed steel and instructions regarding its hardening, together with notes on the forging and tempering of the regular Toledo carbon tool steel.

KEUFFEL & ESSER CO., Hoboken, N. J. Leaflet calling attention to the fact that during the summer months quick-printing blue print paper should not be carried in stock more than one month, because the heat and moisture at this time of the year is detrimental to the paper.

GENERAL ELECTRIC CO., Schenectady, New York. Bulletin No. 4675, describing and illustrating a new single-phase induction motor of the repulsion induction type, designated as the type RI. Bulletin No. 4677, containing data relating to the Sprague-General Electric Type M system of control.

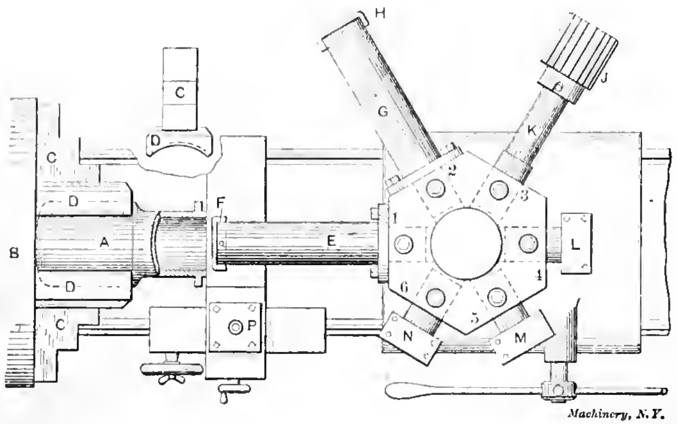
RUSSELL, BURDSALL & WARD BOLT & NUT CO., Port Chester, N. Y. Catalogue of bolts and nuts, comprising Philadelphia turned head eagle carriage bolts, turned bevel head carriage bolts, loom bolts, cold punched square and hexagon nuts, square head cap screws, machine screws, rivet heads, etc.

Supplement to MACHINERY, October, 1909

Operations for the Article in this number entitled "Machine Shop Practice—Boring Cylinders"

SHOP OPERATION SHEET NO. 112.

Oscar E. Perrigo. MACHINERY, October, 1909



Machinery, N.Y.

Boring and Turning an Automobile Engine Cylinder Casting.

Note.—The turret lathe is supposed to be provided with a hexagonal turret, and a carriage supporting a rectangular revolving tool-post, with provision for four tools. The turret faces are also assumed to be bored for tool shanks, and drilled and tapped for bolting on large and heavy tools. The chuck *B* should be provided with strong and massive jaws for doing work of this kind.

1. To the soft chuck jaws *C* fit secondary jaws *D* having grooves formed in them for fitting the jaws *C*, as shown in the end view. Fasten these secondary jaws by small screws, and bore them out to fit the large diameter of the cylinder.
2. Provide the boring-bar *E*, with a shank fitting the hole in the turret, and a flange for bolting on to the turret face, and having its front end slotted and provided with the flat boring cutter *F* secured in place by a pin. The cutter should be of such length as to fully clean the rough bore of cylinder *A*, and should have its front corners somewhat rounded. Bolt this bar to turret face 1.
3. Provide for turret face 2 a boring-bar *G*, similar to that described in step 2, except that its cutter *H* is of proper length to bore 1/64 inch smaller than the finish diameter of the cylinder.
4. Provide for the turret face 3 a shell reamer *J*, of the exact diameter of the finished bore. The ends of the teeth should be somewhat rounded, and the reamer fitted loosely to the arbor *K*.

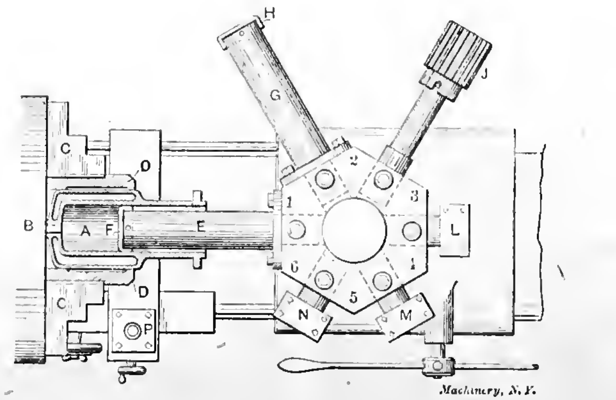
Note.—It is the practice in many shops, particularly where gasoline engines are manufactured, to finish the bore of the cylinders by grinding.

5. Provide and place in turret faces 4, 5 and 6, tool-holders *L*, *M* and *N*, suitable for holding square tools.

Note.—The tools for use in the holders *L*, *M*, *N*, and in the rectangular tool-post *P*, will be described in Operation Sheet No. 113, as they are necessarily brought into use in connection with the facing operations.

SHOP OPERATION SHEET NO. 113.

Oscar E. Perrigo. MACHINERY, October, 1909.



Machinery, N.Y.

Boring and Turning an Automobile Engine Cylinder Casting.

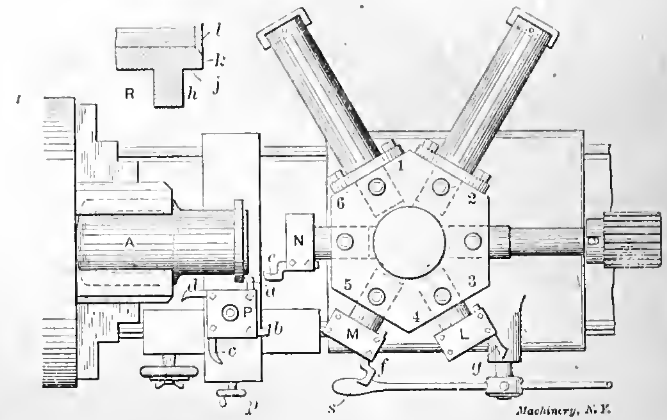
Note.—The cylinder *A* is shown in section, held in place by the secondary jaws *D*, which are attached to the regular jaws *C* of the chuck *B*, and with its large end resting against the face of the chuck. The turret is fitted with the tools necessary for the operations, which have been previously described.

1. Place the casting A within the jaws *D*, and screw up the chuck jaws lightly. Start the machine slowly, holding a piece of chalk against the outside of the rough casting at the outer end. If necessary, slightly change the position of the casting *A*, as indicated by the chalk marks, until the casting runs practically true. Screw up the jaws gradually and successively until the casting is fully secured; proper care should be taken to prevent crushing its thin walls. When the casting is clamped, it should be again tested and adjustment made if necessary.
2. Bring up the rough boring-bar *E*, and start the cut with its tool *F*, using a coarse feed. If the tool chatters, it will be necessary to reduce the feed. Stop the feed as soon as the rounded corners of the cutter have cleaned the bottom of the bore.
3. Withdraw the roughing tool-bar *E*, bring the sizing tool-bar *G* into operative position, and take a second cut, using the same care as to the feed, and stopping it when the bottom of the bore is reached.
4. Withdraw the sizing tool-bar *G*, turn the turret until the reamer *J* is in operative position, and proceed to ream the bore by forcing the reamer carefully, by hand, to the bottom of the bore.

Note.—While the roughing and sizing cutters are at work, chips may collect in the bore so as to make it necessary to withdraw the tool and clean them out. This will most likely occur if a small or distorted core was used in making the casting. If chips are allowed to clog the cutters, the surface of the bore may be "roughed up" by them.

SHOP OPERATION SHEET NO. 114.

Oscar E. Perrigo. MACHINERY, October, 1909



Machinery, N.Y.

Boring and Turning an Automobile Engine Cylinder Casting.

Note.—The casting *A*, which has been bored and reamed, remains in the chuck at the conclusion of those operations. The form of the mouth of the cylinder bore and the flange surrounding it is shown on an enlarged scale at *R*. The cross slide carriage is clamped to the bed throughout these operations.

1. Place a bent rough facing tool *a* in the tool-post *P*. Set it to face the front *h* of the flange to 1/32 inch of finish dimension and take the cut.
2. Place a bent finish facing tool *b* in the tool-post *P*. Set it to face the front *h* of the flange to the finish dimension and take the finishing cut.
3. Place a bent rough facing tool *c* in the tool-post *P*. Set it to rough face the end *k* of the cylinder to 1/32 inch of the finish dimension and take the cut.
4. Place a bent finish facing tool *d* in the tool-post *P*. Set it to finish face the end *k* to finish dimension and take the cut.
5. Place the offset rough turning tool *e*, in turret tool-holder *N*, and set it 1/16 inch over finish diameter at *j*. Bring the tool up and rough turn this portion down to the face *h*.
6. Place the offset finish turning tool *f* in the turret tool-holder *M*, and set it to finish diameter *j*. Bring the tool up and finish this diameter down to the face *h*, making a sharp corner.
7. Place the straight chamfering tool *g* in the turret tool-holder *L*, and set it to cut the chamfer *l* to the angle required. Bring up the tool and cut the chamfer, using the hand feed.

Note.—It is understood that the regular adjustable stops of the machine are to be used in limiting the travel of the tools; that the hand wheel *p* is used for operating the tool-post *P*, and the pilot *s* for operating the turret tools on short cuts, etc.

FORMULAS FOR CONE CLUTCHES

H.P. = horse-power transmitted,

N = revolutions of crank-shaft per minute,

r = mean radius of friction cone, in inches,

r_1 = large radius of friction cone, in inches,

r_2 = small radius of friction cone, in inches,

R_1 = outside radius of leather band, in inches,

R_2 = inside radius of leather band, in inches,

v = velocity of a point at distance r from the center, in feet per minute,

F = tangential force acting at radius r, in pounds,

P_n = total normal pressure between cone surfaces, in pounds,

P_s = spring pressure, in pounds,

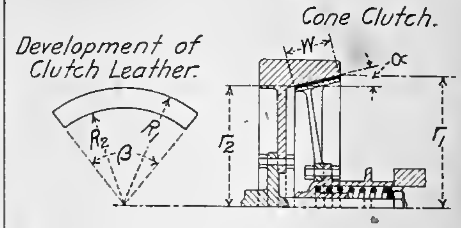
α = angle of clutch surface with axis of shaft = 7 to 13 degrees,

β = included angle of clutch leather, when developed, in degrees,

f = coefficient of friction = 0.20 to 0.25 for greasy leather on iron,

p = allowable pressure per square inch of leather band = 7 to 8 pounds,

W = width of clutch leather, in inches.



$$R_1 = \frac{r_1}{\sin\alpha}$$

$$R_2 = \frac{r_2}{\sin\alpha}$$

$$\beta = \sin\alpha \times 360$$

$$r = \frac{r_1 + r_2}{2}$$

$$v = \frac{2\pi r N}{12}$$

$$F = \frac{H.P. \times 33000}{v}$$

$$W = \frac{P_n}{2\pi r p}$$

$$H.P. = \frac{P_n f r N}{63025}$$

Engagement with some slip:

$$P_n = \frac{P_s}{\sin\alpha}$$

$$P_s = \frac{H.P. \times 63025 \sin\alpha}{f r N}$$

Engagement without slip:

$$P_n = \frac{P_s}{\sin\alpha + f\cos\alpha}$$

$$P_s = \frac{H.P. \times 63025 (\sin\alpha + f\cos\alpha)}{f r N}$$

Contributed by C. A. Schaefer

HORSE-POWER OF AUTOMOBILE ENGINES

Horse Power of Automobile Engines.
Based on the A.L.A.M. Standard Horse Power Formula, assuming a piston speed of 1000 feet per minute.

$$H.P. = \frac{(\text{Diam. of cyl.})^2 \times \text{No. of Cylinders}}{2.5}$$

Diameter of Cylinder		Horse Power			
Inches	Millimeters	1 Cylinder	2 Cylinders	4 Cylinders	6 Cylinders
2 1/2	64	2 1/2	5	10	15
2 5/8	68	2 3/4	5 1/2	11	16 1/2
2 3/4	70	3	6	12 1/10	18 1/5
2 7/8	73	3 5/16	6 5/8	13 1/4	19 7/8

October, 1909

THE DESIGN AND MANUFACTURE OF A HIGH-GRADE MOTOR CAR*

RALPH E. FLANDERS†

FOUR years ago, at the New York Automobile Show, the writer's attention was first attracted to the Stevens-Duryea machine, particularly from the standpoint of design. It exhibited a thoroughness and consistency in the proportions and arrangement of its mechanism, which was at that time much rarer in automobile construction than now. The good impression then produced has been deepened by a recent visit to the factory, where the management very courteously granted the freedom of the shop, and answered without a quiver or qualm all the questions that a prying editor could think to ask. Some of the results of this visit are here set forth.

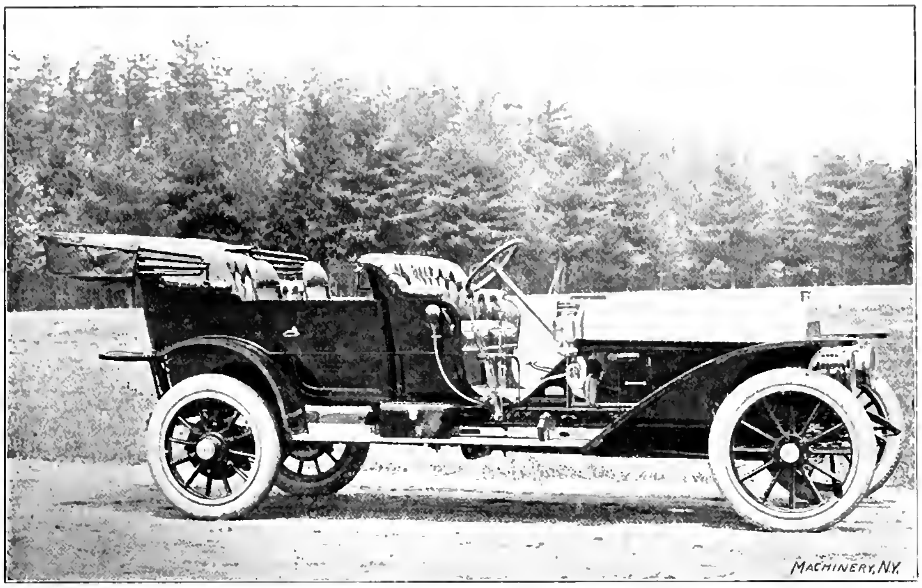

Fig. 1. Stevens-Duryea "Big Six" Motor Car, 1910 Model

The Factory and its Product

The shops of the Stevens-Duryea Co. are located at Chicopee Falls, near Springfield, Mass., in part occupying buildings originally used by the Spaulding bicycle factory. The business was founded by Mr. J. Frank Duryea and Mr. William H. Remington, who began experimenting with automobiles in 1892. Mr. Irving H. Page later became interested in the work, and his firm, the J. Stevens Arms and Tool Co., commenced making cars for the market in 1899. The business grew so rapidly that it was found wise in 1905 to organize a separate firm—the present Stevens-Duryea Co.

These shops are at present building a 40 H. P. six-cylinder machine, a "light six," 35 H. P., and a four-cylinder 24 H. P. car made in two lengths of base. Many of the engine and transmission parts of the 40 H. P. and the four-cylinder machines are identical, thus simplifying the manufacture to a marked extent.

Description of 40 H.P. Six-cylinder Machine

Without doubt there are many readers of MACHINERY who are quite familiar with the automobile as a machine. There are as many who are not, however, so if the knowing ones will skip the next four or five pages, they will come to an article relating to manufacturing methods, which will doubtless be of more value to them. The average reader, however, should be interested in an elementary description of this car, which, except for certain important details which will be mentioned, may be taken as typical of the design of high-grade cars in general.

In Fig. 1 is shown a side view of the "Model Y," 40 horse-power, six-cylinder machine, with 36-inch wheels and 112-inch wheel-base. An automobile may be divided into two parts—the body and the "chassis." The former is the product of the carriage-maker's art, the latter of the mechanic's and engineer's. The chassis of this machine is shown in Figs. 2 and 3, to which reference should now be made.

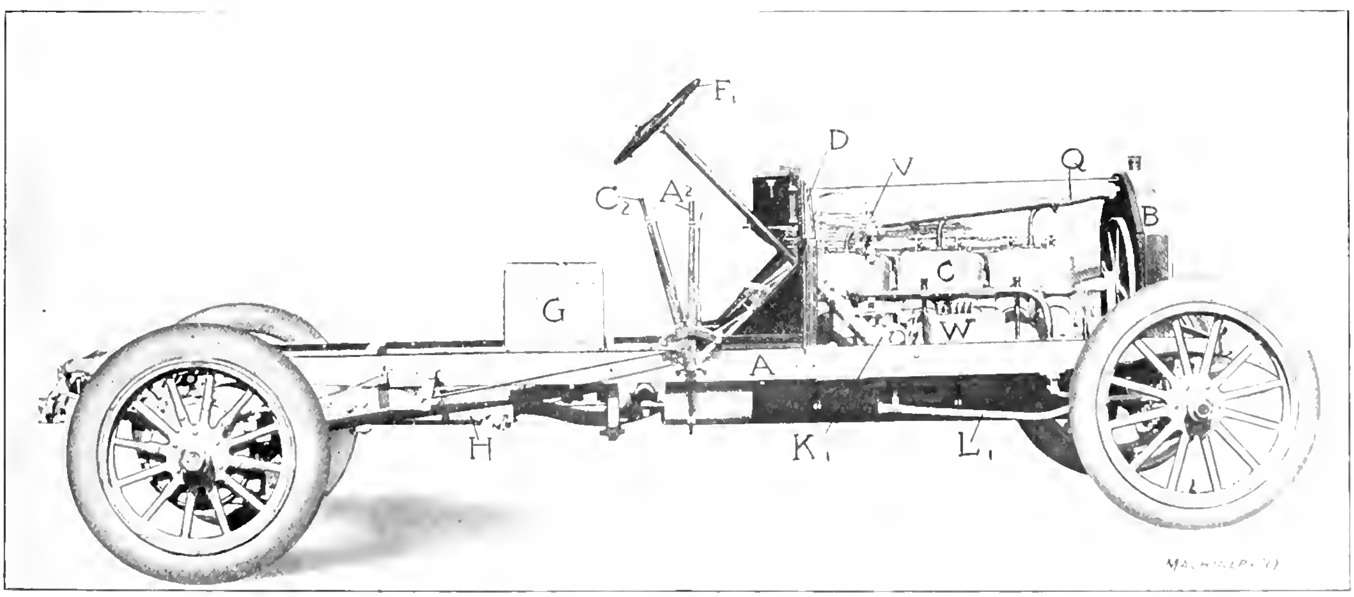

Fig. 2. Side View of Car with Body Removed, showing Chassis

The mechanism and body of the car are supported by a frame whose side members, of chrome nickel steel, are shown at *A*. These are connected by four cross pieces, and are supported on the front and rear axles by the spring connections shown. The cross pieces are also pressed from chrome nickel steel, and are hydraulically riveted to the side frames. A platform spring suspension is used at the rear, hung on connecting shackles designed to overcome the side roll met when round-

* For further information on this subject, see "Machines and Tools for Automobile Manufacture," June, 1909, and articles there referred to.
† Associate Editor of MACHINERY.

ing curves in large and fast cars. The springs are made from steel selected after careful tests of both American and imported materials. The cost of the brand selected was far in excess of the nearest competitor, but it gave an endurance under repeated shock and reversal of stress not met with in any other make.

On the chassis frame are mounted, first the radiator *B*, next the engine *C*, then the dash-board *D* with its steering and controlling mechanism, the clutch and speed change mechanisms at *E* and *F* respectively, the gasoline tank *G*, the muffler *H* for the exhaust, the propeller shaft *J* for transmitting the power to the rear axle, and the rear axle with its differential gearing at *K*.

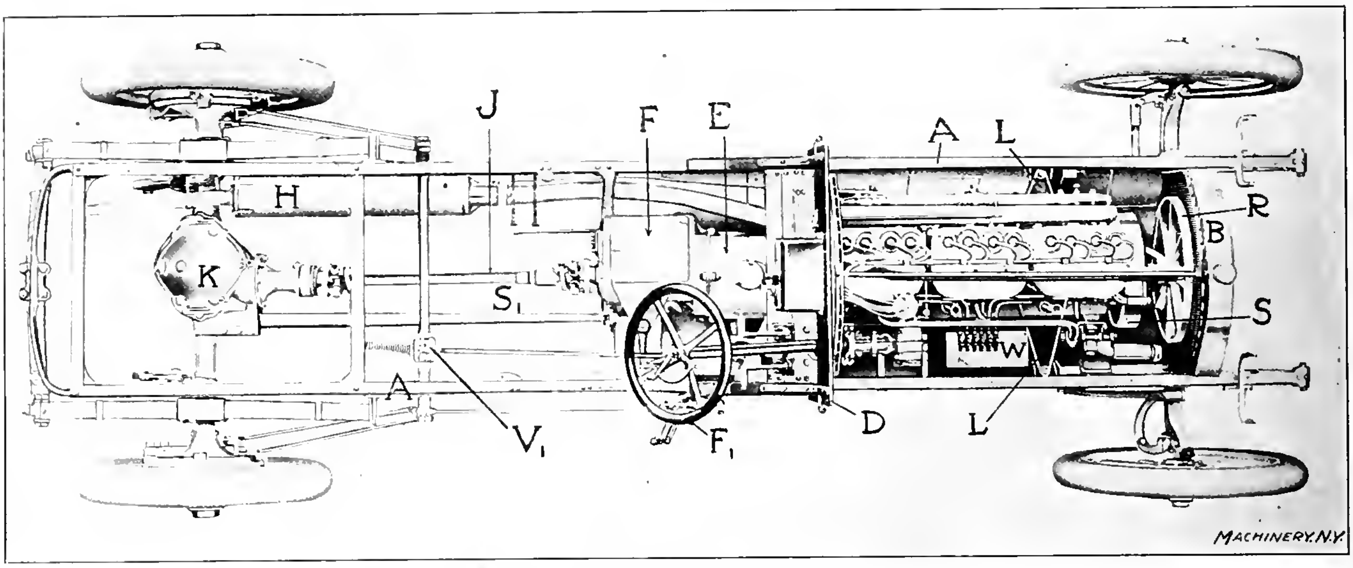

Fig. 3. Top View of Chassis, showing Arrangement of the Mechanism

The Unit Power Plant, with Three-point Support

The engine is shown more clearly in Figs. 4 and 5, which show the "unit power plant" form of construction, one of the important original features of the design. This peculiarity consists in mounting the engine, clutch, and transmission casings as a single rigid member, supported by a three-point bearing on the flexible frame. Supports *L* bear on the two side frames, while pivot *M* is riveted to one of the cross pieces. This allows the whole of the contained mechanism to run without distortion or bending, even on roads which rack the frame severely, and thus results in less friction and lighter structural parts, giving a high available horse-power per hundredweight of load. It also permits the power plant to be assembled as a whole and to be bolted in place without fitting. This construction, which is the distinctive point in the design of this motor, has been successfully followed by the builders for the last five years, and it is one of the things which serve to give an attractive mechanical appearance to the whole mechanism. Only one double set of universal joints is required, that connecting the propeller shaft with the transmission gearing at one end, and the differential gearing at the other.

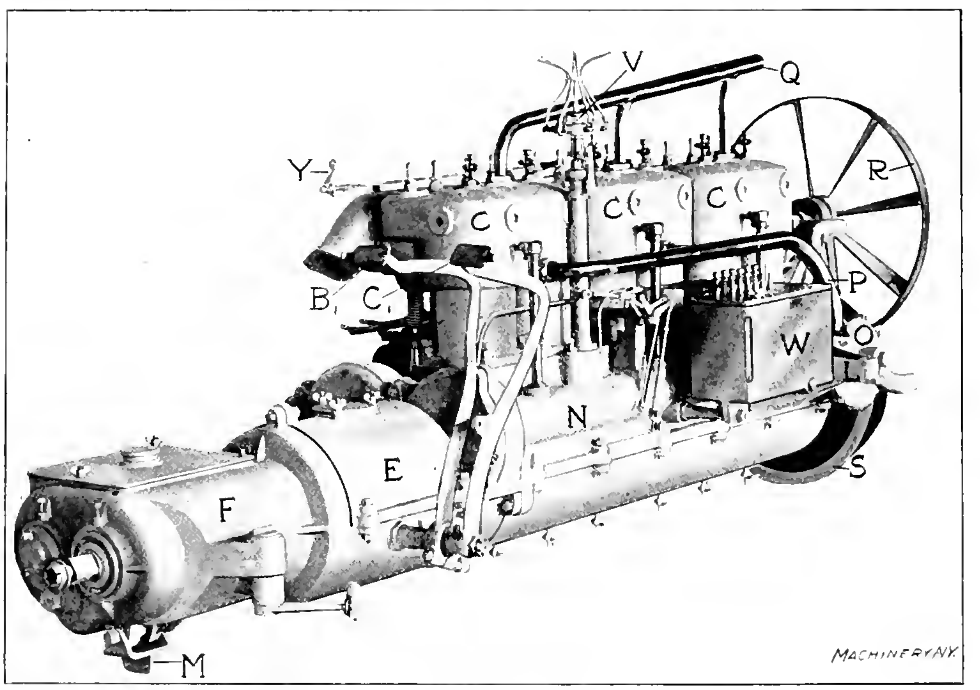

Fig. 4. The Unit Power Plant, comprising Engine, Transmission, etc.; View taken from the Timer and Lubricator Side

The cylinders are grouped in three two-cylinder castings *C*, bolted to the crank case *N*. As is common with internal combustion engines in ordinary practice, they are water jacketed, there being a continuous circulation from radiator *B* through centrifugal pump *O* and pipe *P* to the water jackets, thence back again through the return pipe *Q* to the top of radiator *B*. Here the heated water is cooled by passing through sheet metal channels, having a large radiating surface exposed to the draft of wind produced by the passage of the machine through the air. This draft is increased by an aluminum fan *R*, belted to the pulley on the outside of fly-wheel *S*. An automatic tightening arrangement assures a serviceable drive throughout the life of the belt.

It should be mentioned that the placing of the fly-wheel at the forward end of the crank-shaft, as here shown, is unusual, the common construction being to locate it between the crank-shaft and the clutch. It tends, for instance, to bring more of the weight onto the front wheels, off from the heavily loaded rear wheels of the machine, and permits the reducing of the clearance over the roadbed in the center of the chassis, where there is the greatest danger of striking on high water bars, railroad crossings, etc. It will be readily seen that more clearance is required at the center of the machine than at the axles, when crossing a hump in the road.

Lubrication, Ignition, etc.

Two shafts mounted in the crank casing, on either side, above and parallel to the crank-shaft, are driven from it by enclosed gearing. The one at the side shown in Fig. 5 is the cam-shaft and is provided with twelve sets of cams for operating the six inlet and six exhaust valves, whose stems and

closing springs are plainly shown in the engraving. The driving gear of this cam-shaft is also connected with a pinion on the armature shaft of the magneto, whose function will be described later. The shaft on that side of the machine shown in Fig. 4, is known as the lay-shaft. Its office is the driving of the timer V which controls the ignition, the driving of the forced lubrication mechanism at W, and of the water jacket circulation pump O.

gasoline, and a supply of fresh air to furnish the oxygen for the charge. The gasoline is received in a float chamber, where the level of the liquid is maintained by a suitable float and valve. An automatic valve provides for a constant proportion of oxygen and fuel at widely-varying speeds. The carburetor is provided with a throttle which controls the needle valve connection in the feed pipe, together with the butterfly valve in the suction to the cylinders, thus providing

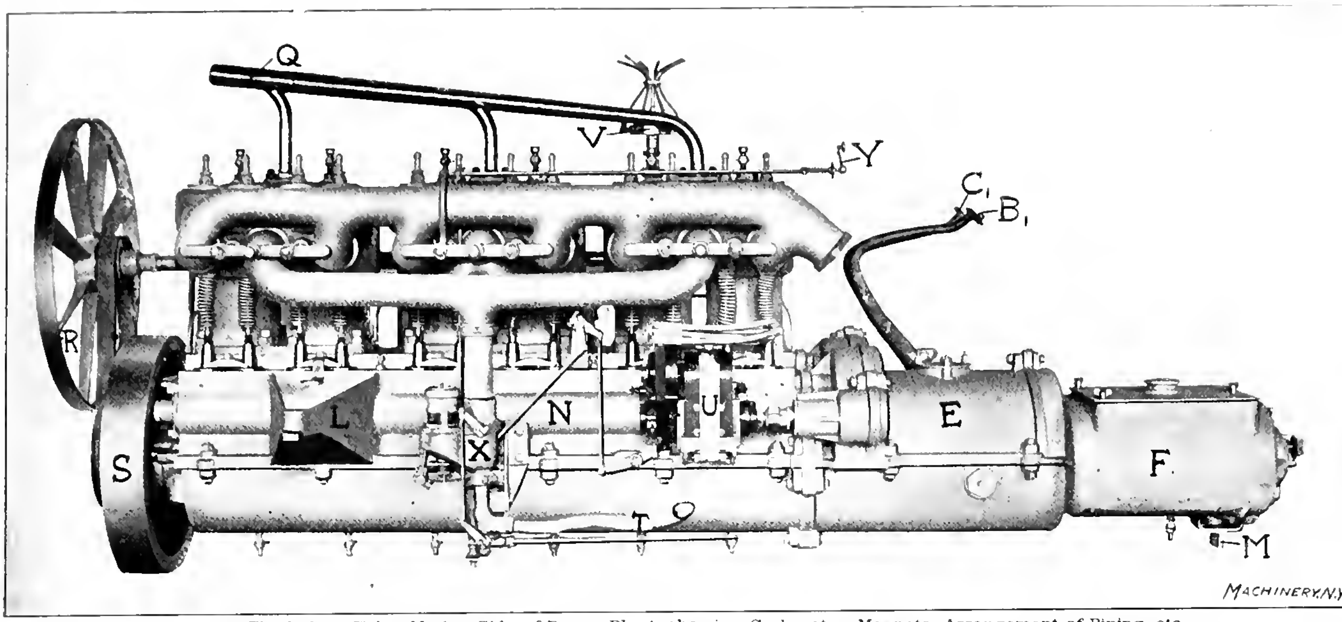

Fig. 5. The Left or Valve Motion Side of Power Plant, showing Carburetor, Magneto, Arrangement of Piping, etc.

The lubricator gives a forced oil supply with sight feed, and is always in operation when the engine is in motion. The six-throw crank-shaft is mounted in four bearings in the crank case, with two cranks between each pair of bearings. The boxes at these points are connected with the lubricator W. The lower half of the crank case forms a reservoir for

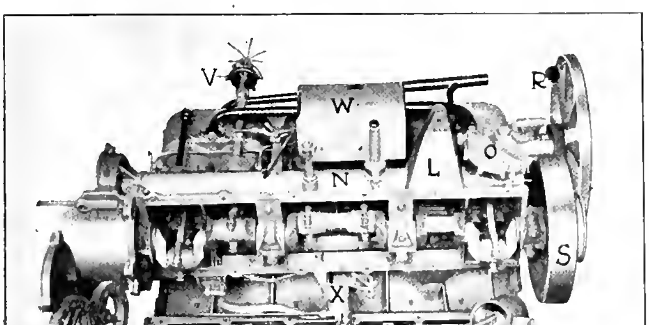

Fig. 6. View of Engine from Beneath, showing Removal of Piston, Cam, and Lay-shafts, etc., without Dismantling

the oil escaping from the main bearings. The connecting rod splashes into this and thus supplies the pistons, connecting-rod bearings, etc., with the necessary lubrication.

The ignition in each cylinder is effected by either of two systems, the one by storage or dry battery and induction coil, and the other by means of a magneto U connected by gearing with the crank-shaft. The battery and spark coil is used in starting, while the magneto is used for regular running. The spark coils and switches are located on the dash-board. A lever on the steering wheel, as will be described, is connected with the commutator or timer V, which distributes the current to the six cylinders, in such a way as to enable the operator to advance or retard the spark at will.

The Carburetor and Fuel Supply

An important and rather delicate piece of apparatus essential to the operation of the gasoline engine, is the carburetor, shown at X in Fig. 5. This receives a supply of gasoline through a feed pipe from the tank G (see Fig. 2), a supply of air through T heated by the exhaust gas for vaporizing the

the driver with means for varying the amount of charge furnished the machine; this controls the speed without shifting the gears in the transmission case. The automatic air valve is controlled from the seat by a handle Y on the dash-board, which permits the obtaining of a proper mixture for the starting. A button at the front of the radiator, where the machine is cranked for starting, also provides means for flooding the carburetor with fuel for a send-off. The throttle is controlled from a lever on the steering wheel concentric with the spark control lever or from an "accelerator pedal" on the foot-board.

The gasoline supply tank G is located under the front seat. It contains a partition near the bottom which saves about three gallons out of its twenty gallons' capacity, for use in emergency. By the manipulation of cut-off valves passing

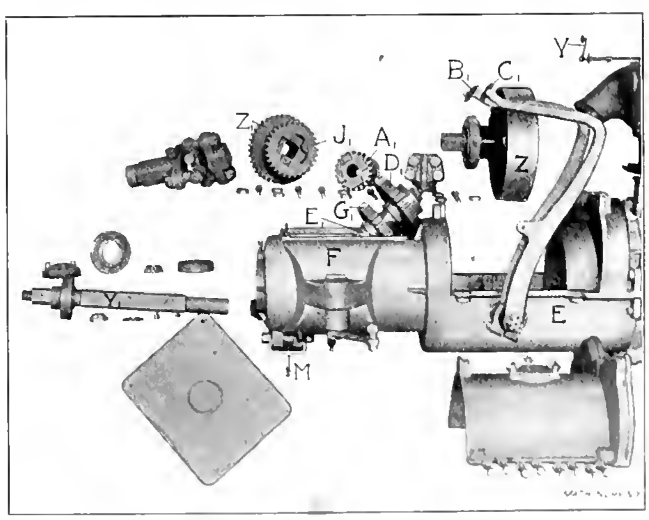

Fig. 7. Clutch and Transmission Gear Members Dismantled to show Construction

through the left side frame of the chassis, it is possible to use this reserve supply after the tank has been otherwise exhausted. This provision is a great comfort to the motorist at critical times.

The Clutch and the Transmission Gearing

In casing E is mounted the clutch Z (Fig. 7) connecting the engine with the transmission to the driving wheels. This is of the multiple disk type, with alternate disks keyed to the

driving and driven members. The driving disks have a wired asbestos facing which makes a superior friction surface, and gives a high resistance to heat as well. This construction obviates, and in fact makes impossible, the use of oil in the clutch. The friction surfaces are held in engagement by a spring, and are released by a pedal B_1, which projects through the foot board at the driver's side of the machine. The spring is so proportioned as to give a smooth, easy engagement, entirely out of the control of the driver, who thus finds it impossible to start the machine with a sudden shock. The second foot lever, C_1, is connected with the rear wheel brakes, as will be described. The driven member

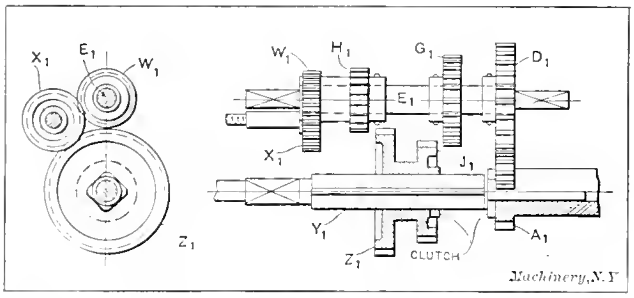

Fig. 8. Sketch showing Arrangement of Gears in Transmission Case

of the clutch is connected with the driving shaft in the transmission case or speed box F. Contained within it is a mechanism which, by the aid of the sliding gears, clutches, etc., permits of the obtaining of three forward and one reverse speed.

The operation of this gearing will be understood from the sketch shown in Fig. 8. Gear A_1 receives its movement from the clutch. It meshes with gear D_1 keyed to the secondary shaft E_1, which is thus in motion whenever the engine is running and the clutch is engaged. This shaft carries also gears G_1, H_1, and W_1, the latter of which drives, in turn, the idler X_1. Squared shaft Y_1 is directly connected by means of propeller shaft J (Fig. 3) and the universal joints with the rear axle. On Y_1 is mounted the double sliding gear Z_1. Clutch teeth are provided in the faces of the gears A_1 and J_1.

In the position shown in Fig. 8, the transmission is in the neutral position, so that the motion from the clutch is not transmitted to the axle. The right-hand end of shaft Y_1 lies loosely in the revolving gear A_1. When the sliding gear is thrown to the extreme right, the clutch faces of A_1 and J_1 are engaged, so that shaft Y_1 is driven directly, and at the highest speed, from the clutch. By shifting it a step to the left, J_1 is thrown into mesh with G_1, thus giving a lower rate of speed through the back gear shaft E_1. A still further movement to the left, past the neutral point shown in the engraving, brings Z_1 into engagement with H_1, giving the lowest forward speed. A final movement to the left engages Z_1 with idler X_1, thus reversing the drive.

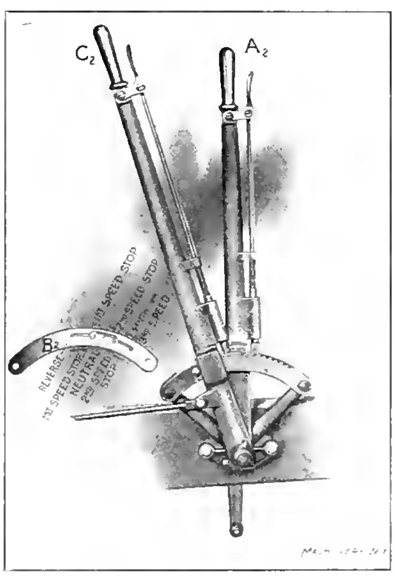

Fig. 9 The Speed Gear Control and Emergency Brake Levers

The shifting of gears Z_1 and J_1 is effected by a forked lever connected with lever A_2 (Fig. 9) at the side of the machine, which thus controls the speed changes. This lever is provided with a latch connected with a pin in the slot of the quadrant B_2, operating in a manner easily understood from the engraving. It will be seen that it is possible to move between the reverse and the lowest speed, or between the second and the high-speed, without touching the latch, and it is possible to make all the movements rapidly and precisely by the sense of touch without looking at the quadrant at all.

The Differential Drive

Propeller shaft J leads from the transmission case F to differential case K on the rear axle. The bevel gear M_1 (Fig. 11) is connected with the two rear wheels by a differential mechanism, whose function it is to give an equal tractive force to each of the two wheels, but at the same time to permit either of them to run ahead or lag behind the other as may be required in rounding curves, riding over obstructions, etc. The principle of this mechanical movement will be understood by referring to Fig. 10.

Referring first to the sketch at the left, N_1 is the pinion on the propeller shaft and M_1 is the driven bevel gear, concentric with the axle. This gear and shell O_2 to which it is bolted, revolve freely on the hubs of E_2 and F_2. Within the shell are mounted radial pivots on which revolve, loosely, bevel pinions D_2. These engage with bevel gears E_2 and F_2, connected respectively with the right- and left-hand axle shafts T_1. It will be seen that under ordinary conditions the rotating of gear M_1 carries gears E_2 and F_2 along with it, by the pull exerted on them by the bevel pinions D_2, which are stationary; thus the two rear wheels are driven at the same rate of speed. Suppose now that the right-hand wheel be held from turning, so that gear E_2 is stationary, then the rotating of bevel gear M_1 will roll pinion D_2 about on E_2 with

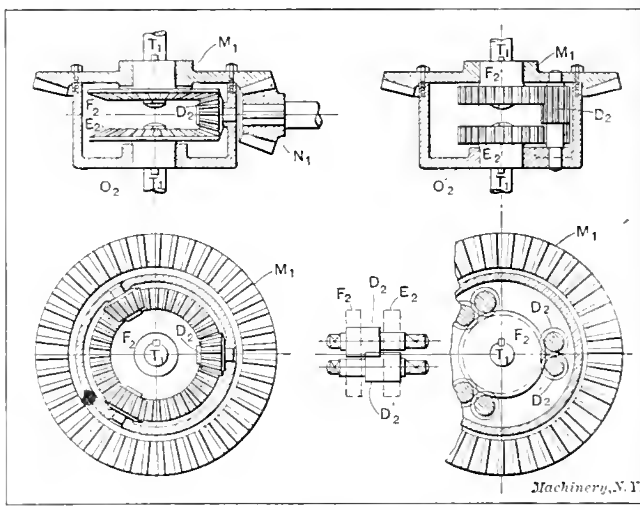

Fig. 10. Sketch showing Principle of the Bevel and Spur Gear Types of Differential Gearing

a compound action, which will give F_2 twice the rate of speed it had before. In the same way, F_2 can be held from revolving, in which case E_2 will have twice its normal speed, or either of them may be slowed down, in which case the other is speeded up correspondingly. The driving force on both wheels, however, is always the same.

An alternative form of this device is shown at the right of Fig. 10, in which each of the bevel gears D_2 is replaced by a pair of spur pinions D_2 and D'_2, meshing with each other and with spur gears E_2 and F_2 as shown. A little study will show that the action of this device is identical with that shown in the sketch at the left of the figure, the only change being the employment of spur gearing in place of bevel gearing. The differential used on the Stevens-Duryea machine is of the second or spur gearing type.

The Full Floating Type Rear Axle

The differential gearing is contained in the casing O_1, which forms the central member of the axle. Tubular extensions to either side carry the spring supports P_1 on which the weight of the car rests. The brake flanges Q_1 and the wheel bearings at R_1, all of which are solid with each other, are nonrotating. The rear axle, however, is permitted to rock in spring supports P_1. The torque rod or tube S_1, which is fast in case O_1, extends toward the center of the chassis, where it is hung in a spring suspension as seen in Fig. 3, permitting a limited vibration up or down, with a constant force urging it toward a central position. This construction furnishes the resistance against the climbing of pinion N_1 on bevel gear M_1. In case of sudden starting or stopping, a limited amount

of climbing either way is permitted, the torque rod being raised or lowered against the spring pressure to correspond. This greatly decreases the danger of gear breakage.

The construction thus described belongs to what is known as the full floating type axle. The wheels are mounted on ball bearings on stationary journals R_1. Shafts T_1 are provided with squared driving ends engaging sockets in the differential gearing in casing O_1 at one end, and similar sockets cut in driving dogs U_1 at the other end. These latter members have driving slots engaging dove-tails in the hubs of the wheels, to which the power is thus transmitted. The

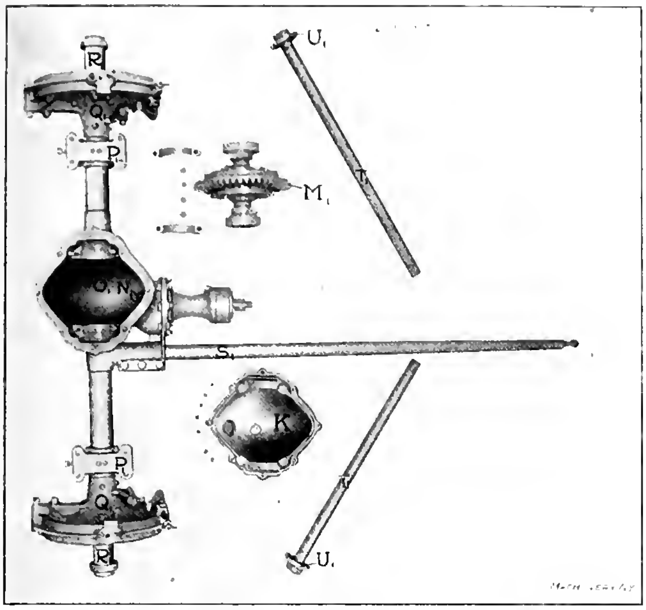

Fig. 11. The Full Floating Type Rear Axle, Differential Gearing, etc.

squared ends of shafts T_1 are rounded to permit a slight rocking movement in their sockets in the differential gearing and driving dogs U_1. This permits the springing of the rear axle under the load without cramping the driving mechanism.

To allow for the springing of this axle under the load, the two sections of tubing on either side, between members O_1 and Q_1, are held in bored seats which point downward at an angle of ½ degree from the horizontal on each side. Thus the rear axle wheels point in toward each other at the bottom on an angle of ½ degree from the vertical, giving a much better appearance than would be the case if they should by some mischance point the other way. It would take a load in excess of any which would ever be applied to spring the axle and bring the wheels into the vertical plane. It is stated that when the wheels are exactly vertical, they have the appearance of being sprung out at the bottom, into the position occasionally seen in a vehicle of the "one-horse-shay" type.

The Brakes

The brake mechanism of the automobile is of the utmost importance, as is realized by anyone who has had anything to do with these machines whether as driver, passenger or pedestrian. It is usual to provide two complete sets of braking mechanism, one for regular use and the other for emergency. That for regular use is controlled by the foot lever C_1 (see Fig. 4) which is connected with a reach rod leading to double cranks on a transverse rock-shaft at V_1 (Fig. 3). One section of this rock-shaft is connected with the brake at the right side of the machine, and the other at the left. An equalizing lever between the two insures an even pressure on each of these two brakes, even though one be much more worn than the other. The brake is of the band type, applied to the outside of a brake rim fast to the hub of the wheel. The emergency brake is operated by lever C_2 (Fig. 2). This, by means of a second rock-shaft concentric with V_1, controls internal expanding ring brakes in the hubs of the wheels.

The Control of the Machine

The steering gear will be best understood from Figs. 2, 3 and 12. The wheel F_1 is mounted on a tubular shaft which carries at its lower end a worm engaging the segment of a worm-wheel G_2 in casing K_1. To the hub of this segment is connected a bell crank H_2 which, through the operation of the steering rod L_1 (see Fig. 2) and suitable connecting cranks and links, turns the front wheels to the right or left as may be required. Spring cushions are provided at the ends of steering rod L_1 so that sudden shocks and twists of the wheels are not transmitted to the worm-gearing and the steering wheel, even when traveling at a high rate of speed. As most of our readers doubtless know, the center line of the pivots about which the wheels are swiveled meets the road at about the point where the tire touches it. This makes it possible to turn the wheels easily when standing still, and decreases the danger of accident while running, as well.

As previously stated, the throttle control and the timing of the spark are effected from levers placed at the hub of the steering wheel. Lever K_2 controls the throttle. This is mounted on a tube passing through the steering wheel tube and connected at its lower end by bevel gear segments with a bell crank L_2, which is, in turn, connected by suitable rods and levers with the carburetor. Inside of the throttle lever tube is still another fixed tube on which is mounted the segment M_2, which is thus held stationary. This is provided with notches for locating lever K_2, and lever J_2 as well, which latter controls the timing of the spark. This is mounted on a rod which passes through the center of the system of tubes and is connected by bevel segments with lever N_2 leading to the commutator or timer V.

It may be well to recapitulate as to the functions of the levers, etc., used in the control of the machine. At the front of the radiator is the crank by which the motor is turned, for starting. By the side of it is a button connected with the carburetor, for flooding the latter at starting to obtain a rich mixture on the first stroke. On the dashboard is mounted a lever Y, for setting the automatic air valve to supply the proper amount of oxygen for starting. Beside it is a switch for throwing the ignition spark from the battery to the magneto when the machine is changed from the starting to

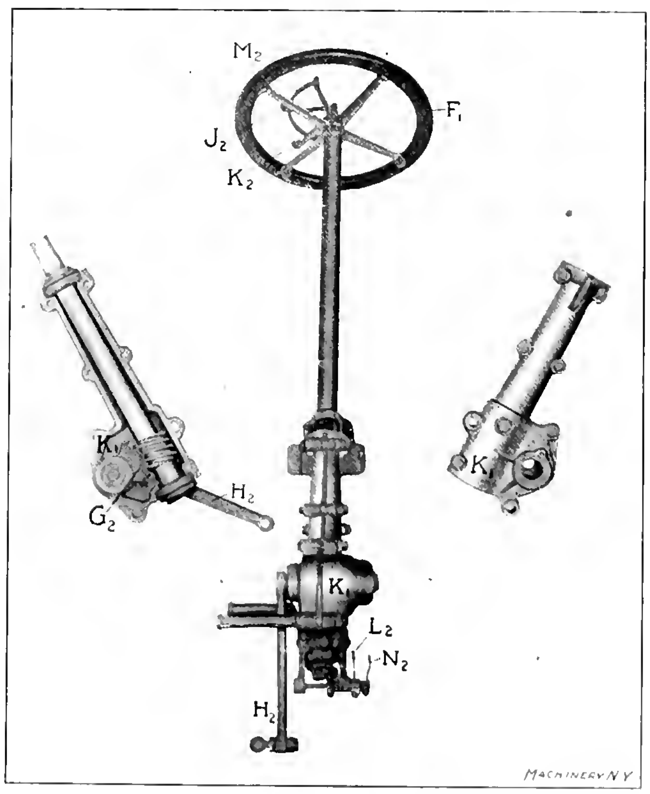

Fig 12. The Steering Post, with its Throttle and Sparking Connections

the running condition, and *vice versa*. On the dashboard are also mounted the spark coils. Through the foot board project the two pedals B_1 and C_1 controlling the clutch and the operating brake respectively, as described. Hand levers C_2 and A_2 control the emergency brake and the speed changes respectively.

Two small pedals are also provided on the foot board. One of these is connected with the throttle in such a way that this may be controlled by the foot instead of by the hand if required. It is called the accelerator. By its use, when the hand throttle lever has been set to a certain point, the valve may be opened clear out to the maximum, as desired, by the

foot, thus giving immediate control under varying conditions of traffic. The other pedal operates a valve which cuts out the muffler. This is occasionally done to make the exhaust audible, for finding out how the engines are working, and also for removing the back pressure, and thus giving every ounce of power possible on critical occasions. At times, too, it would seem to the disinterested bystander that the muffler is cut out from "cussedness" pure and simple.

These levers, pedals, etc., with the main and supplementary gasoline supply valves previously mentioned, give the driver complete control of a powerful, swift machine, if he has the knowledge, experience and nerve to use them properly.

General Considerations in Automobile Design

A glance at the illustrations will serve to show that the chassis of the modern high-power automobile is a rather complicated, highly-specialized, and carefully-designed piece of mechanism. It is within the memory of the child in kindergarten when this was not the case, and the writer has painful memories of his duties as consulting physician to one of the best of the machines in existence six years ago. At that time, the mechanism of the automobile did not have the homogeneous, appropriate structure that the successful machines of the present day possess. It had a gasoline engine, an epicyclic speed change mechanism, a jack-in-the-box differential gear, and chains leading to the rear wheels of a "horseless carriage." Over the mechanism thus described wandered a maze of levers, braces, pipes, wires, etc., supported at intervals at any part of the mechanism which happened to be in convenient reach. That, however, was before the automobile "found itself." The present development has been the result of the experience of many men with break-downs and failures, as well as of an enormous amount of theoretical work in the matter of testing of materials and analysis of conditions. These theoretical and practical results have been combined on the drawing board and the resulting machine has the appearance of having been *designed* rather than simply *built*.

The guiding principles in the design of the automobile relate to strength, power, lightness, durability, accessibility, and economy in operation. The matter of economy in construction and materials is about the last thing to be thought of, instead of the first, as with many other classes of machinery. The severe and often reckless usage received by one of these machines demands special treatment in the design and construction which should not ordinarily be necessary.

As an illustration of what has been said in this respect, attention may be called to the method of connecting the driving members of this machine from the engine through to the wheels. In no place throughout the length of the chassis are keys used for this work. Reliance is everywhere placed on square joints or dovetailed flanges. The crank-shaft is connected with the driving member of the clutch by a square taper socket. The driving member of the clutch is connected by a square socket with the driving shaft of the transmission gearing. The sliding gears of this mechanism are mounted on squared shafts, and the same squared drive is used for the universal joints, propeller shafts, pinion shafts, etc., through the intermediate pinions in the differential gearing at M_1 in Fig. 11, and through driving shafts T_1, to the driving dogs on the wheel hubs. These latter, as well as the side plates of the differential gearing, drive or are driven by the engagement of dovetailed teeth. The possibility of the shearing of keys, always present in machine parts subject to shock, is thus avoided. The makers believe themselves to be the only firm employing a complete drive of this kind.

In the matter of accessibility, a study of Figs. 6 and 7 will be found interesting. By removing the lower crank chamber casing and turning the crank-shaft to the proper position, the piston and piston rod may be removed without further trouble, and without removing cylinders or cylinder heads. The same is true of the cam- and lay-shafts. The covers provided for the clutch and transmission casings give evidence of care in providing easy means for inspection and removal of all parts likely to need attention. With a well-designed machine the man on his back under the motor car is a mere figment of the imagination.

Take it all in all, the present-day automobile is a machine of which the mechanic and engineer may well be proud.

MANUFACTURING METHODS IN THE STEVENS-DURYEA AUTOMOBILE WORKS

The subserviency of manufacturing considerations to considerations of strength, durability, accessibility, etc., mentioned in the preceding article, results in the design of parts which require special and interesting provisions for their economical production. Only a few of the operations particularly noticed in the Stevens-Duryea factory will be described here. They will serve, however, to give an idea of the general practice in such work, and will illustrate the ingenuity required for the solution of some of the problems.

Operations in the Machining of Cylinders

In Fig. 1 is shown a Beaman & Smith combined horizontal and vertical milling machine engaged in surfacing the base,

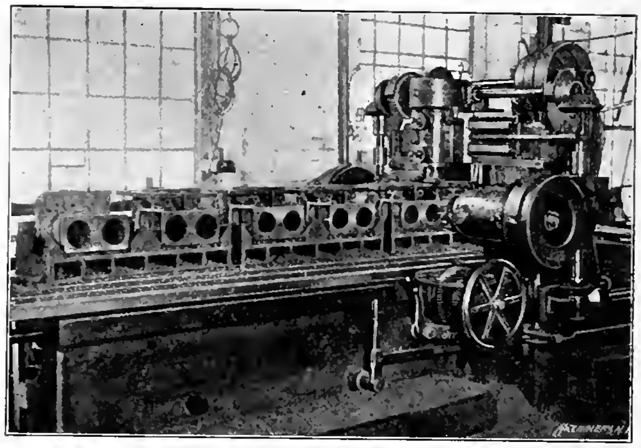

Fig. 1. Gang Milling Operation. Surfacing Cylinder Sides and Ends

exhaust and inlet flanges, and the spark plug bosses of a series of cylinder castings. The work is mounted in gangs according to the most approved methods. The picture is chiefly interesting in that it shows that the builders take advantage of wholesale manufacturing methods even in the building of a $4,000 machine. Of course, an extensive use of jigs and fixtures, besides reducing the cost of manufacture, results in a greater uniformity in the product and thus gives the advantage of an easy renewal of worn or damaged parts.

Fig. 2 shows a Beaman & Smith boring machine of a type we have illustrated and described in these columns. Fixtures mounted on the rotating table give provision for holding four double-cylinder castings. This table can be rotated and ad-

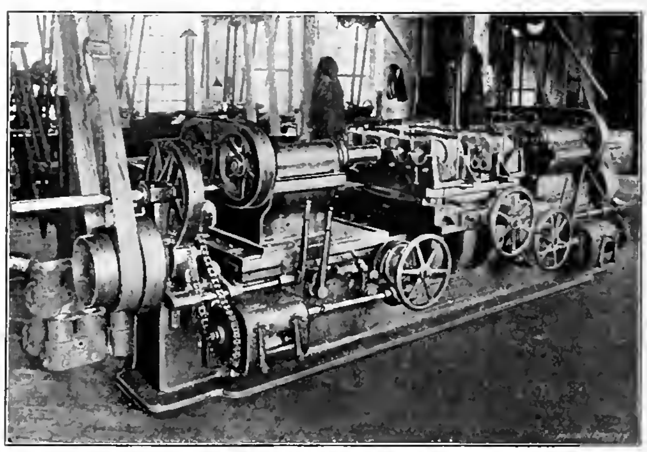

Fig. 2. Four-cylinder Boring Machine with Revolving Table

justed across the bed of the machine. On each side of the table, double boring heads may be fed in along the bed, one carrying roughing and the other finishing cutters, the feeds and speeds of the two heads being independent. A set of two castings being in place on the roughing end, the head is fed into them and one hole in each casting is roughed out. The work-table is then shifted, by means of the hand-wheel, against suitable stops and the other bore of each cylinder is roughed. The table is then indexed to bring these castings to the finishing side, where the same operation is repeated, the boring being here carried to size for grinding. This rotating of the table, in turn, brings a new set of the cylinders up to be rough-

bored. The process is continuous, the work being removed from the finishing side and new cylinders clamped in, while the rough boring is being completed.

For setting out the cutters in the boring bars, a construction is used which is similar to Fig. 16 of the Data Sheet of the May, 1909, issue of MACHINERY, except that a taper screw is used for forcing the blades out simultaneously. This is shown in Fig. 3 at the left. The cutters *B* bottom on this taper-headed screw *C*; filister head screws *D* serve to keep the blades forced down to their bearing on *C*, and so draw them firmly against the side of the slot. By this means two or more blades may be set out simultaneously for regrinding to exact size. A similar arrangement (see view at the right of Fig. 3) is used for cutters in the middle of long boring bars, except that the taper point of a screw tapped into the bar from the side, is used in place of the corresponding taper-headed screw in the first case.

The bore of these cylinders is finished in Heald internal grinding machines especially built for this work. These are

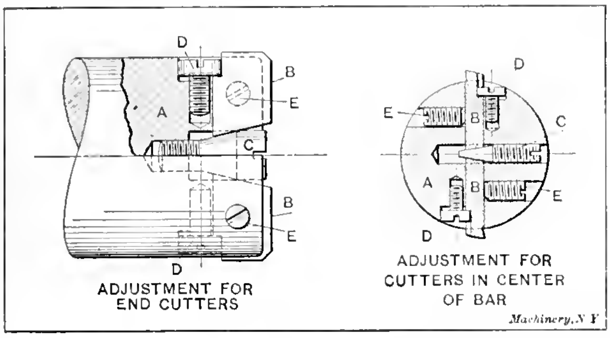

Fig. 3. Adjustment used for Boring-bar Blades

of the type in which the work remains stationary while the axis of the spindle is revolved about the center line of the bore and parallel with it, on such a diameter as to bring the outer periphery of the wheel in contact with the inner surface of the bore. The grinding spindle is fed out so as to rotate in a larger circle as the diameter of the bore is increased. An interesting feature shown in Fig. 4 is the provision of a flexible suction tube for drawing out the dust of the grinding through the inlet and exhaust ports, and also the provision made for water cooling. The water is not applied directly to the wheel, as in an ordinary external grinder, but is forced

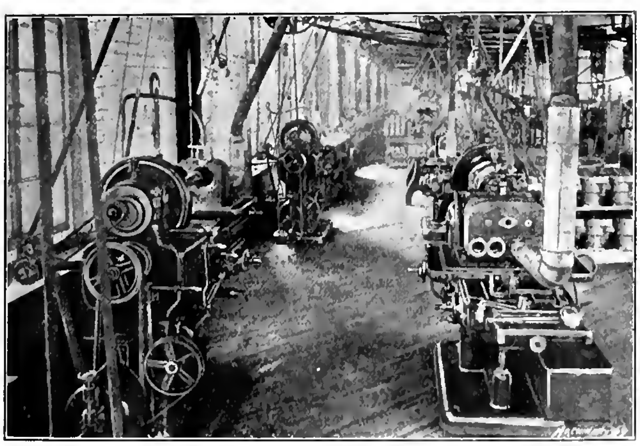

Fig. 4. Grinding the Cylinders. Note Connections for Exhausting the Dust and the Use of the Water Jacket for Cooling

instead through the regular water jacket of the cylinder casting. This reproduces, in a measure, the conditions met with in actual use, and so tends toward accurate work.

Machines and Fixtures for Grinding and Lapping

There are other operations of interest in the grinding department besides that of finishing the bore of the cylinders. Extensive use is made of the Pratt & Whitney face grinding machine for finishing flat surfaces; in fact, it has largely displaced the vertical milling machine for this work, on parts in which the surface to be finished is clear of projections or obstructions to the sweep of the wheel. The faces of the various castings, covers, inlet and exhaust pipes, etc., are finished on this machine. At the time of the writer's visit, most of these parts were still being made from castings on which 3/16 inch of stock had been left, in accordance with the usual practice of milling. The castings come true enough to shape, however, to permit this finish being reduced to 1/16 of an inch, or thereabout, thus materially reducing the time required.

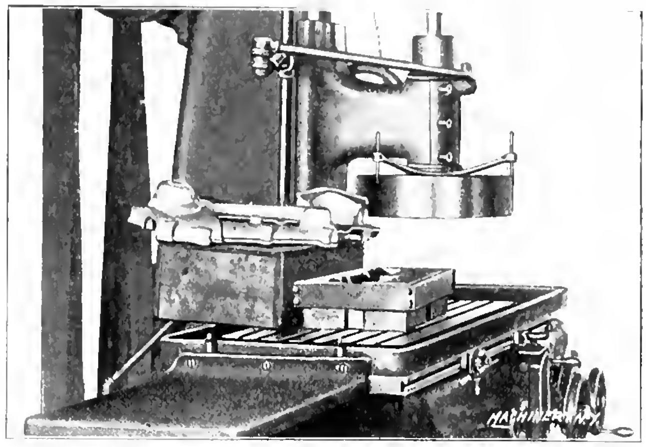

Fig. 5. The Acme of Simplicity in Fixture Making. Face Grinding the Steering Gear Casing

Even when removing 3/16 inch of stock the grinding machine has proved its superiority to the milling machine in the matters of cost, finish and accuracy. The foreman of the grinding department discovered that a little experimenting and investigating along the line of the grading of wheels made a tremendous difference in their durability and effectiveness in removing metal. For aluminum work a Vitrified

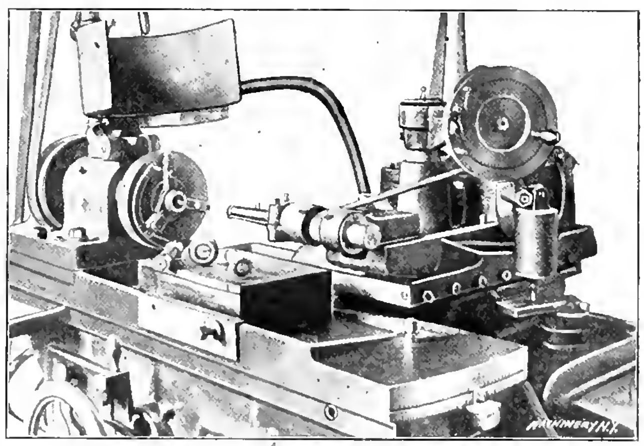

Fig. 6. Grinding the Bore of the Cams Concentric with the Cylindrical Surface

carborundum wheel of about No. 24 grain and grade H hardness is used, a soda compound being employed for cooling.

The cover side of the steering gear casing is one of the parts surfaced on the face grinder. A ridiculously simple fixture is used for holding it. This fixture, as may be seen in Fig. 5, is nothing more or less than a mass of lead melted and poured around a sample casting as a form. The work is set into the bed, thus prepared to receive it, and is supported on the table by its own weight, no fastening being necessary. The castings come uniformly enough so that they fit well in this device, except at certain points around the gates and sprues, where it is found necessary to relieve the form slightly to allow for these variations. It may be mentioned that the other or main member of the steering gear casing has a boss projecting above the finished surface of the joint, making it necessary to mill that surface. The joint is thus formed of one ground and one milled surface.

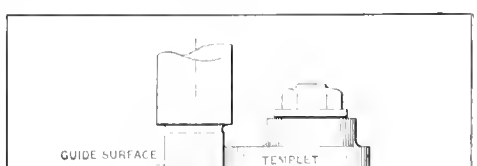

Fig. 7. The Simplest and Stiffest Arrangement for Cam Cutting

In Fig. 6 is shown the operation of grinding the holes in the cams. It is quite important that the cylindrical portion of the cam shall be exactly concentric with the cam-shaft to prevent shock or jar during the period when the valves are supposed to be closed. To make sure that this surface is concentric, the cam is located by it in the grinding fixture as shown. After the fixture has been mounted on the faceplate of the machine, the gripping surfaces of the two jaws at the right are ground out by the internal grinding attachment, to the radius of the cylindrical dwell of the cam. The cam is clamped against the surface thus prepared, by the lever, which forces a wedge across and down upon the cam, holding it firmly into the corner in both directions.

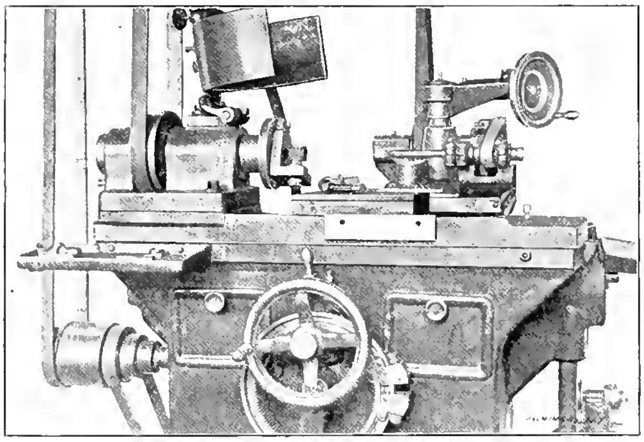

Fig. 8. Grinding the Holes in the Universal Joint Pivots

It will be seen that this car does not employ the integral cam-shaft. By giving careful attention to the locating of the cams on the shaft and by being careful to obtain a strong drive fit between them, the difficulties of loosening and dislocation, which the integral construction is expected to cure, have been avoided. It is thus permitted to cut the cams in a way which gives the best chance for producing accurate shapes and smooth finish. The obvious scheme shown in the sketch, Fig. 7, is followed, the operation being performed on a profile machine. The connection between the forming cam and the work is so close that the difficulties of springing and chattering, met with in the construction of the more elaborate machines required for integral cam-shaft, are avoided.

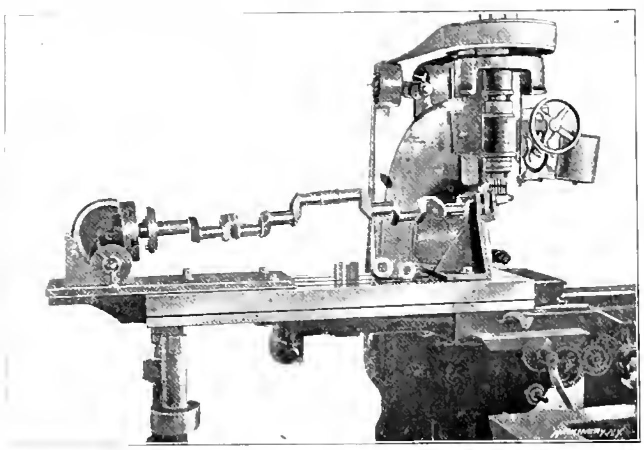

Fig. 9 A Vertical Milling Machine set up for Milling the Tapered Square Drive on the Crank-shaft

Another faceplate fixture for internal grinding is shown in Fig. 8, where it is employed for grinding the hole in the hardened nickel steel sockets used for the universal joints (see Fig. 7, previous article). The socket is held in the same way as when in use, by a nut screwed onto its threaded shank. It is also located in the same way, a pin in the fixture engaging a slot in the flange as shown. A limit of 0.0005 inch only is permitted in this operation, and an allowance of about 0.003 inch for the depth of the hole is the maximum, just enough being permitted for proper lubrication by the grease supply provided. This fixture is kept in place on the machine practically throughout the season. If at any time it is necessary to remove it, however, it can again be trued up by clamping a model socket in place, inserting a plug in the ground hole, and truing up the plug. These studs are held in the same way in the screw machine for roughing out the hole preparatory to grinding. The form of internal grinding spindle used should be noted. One of them is shown detached in Fig. 6, lying on the table of the machine. These spindles and their bearings are self-contained, interchangeable and adapted to work in holes of various sizes. The clutch drive provided rotates the spindle without side pressure on the bearings.

Machining the Members of the Squared Drive

As previously mentioned, the use of keys is tabooed in the drive of the Stevens-Duryea machine, their place being taken by square sockets throughout. A tapered square drive is used to connect the crank-shaft with the driving member of the clutch. The method of machining this is shown in Fig. 9. It has been found advisable to keep the milling machine set up for this work, continuously, owing to the difficulty of making a good taper square fit. When the machine has once been set it is kept so throughout the season. An ordinary dividing head is used, as shown, tipped up to the angle of the taper. To the face-plate of this dividing head is clamped the fly-wheel flange of the crank-shaft. The outer end of the crank-shaft is supported in a suitable steady-rest as shown. For shorter lengths of crank, filling pieces are employed, having flanges bolted to the face-plate at one end, and to the work at the other. The use of filling pieces permits machining of the full line of crank-shafts without disturbing the adjustments.

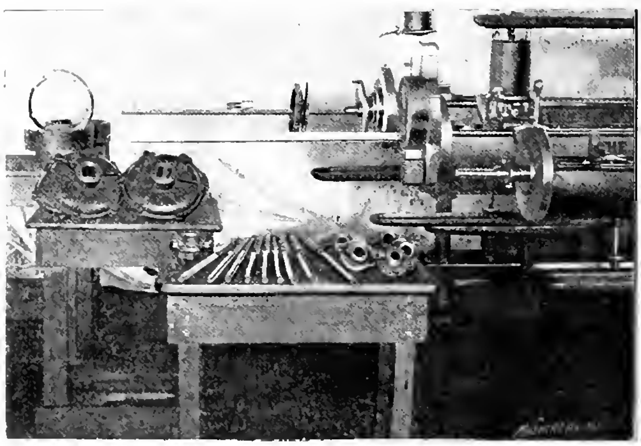

Fig 10. A Set of Interesting Broaching Operations

The automatic cross-feed is employed in feeding the work past the end mill in the vertical milling attachment. The table has to be so far overhung that an out-board support is provided as shown, which permits this cross-feed. This consists of a sliding guide, supported by two standards, reaching to the floor and provided with jack screw adjustments for careful leveling.

The squared holes of the drive are finished on a La Pointe broaching machine in the usual manner. The further machine shown in Fig. 10 is engaged in finishing taper square holes in the clutch driving flange, this being the member into which the taper squared end of the crank-shaft shown in Fig. 9 fits. The hole is first reamed out to a taper a little larger than the distance across the flat of the finished hole. The work is then mounted on a broaching machine on the fixture shown in place. As may be seen, the broach cuts one corner of the square hole, and one-half way up each of the two adjacent sides, into the relief formed by the taper hole. A dog is fastened to the hub of the work, and the latter is mounted

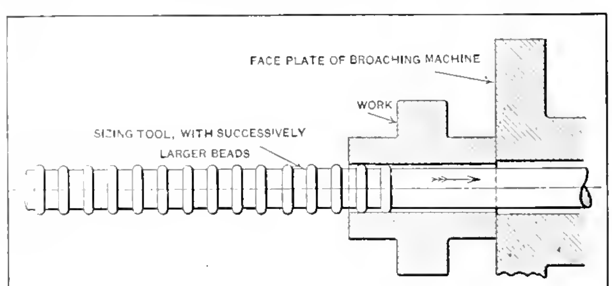

Fig. 11. Method of Sizing Phosphor-bronze in the Broaching Machine by Compression

on a taper plug fitting the hole, with the tail of the dog located by a pin in the face-plate of the fixture, the latter being mounted on the face-plate of the machine at an angle as shown, to agree with the angle of the corner of the tapered sides. This broaching operation was described in October, 1908, page 151.

One pass of the broach finishes one corner of the tapered hole. The broach is then returned to the starting position, the work is drawn off the taper plug, the dog indexed to the second pin on the face-plate, the work is put in position and the second corner broached. This operation is repeated until the four corners have been machined, and the square hole finished, the work being centered on the taper plug of the fixture throughout the whole operation. A taper square gage is shown lying on top of the broach in the engraving. This is used for testing the fit of the holes and the accuracy of the work, and a most accurate fit is made on this by no means easy operation. In the machine in the foreground, another operation is being done—that of broaching the driving slots in the driving clutch members for the multiple disks.

the sizing tool in the broaching machine, it will be found that the hole will be somewhat larger in the large diameter of the work than in the hubs. It has been found that this difference in size can be practically avoided by passing the sizing tool through the work three or four times. Few pieces of this kind are found, however. The operation is a rapid one as compared with reaming.

An Adaptable Lapping Machine

The machine shown in Fig. 12 was built mainly in the factory, use being made, however, of the adjustable columns of a Taylor & Fenn sensitive drill press. This special machine is intended for lapping out the square holes of the drive, but is provided also with a rotary movement in addition to the vertical movement thus necessary, so as to provide for cylindrical lapping as well. The driving pulley at the right gives the reciprocating motion, while the pulley at the left rotates the spindles through the medium of the regular geared speed drive. The sprocket wheels shown, driven from the right, are loose on the driving shaft, and carry eccentrics whose rods are extended to form racks engaging, through a

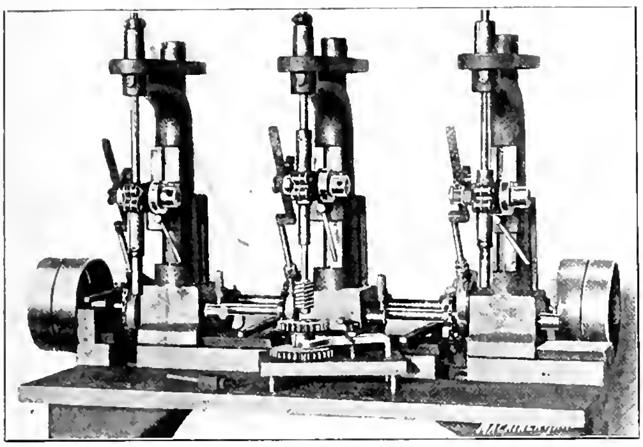

Fig. 12. Machine for Circular and Square Lapping Operations

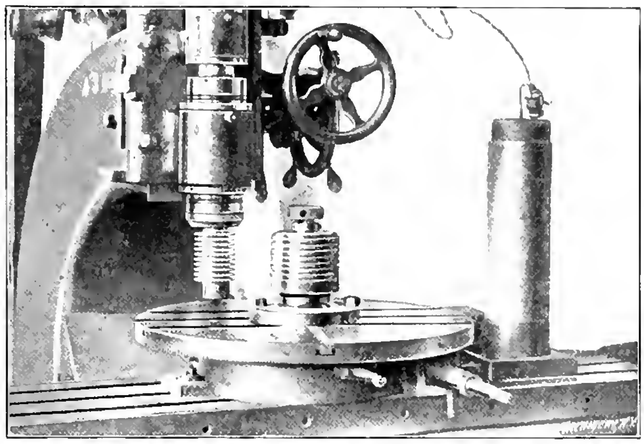

Fig. 13. Cutting out Piston Rings in the Vertical Milling Machine

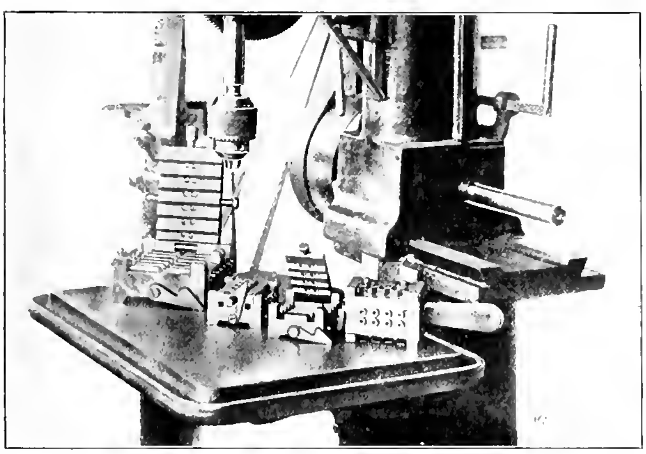

Fig 14. Interesting Drill Jigs for a Simple Operation

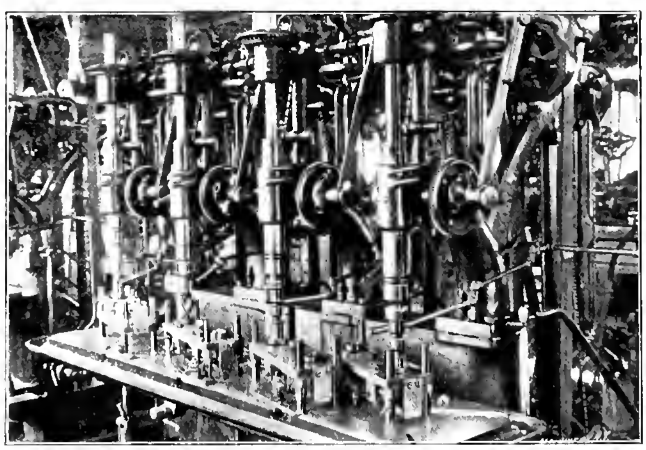

Fig. 15. Gang Drill used in Drilling and Reaming Connecting-rod Ends

Sizing Round Holes in the Broaching Machine

Another unusual operation for which the broaching machine is here used, is that of sizing holes in hard phosphor bronze bushings. This material, as any mechanic who has had any experience with it knows, is as hard on a finishing reamer as anything well can be. It is tough, elastic and slippery, and the less there is to ream the more difficult becomes the operation. Instead of reaming such holes, the tools shown in Fig. 11 are used in this shop. It will at once be seen that the operation is that of compressing the metal in the sides of the hole, until it has been enlarged to the finished size. The tool is drawn through the work. Each of the rounded rings or beads is a little larger than its predecessor, thus gradually compressing the metal the desired amount. The finished hole springs to a size smaller by some few thousandths than the diameter of the largest ring on the tool, so that the size of the latter has to be determined by experiment. This allowance varies slightly also, as may be imagined, with the thickness of the wall of metal being pressed. In such a part as that shown in Fig. 11, for instance, after drawing through

suitable clutch connection, the pinion shafts by which the spindle quills are fed up and down. It is thus possible to give a rotating and reciprocating movement to the spindles, either together or separately.

Separating Piston Rings

Another milling operation is shown in Fig. 13. It is a common practice to make piston rings on an automatic machine specially rigged up for the purpose, separating the rings from the finished casting by means of a series of parting or cutting-off tools, each of which is set a little in advance of the other so that the rings will cut off in regular succession. The parting tool, however, especially when used in severing cast iron work like this, having an eccentric bore, leaves a considerable burr. In the method of severing the rings shown here, the eccentric cylinder is first finished complete on the turret machine. Then it is mounted on an internal expansion chuck on the face-plate of the cylindrical attachment of the Becker vertical milling machine, as shown. This chuck is provided with clearance grooves for the gang of saws shown in the engraving. These are sunk into the cylinder, and then the

work is rapidly revolved, cutting out the eight rings at once. The saws are permanently mounted on their arbor, with separating collars ground to the proper thickness.

Examples of Fixtures used for Drill Press Operations

The drilling department seemed unusually small, when compared with the size of the whole plant, and gave the appearance of being worked at high pressure. The large output required was evidently maintained by the universal use of highly developed jigs for all manufacturing operations. Multiple spindle drill presses are used to almost the entire exclusion of the single spindle type.

Fig. 14 is interesting as showing the development in the jig for a comparatively simple operation—that of drilling

Fig. 16. An Unusual Array of Automatic Chucking Machinee; Thirty-one are used in this Department

the cotter pin hole in a headed cylindrical stud. In the first apparatus employed (not shown) the stud was pushed into a hole up to its head, and held there by a lever, one piece being done at a time. This rigging had two faults. One piece at a time is held, and trouble with chips and burrs was experienced, as might be imagined. An improvement on this device is shown in the two jigs at the right, where a base with a set of V's is provided in which several of the pins may be placed, their heads being pressed up against the end of the V-block by springs. The cover being clamped down on the work, the parts are thus held for the drilling operation. This, however, was not quite easy enough to clean to suit the ideas of the tool designer, so the fixture shown at the left was used for the next tool of this kind that had to be made. Here hinged sides are used instead of springs as in the previous

Fig. 17. The Engine Assembling Department

case. These sides fold up and press the heads of the work against the edges of the V-block. When they are turned down and the cover of the V-block is raised, the top surface of the V-block is all clear, so that the presence of chips shows inexcusable carelessness on the part of the operator. When the sides are folded up against the work and the cover is brought down, the latter, by means of wedge surfaces, presses the sides in, holding the heads of the work firmly in place and clamping them down on the V-block at the same time.

The jig shown at work in Fig. 15 is used for drilling and reaming the connecting-rod holes. It is of the "four-legged table" variety, with suitable clamps and hook bolts for taking the strain of the cut without permitting noticeable deflection and consequent inaccuracy in the work. A feature of the construction which is probably old enough, but was new to the writer, is the provision made for both drilling and reaming with a fixed bushing, thus avoiding the use of slip bushings of different diameters. For drilling, the jig is used as shown in the engraving, with the work clamped beneath the plate and the jig bushings above, guiding the drills. For reaming, the jig is reversed and a reamer is used having a pilot, which passes through the work into the jig bushing (now on the under side of the plate) by which it is guided.

Fig. 16 shows what is by long odds the largest aggregation of automatic chucking machines the writer has ever seen. There are thirty-one of the Potter & Johnston type. Practically every turned part not made in the screw machine from the bar is produced on these machines. That old standby, the engine lathe, appears to be about the rarest machine tool in the shop.

Fig. 17 shows a section of the engine assembling room. It will be noted that machine tools are few and far between, the only ones in sight being a drill press, speed lathe, and two or three grinding stands for sharpening tools. This shows that the manufacturing operations have been performed with great exactness. The question of assembly is simply one of bolting and screwing the separate parts together. The engines here shown are of the four- and six-cylinder type. The overhead trolley lines should be noted.

One of the most interesting departments in this factory is that for testing the completed engines. This, however, deserves an article by itself, and will be so treated in a future issue.

* * *

AN EARLY DEVELOPMENT OF INTERCHANGEABLE MANUFACTURING

An interesting feature of trading and manufacturing in Siberia, also common in European Russia, is mentioned in an article on Siberia in the September issue of *Cassiers' Magazine*. The system is referred to as the "Artel" system. The Artels are combinations of artisans, representing individual occupations and handicrafts, and are especially common in village communities. They are cooperative associations, the work being parceled out among the members and the profits on the work being divided among them in accordance with the rules of the Artel. The members carry on their work in their own cottages, much of the work being done in the winter time during the season when there is no work required for cultivating of the land. One common industry is that of making winnowing machines used by farmers for separating the grain from the chaff after threshing. These are sold in thousands, and are manufactured both in Russia and Siberia by these peasant associations. The machines are very satisfactory for their purpose, and are sold at an extremely low price, due to the system of manufacture followed by the Artels. Each man has a special part of the machine to make, and is provided with a templet for its making. The parts are produced in lots of hundreds and are brought together from the various workers and assembled by another group of workmen who have specialized in this part of the work. This system is exactly the same as that known to modern industries as the interchangeable plan of manufacturing, but it has been in vogue in Russia in the form just described long before it was thought of elsewhere. The trade in this particular machine is so enormous that more than one firm manufacturing agricultural machinery has endeavored to secure a portion of the business, but so far all have failed because no one has been able to produce and sell the machines at the price at which the Artels are able to sell them. Of course, it is only the very simplest machines that can thus be made by the Artels, and they are not able to extend their operations in directions where a higher degree of skill is required, but it is nevertheless interesting to note that the underlying principle of modern shop practice has been applied to the very crudest form of manufacture in countries usually considered so far removed from industrial progress as Russia and Siberia. The recognition and application of the principle are the important facts.

CHAPTERS IN THE EARLY HISTORY OF MACHINE TOOLS—2

JOSEPH G HORNER*

In the lathe we see the earliest developments of machine tools, not only as the lathe and its allied forms are concerned, but because of the influence which this tool has had in the evolution of other types. The mandrel and its bearings occur in other machines, and the self-acting slide and tool-holder also, as well as many of the smaller details - lead screw,

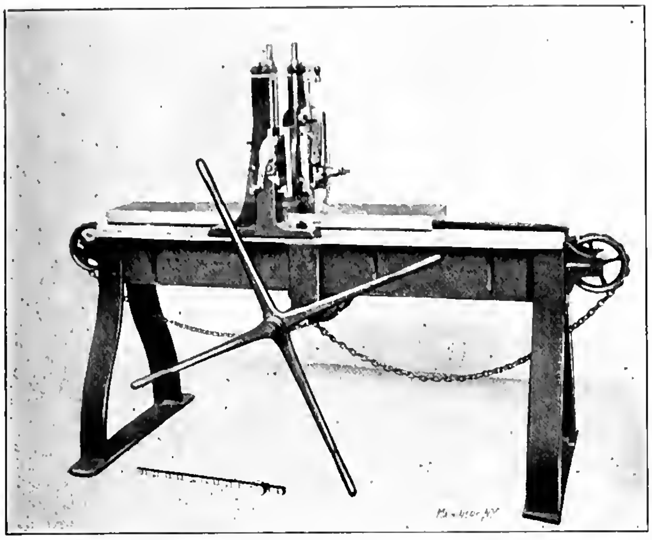

Fig 8. Roberts Planing Machine, Table 52 inches Long by 11 inches Wide (1817), South Kensington Museum

change gears, feed rods, methods of take-up, and so forth. The lathe preceded all other tools and influenced their design.

Planing Machines

After the slide-rest had become developed into a traveling element the principle was not long in being applied to other

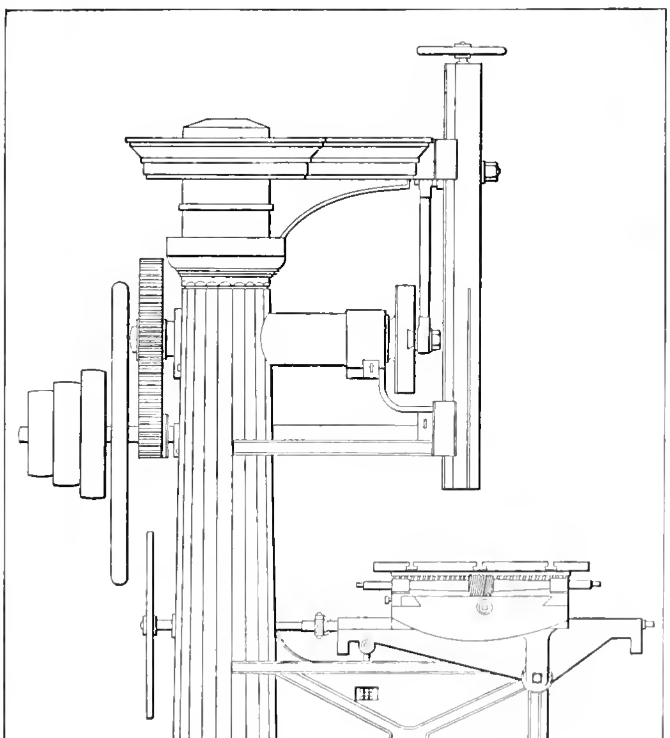

Fig. 9. Self-acting Slotting Machine, Caird & Co., Greenock (about 1846)

machines. First came the planing machine, pioneer of a long line of machines, the principal value of which is due to the coercion exercised on the tool by the sliding action. The honor of its invention appears to lie between four claimants, Roberts, Clements, Fox, and Murray, working during the period of about 1814-1820. This was a very prolific epoch in the history of machine tools; an age of great inventors, pupils, and followers of Bramah and Maudslay.

The planing machine by Richard Roberts of Manchester, now in the South Kensington Museum, Fig. 8, still bears evidence of the hand work done in fitting it up. It is chain-driven, the chain passing round a drum underneath, about the center, going thence over guide pulleys at each end, and attached to each end of the bed. The movements were operated by the large cross handle seen on the axis of the drum. The bed is cast in two parts, of angle section, bracketed and bolted to the legs. Its top edges are inverted vees, doubtless made thus with the intention of preventing lodgment of the chips.

The upper work is remarkable from the fact that the tool-holder is nearly as large as the standards. These are castings slotted on the front for the clamping of the cross-slide. This is elevated by means of independent screws. The tool-slide is traversed by a feed screw.

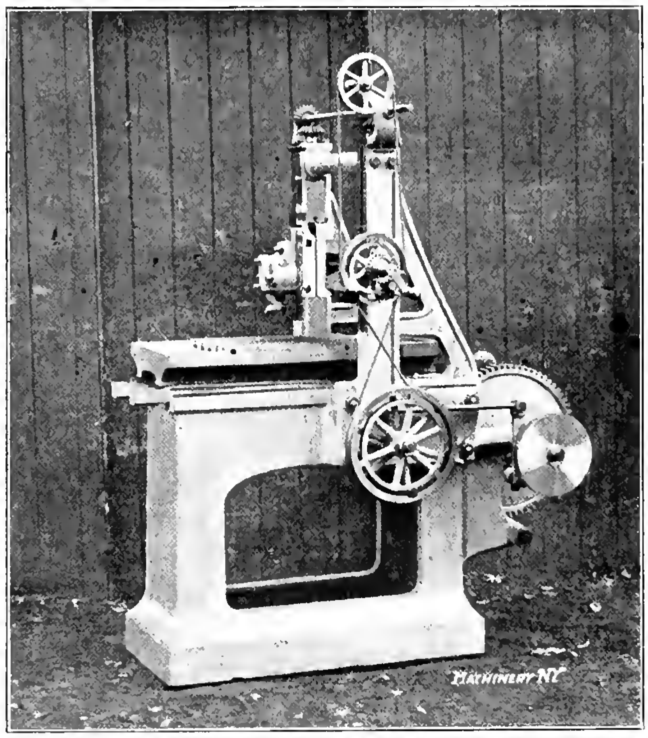

Fig. 10. Whitworth Crank-driven Planer (1868)

During the decade 1830-1840 the demand for high-class machine tools became pressing and extensive, due largely to railway developments. The firm of Sharp, Roberts & Co. was one of the earliest in the field. It had been in existence since 1828, having been engaged in the construction of cotton spinning machinery in Manchester. Roberts was the inventor of the firm, and he designed many lathes, machines for planing, slotting, the cutting of wheel teeth, punching and shearing. Roberts is credited with having invented the system of templets and gages to secure interchangeability of parts in locomotives. This last would be subsequent to 1831, when Sharp, Roberts & Co. started the Atlas Works.

Whitworth stands out a giant among the giants of the time, and his work has eclipsed in poular estimation that of most of his compeers. The period of his activities is marked by numerous improvements and inventions. But the three which have left the most lasting results are the standardization of screw threads, the method of production of a true plane, and measurement by micrometer instruments and by fixed gages. These were the advances which rendered accurate mechanical construction possible. They have been largely instrumental in the displacement of hand work in the construction of machines. They were the incentives to later developments, and they have in some degree dwarfed Whitworth's work in the improved designs of machine tools, or perhaps less attention has been attracted to these. But these are nevertheless very prolific and very interesting. His work has stood the test of time so well that most of the inventions and improvements which he devised have never been superseded. Machines, methods of manufacture, standardization,

* Address: 45 Sydney Building, Bath, England

measurement, and test, bear the impress of his genius; and the great firm which he founded still fully maintains the old traditions and high reputation of its originator.

Whitworth seems to have been the first to design that form of planer in which the work remains stationary while the tool travels. He had patented a machine of this kind in

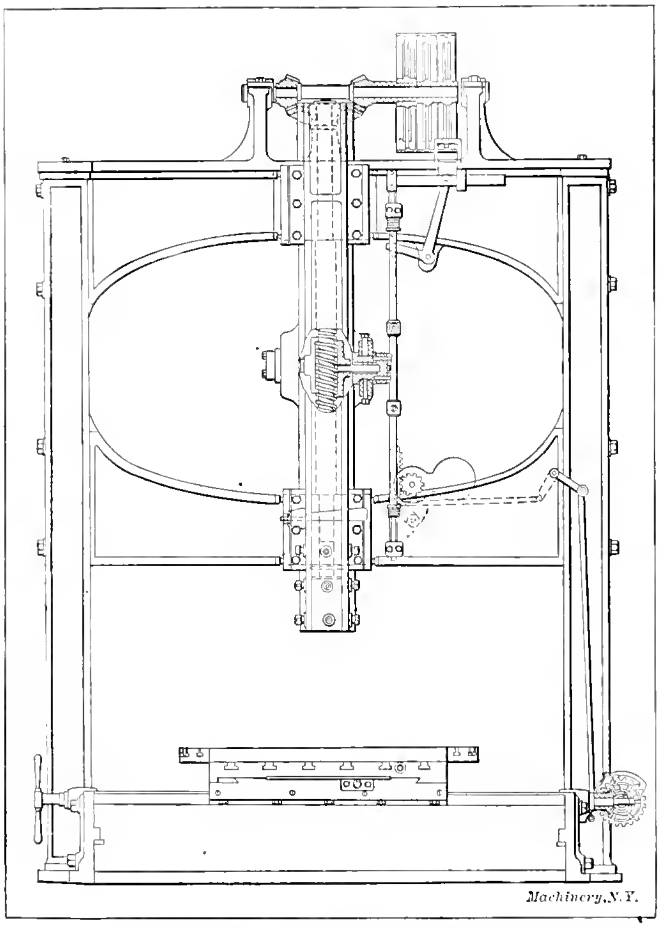

Fig 11. Slotting Machine, Screw-driven. Front Elevation. Joseph Whitworth & Co.

1835, in which the side frames carrying the cross-rail traveled on large wheels on rails low down on each side of the fixed work table.

This Whitworth planer of 1835 was very skeleton-like, if judged by our standards, as indeed all the early tools were; but the resemblances to some features of present-day machines are striking. The lightness of build is illustrated by the fact that flanges were cast on the outside of the framing, and flanges on the traveling heads came just underneath them, with the object of preventing the traveling mechanism from tipping under heavy duty!

Being a traveling head machine, provision was made by three sets of flanges forming ledges within the cheeks for receiving the work tables at three different heights. The cross-rail was elevated by vertical screws and bevel gears, and the cross-slide could be bolted at any height on the face of the uprights.

The crude beginning of the screw worm drive which Whitworth subsequently used on the planers and drilling machines may be traced to this early machine. Two square-threaded screws ran alongside, one flanking each upright and reversing the travel at equal rates. The two side screws were driven from bevel wheels, the transverse shaft having three reversing bevel wheels with claw clutches at the center. Curious recessed rollers were used to transmit the motion of the screw to the uprights, the edges of the rollers, which were set at any angle, entering into the thread spaces. From this device the worm-wheel engagement would naturally follow in time, as it did.

This machine embodied also the reversible tool-box in a crude form, but reversed similarly to later ones by means of a cord round a pulley. The pulley was not in the axis of the rotating box, but on a spindle in front, whence the movement was transmitted through spur gears. The down-feed was accomplished through ratchet mechanism acting on a screw at the head of the tool holder.

In 1837 Whitworth modified the tool-box, introducing the cam groove cut on the rotating body, and which when acted on by a pin operated by the vertical movement of the feed rod imparted the rotary movement. This device has remained permanently embodied in the firm's planer tool boxes of this type.

The fitting of two tools in the box to avoid the rotation of the holder was patented by John Roberts in 1838. In its essentials it is like double cutting holders of to-day, the box being pivoted to throw off the tool which is not in action.

The design of planing machine which has come into considerable prominence lately, in which the tool is reciprocated instead of the work, was being worked out about 1840 by M. Decostre, of Paris, M. Cave and Mr. Hick of Bolton. The first was chain operated, the second by means of a leather belt, the third by a steel belt. In M. Decostre's machine two endless chains were used running the whole length of the machine. The bed was V-grooved, carrying supports, and a cross-rail with the tool-holder. In the machine of M. Cave an endless belt ran over fixed and tension pulleys communicating motion through gears to two racks.

The planing machine had been nearly crystallized in its present design in the forties. The method of driving still lay between rack and screw, for Whitworth had then applied the screw drive to both planing and slotting machines. Quick return in rack-driven machines was effected by larger and smaller fast and loose pulleys driving through gears to the rack pinion. There were three designs of racks then. There

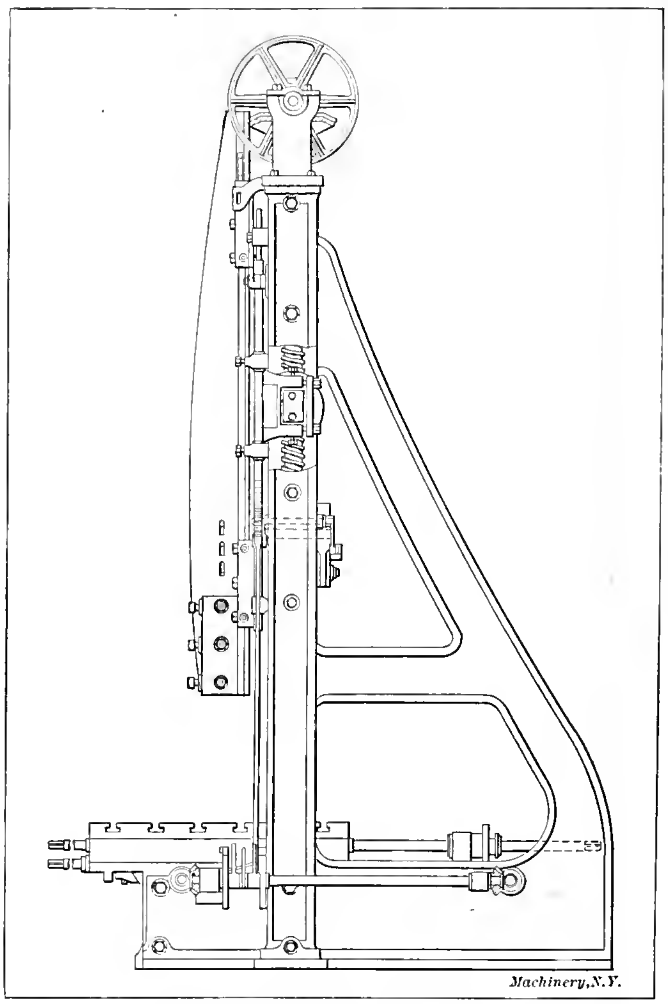

Fig. 12. Early Self-acting Slotting Machine, Screw-driven. Side Elevation. Joseph Whitworth & Co.

was the simple single rack, there were the two racks bolted to the under side of the traveling table with the teeth set to hit-and-miss, and there was the stepped rack with three steps, each step having its teeth equal in length of face to one-third the width of the rack, being set behind its fellow at a distance equal to one-third of the pitch. This was introduced by a Mr. Collier of Manchester.

To the screw reversal the objection was that the return speed was not accelerated, the bevel wheels being of equal sizes. Mr. Shanks of Johnstone modified the gear by placing two bevel wheels of different sizes on the end of the screw, the diameters of which bore the same relation to each other as the speeds of cutting and reverse did. These were operated by pinions on solid and hollow shafts, and the device has been fitted to many machines.

The earliest Whitworth screw did not engage with nuts as at present, but with worm-wheels, being the same device as the rack worm-wheel applied to the lathe lead screw, but duplicated. Two worm-wheels on opposite sides of the screw, and having their spindle bearings secured to the under side of the table, were revolved by the rotation of the screw, and thus carried the table along. The same method was applied to the spindles of drilling machines. The device was first applied by Whitworth in 1835 for the motion of the carriage of a self-acting spinning mule.

A favorite type of small planing machine in and around the Manchester district is the crank-driven design. One of these of date of 1868 by Whitworth & Co. is shown in Fig. 10. It is driven by a cone pulley through crank-pin and slotted link, adjustable for stroke, and giving quick return. The slotted link is provided with a connecting-rod, one end of which is attached to the table. The feed is operated from an edge cam keyed to the crankshaft. This rotates at each end of the stroke through bevel gears the cord pulley at the bottom of the upright. The cord fixed to this pulley passes round the several pulleys shown, and gives a variable horizontal feed by means of the ratchet gear on the end of the cross-slide, and a variable vertical and angular feed by ratchet gear on top of the tool slide.

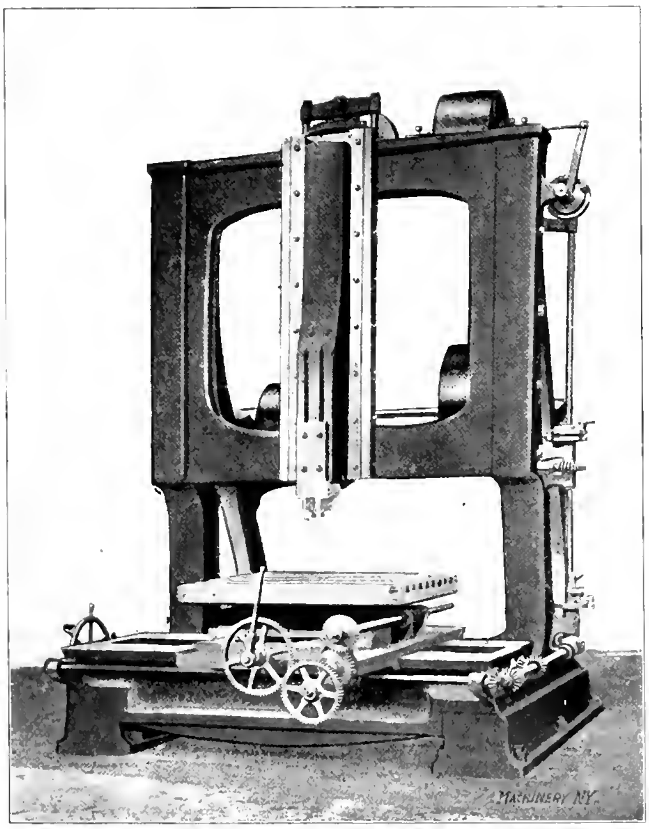

Fig. 13. Slotting Machine. Joseph Whitworth & Co. (1874)

At an early period the American planing machines were improved and developed on different lines from the English ones. Some of the early chain machines remained in use in England, and in the States as late as about 1880, side by side with many of the improved forms which are even now regarded as modern. The Sellers' drive was then in existence—the spiral pinion working diagonally in its rack, an improved form of Bodmer's worm and rack. The rack-and-pinion drive was also in use. The plain rack and the stepped rack divided favor in England, but the pinion was always small, with a tendency to lift the table. The large driving or bull wheel was early adopted in America. The single belt for driving and reversing was early abandoned in America for two belts, one driving, the other for reversing; and high speeds and narrow belts also were adopted, and the shifting of one belt at a time. The feed gear was operated from the driving gears instead of by tappets on the table.

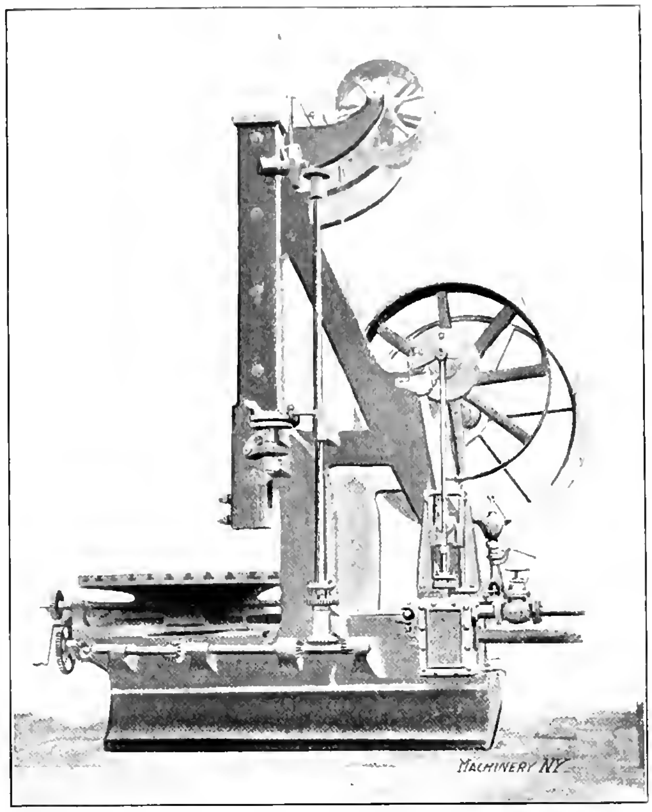

Fig. 14. Slotter driven by Steam Engine. Joseph Whitworth & Co. (1867)

Mr. Richards has a hit in an old pamphlet at the ornamentation which was a common feature in early machine tools. He said "The strains that fall upon the standards of planing machines are so obvious that there should be no difficulty in determining the best form; but these standards offer so inviting a field for architectural ornament that only a few tool makers forbear adding some filigree work. The beads, moldings, and ornaments of cast-iron machine parts were long ago discarded by the better class of engineers, and are at present seldom seen except in New England or in France.

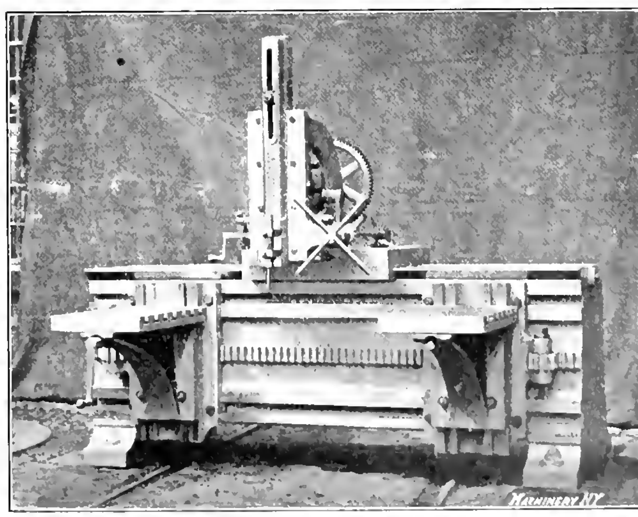

Fig. 15. Special Slotting Machine with Lateral Feed. Joseph Whitworth & Co (1865)

As a rule the want of good fitting and want of true proportions in machine tools is directly in proportion to the amount of attempted ornament."

Three large wall planing machines were among the equipment at Soho. The largest covered a wall space of 27 feet by 9 feet. The traversing screw was 4 inches diameter, of 5/8-inch pitch, double threaded, and the nut of 2 feet in length embraced only the upper part of the screw. An interesting feature was the double cutting tool box of the rocking type

reversed by a trip lever, and it carried four tools, two facing in each direction.

The Richards side planers were first described in a pamphlet printed in Philadelphia in 1882. They are there termed combination, or compound planing machines, because they perform the functions of both planing and shaping machines, and the features there described, now familiar, had the claim of novelty: "The time required to fasten work is not one-half as much as with a common machine. The tools always

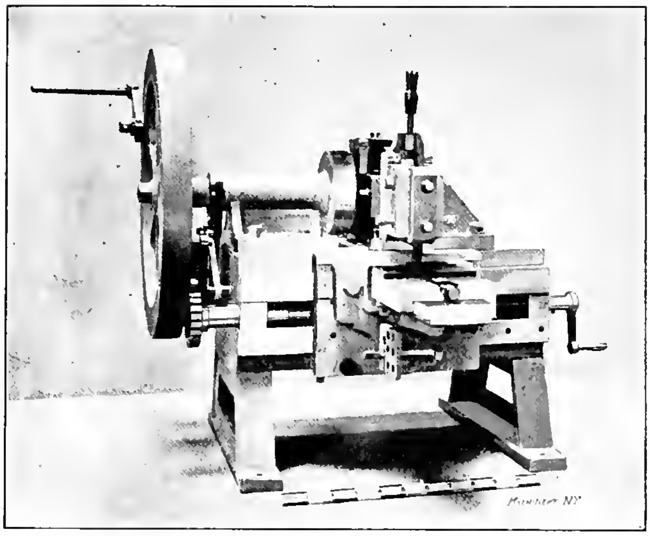

Fig. 16. Shaping Machine designed by James Nasmyth. South Kensington Museum

operate at the same level, and the range of movement is nearly as accurate as with crank motion. The stroke is as complete at 2 inches as at 50 inches." The entire absence of gear wheels is mentioned, and the noiselessness of running. Two sizes of machines only were made at first, one to plane 50 inches by 20 inches, weighing two tons; the other to plane 60 inches by 25 inches, and weighing three and a half tons. Mr. J. Richards, who did so much for machine tool development in America, early advocated the fixed work, and the traveling tool embodied in his side planer. He said in a paper published in San Francisco in 1880: "When work becomes many times as heavy as the implements required to cut it, there are good reasons for moving the tools instead of the piece. The principle is traceable through all machine tool practice of our day, but is especially marked in the case of planing appliances. Mammoth machines with running platens to plane eight, ten, or twelve feet square are now seldom made except in this country. Four feet square may be called an economic limit for moving platen machines. . . . A large sole plate with portable tools for planing and boring is in most cases all that is required."

Slotting Machines

The slotting machine was invented by Richard Roberts, but the idea was borrowed from a machine by Maudslay used for cutting the mortises in ship's blocks. Roberts' machine was in general appearance and design similar to present-day machines, but there was no quick return. Nasmyth, seeing the objection to the limitations in diameter due to the presence of the gap, designed in 1836 a table machine in which the slotting ram was placed below in a pit. The advantages which he claimed were that it was capable of operating upon wheels of any diameter, that it would take a much deeper cut, there being an entire absence of any source of springing or elasticity in its structure, that it operated with more precision, occupied less space, and did not cost above one-third of the other machines. This might be regarded as the prototype of the keyway seating machines.

There was a slotting machine at Soho foundry attached, like so many of the machine tools there, to the wall. The base-plate, with table and slides was on the floor. The ram moved in dovetailed slides, and was driven by a single threaded screw of $4\frac{1}{2}$ inches diameter and 1 inch pitch, the cutting and return movements being effected by a nest of bevel gears at the top of the machine. The screw ran in a nut at the head of the ram, the weight of which was counterbalanced. Power feeds were fitted to the table slides.

The early form of slotting machine was obviously an adaptation of the planer, but crank-driven. Though it had no quick return, and no self-acting table feeds it had the two rectilinear and the circular movements imparted by hand, and a tilting table, and thus marked a very great advance in the methods of the machine shop. An example by Caird & Co., Fig. 9, previous to 1847, is curious for its architectural features, its fluted column, and architrave on the overhanging head.

One of Whitworth's early slotting machines with the ram, screw-driven as previously mentioned, Figs. 11 and 12, avoided the difficulty of the obstruction of the standard by employing two uprights bolted to the base, and leaving a clear space between them from front to back. Two stretchers bolted between the uprights provided the guides for the ram. Fig. 13 is a similar machine of date 1874.

Among the tools at the old Lambeth works was a slotting machine by Sharp, Roberts & Co. of Manchester, bearing date 1840. The framing was arched at the top. A six-stepped belt cone drove the ram through a slotted crank and connecting-rod arranged at the back, but at the side of the main frame, which was a very skeleton-like affair. The table was provided with all motions, including the circular, and an elevating motion of its base between the main framing. Feed was self-acting from a cam on the cone shaft. A trunnion fitting to the table provided for taper slotting.

A large Whitworth slotting machine (1867) for general and locomotive work is shown in Fig. 14, driven by a steam engine with governor attached. The stroke was about 4 feet. The tool ram is actuated by means of a quick threaded screw from the drum of the engine crankshaft by shifting belt to top pulleys, thence through bevel gear for the cutting stroke, and miters for quick return. The bottom of the main screw is

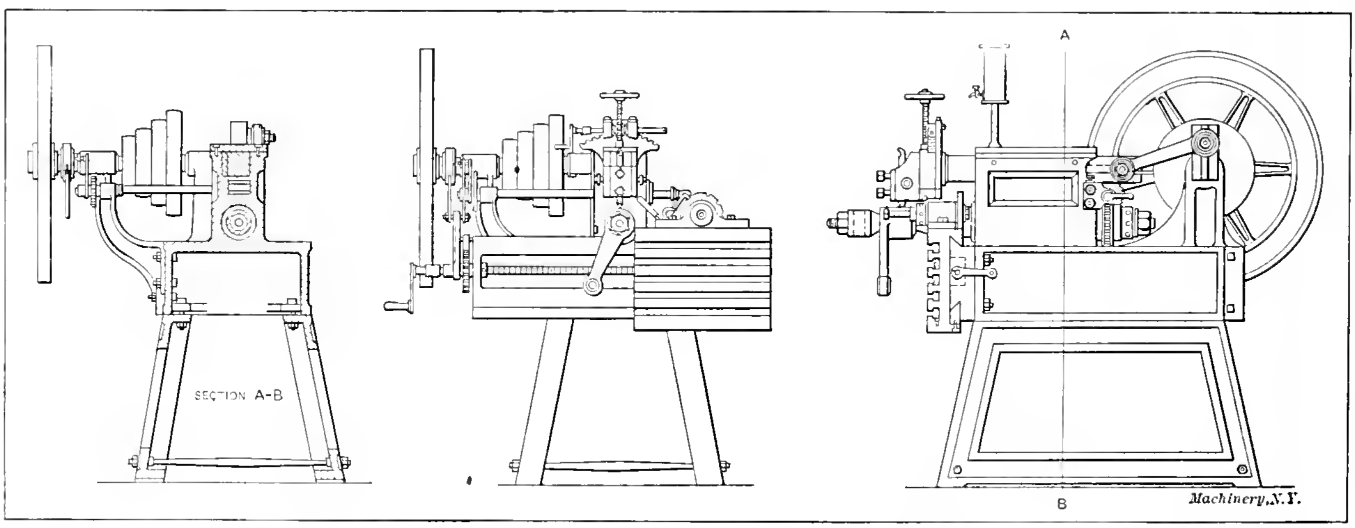

Fig. 17. Compound Planing Machine or Shaper. Nasmyth & Gaskell

fitted with small bevel gears giving motion to a worm and worm wheel which rotates the slotted disk. This is provided with tappets adjustable for length and position of stroke. The tappets actuate the long vertical shaft, the top of which is coupled to the belt striking gear, and the bottom to the variable reversible feed motion in the longitudinal, transverse, and circular directions. The table is 6 feet 6 inches diameter and the distance between the uprights is 8 feet 6 inches.

A Whitworth machine which embodies features of the shaper and slotter is shown in Fig. 15. It was a special slotting machine (1865) made for slotting out the port holes in the cylinders of locomotives, and doing ordinary work on the table of the machine. The tool ram is driven from a balanced counter-shaft by means of the single pulley seen at the back of the head, thence through the spur gears, slotted disk, and connecting-rod, adjustments for length and position of stroke being provided for. The variable feed is operated from an edge cam on the disk shaft through the slotted lever seen on the right-hand side of the head; thence by ratchet wheel, miter wheels, and revolving nut on the screw in the bed, for longitudinal feed; and by the left-hand ratchet gear, miter, and screw, for the transverse feed.

Shaping Machines

Nasmyth invented the shaping machine in 1836 with the object of tooling the smaller details which were not suitable to go on the planing machines. It was known as "Nasmyth's steam arm," of which the arbor for segmental work formed an important element. Said he: "None but those who have had ample opportunities of watching the progress of executing the detail parts of machines can form a correct idea of the great amount of time that is practically wasted and unproductive, even when highly skilled and careful workmen are employed. They have so frequently to stop working in order to examine the work in hand, to use the straightedge, the square, or the calipers, to ascertain whether they are 'working correctly.' During that interval the work is making no progress; and the loss of time on this account is not less than one sixth of the working hours, and sometimes much more; though all this lost time is fully paid for in wages."

An early form of the Nasmyth shaper, hand operated, is in South Kensington, Fig. 16. A somewhat later design, power driven, is illustrated by the drawing Fig. 17. This was termed a compound machine, because it included circular tooling on the mandrel, which did away with a deal of hand chipping and filing on lever ends and similar work. It had no quick return at first. Whitworth was the first to fit that. It was just a short stroke machine substantially like present day successors only of rather bizarre appearance. It was belt-driven on cones, with adjustable stroke and self-acting feed to the arbor.

Yet the original of the shaper may be traced to a machine in Maudslay's shop. Two girders supported on legs carried the sliding work bed, over which the the tool-box was traversed and reciprocated between two round bar guides. These movements were derived from a large cord-driven stepped pulley, crank and connecting-rod, to the tool-box. The latter with its guides could be adjusted vertically by four screwed pillars, with nuts above and below the bosses of the guide bars which fitted over the pillars. An interesting feature is that the tool box was rotated through 180 degrees at the end of each stroke, to cut on each stroke.

* * *

The question of supplying power to Paris by means of an electric generating plant at the Rhone falls now appears to have reached the stage of probability. It is planned to transmit 150,000 kilowatts direct current at a voltage of from 120,000 to 200,000, although there is doubt on the question whether the three-phase system would not be preferable. The capital cost for the whole project is estimated at $20,000,000 and an important factor yet to be decided is whether it will be possible to deliver current at the capital at lower cost than when generating locally by steam. It is, however, probable that manufacturing towns would grow up around the falls, similarly as has been the case around Niagara, and in this case the project of establishing a large power station would be entirely feasible.

STRESSES PRODUCED BY SHOCKS

A. P. ELTOFT*

A. P. Eltoft†

The opinion that, in general, a certain static load can be substituted for a shock produced by a body in motion, is often met with among engineers. This opinion, however, is true only within certain limitations; that is to say, in each concrete case there exists a certain force which will produce the same maximum stress as that due to a given shock, but this force may vary greatly in different cases even if the energy, by which the shock is measured, remains the same. The magnitude of a shock must be measured in units of energy, and, therefore, cannot be directly compared to a force.

Although in some cases a close approximation to an exact calculation of stresses produced by shocks may be attained, it is often found a complicated, and sometimes an impossible, task to determine, even theoretically, the effects of a shock, and the object of the present article is more to give a clearer understanding of the principles involved, than an attempt at exact calculation.

TABLE 1. STRESSES PRODUCED IN BEAMS BY SHOCKS

Method of Support, and Point Struck by Falling Body.	Fiber Stress p produced by Weight Q dropped through a Distance h.	Approximate Value of p.
Supported at both ends; struck in center.	$p = \frac{QaL}{4I}\left(1 + \sqrt{1 + \frac{96hEI}{QL^3}}\right)$	$p = a\sqrt{\frac{6QhE}{LI}}$
Fixed at one end; struck at the other.	$p = \frac{QaL}{I}\left(1 + \sqrt{1 + \frac{6hEI}{QL^3}}\right)$	$p = a\sqrt{\frac{6QhE}{LI}}$
Fixed at both ends; struck in center.	$p = \frac{QaL}{8I}\left(1 + \sqrt{1 + \frac{384hEI}{QL^3}}\right)$	$p = a\sqrt{\frac{6QhE}{LI}}$

I = moment of inertia of section; a = distance of extreme fiber from neutral axis; L = length of beam; E = modulus of elasticity

A number of formulas, however, are included, because many interesting conclusions can be drawn directly from these formulas, which probably also will be of interest to many of the readers of MACHINERY, who, like the writer, have often felt the need of some formulas directly applicable to shocks.

Any elastic structure subjected to a shock will deflect until the product of the average resistance, developed by the deflection, and the distance through which it has been overcome has reached a value equal to the energy of the shock. It follows that for a given shock, the average resisting stresses are inversely proportional to the deflection. If the structure were perfectly rigid, the deflection would be 0, and the stress infinite. The effect of a shock is therefore to a great extent dependent upon the elastic property (the springiness) of the structure subjected to the impact.

The energy of a body in motion, such as a falling body, may be spent in each of four ways:

1. In deforming the body struck as a whole.
2. In deforming the falling body as a whole.
3. In partial deformation of both bodies on the surface of contact (most of this energy will be transformed into heat).
4. Part of the energy will be taken up by the supports, if these be not perfectly rigid and inelastic.

How much energy is spent in the last three ways it is in most cases difficult to determine, and for this very reason it

* Address: 6628 Loomis St., Chicago, Ill.

† A. P. Eltoft is a graduate of the Polytechnic Institute of Copenhagen, Denmark. He has been employed by the Reno Inclined Elevator Co., New York, and the American Bridge Co., Chicago, and for the last four years has been estimator for the Link Belt Co., Chicago.

is safest to figure as if the whole amount were spent, as in case 1. In cases where a reliable judgment is possible, as to what percentage of the energy is spent in other ways than the first, a corresponding fraction of the total energy can be assumed as developing stresses in the body subjected to shocks.

Formulas for Stresses due to Shocks

If, in the accompanying illustration, the weight Q be dropped from a height h to the end of a bar of the length L and cross sectional area A, then the static load P which would produce the same elongation as the maximum elongation produced by the dropping of Q, would be determined by the following formula:

$$P = Q\left(1 + \sqrt{1 + \frac{2\,h\,A\,E}{Q\,L}}\right) \qquad (1)$$

For $h = 0$ this gives $P = 2\,Q$, or a suddenly applied load will produce the same elongation and therefore the same stress as a static load twice as great.

If the elongation y of the bar is small compared to the height h, the formula may approximately be written

$$P = \sqrt{\frac{2\,Q\,h\,E\,A}{L}} \qquad (2)$$

If the unit stress $p = \dfrac{P}{A}$ be introduced in this formula, we get

$$p = \sqrt{\frac{2\,Q\,h\,E}{L\,A}} \qquad (3)$$

From this formula, the interesting conclusion can be drawn that the unit stress p for a given load producing a shock, varies directly as the square root of the modulus of elasticity E, and inversely as the square root of the length L of the rod and the area of section A. Thus, for instance, if the sectional area of a column be increased four times, the unit stress will diminish only one-half. This is entirely different from the results produced by static loads where the stress would vary inversely with the area, and within certain limits be practically independent of the modulus of elasticity and the length L of the rod.

TABLE II. STRESSES PRODUCED IN SPRINGS BY SHOCKS.

Form of Bar from which Spring is made.	Fiber Stress f produced by Weight Q dropped a Height h on a Helical Spring.	Approximate Value of f
Round	$f = \dfrac{8\,Q\,D}{\pi\,d^3}\left(1 + \sqrt{1 + \dfrac{G\,h\,d^4}{4\,Q\,D^3\,n}}\right)$	$1.27\sqrt{\dfrac{Q\,h\,G}{D\,d^2\,n}}$
Square	$f = \dfrac{9\,Q\,D}{4\,d^3}\left(1 + \sqrt{1 + \dfrac{G\,h\,d^4}{0.9\,\pi\,Q\,D^3\,n}}\right)$	$1.34\sqrt{\dfrac{Q\,h\,G}{D\,d^2\,n}}$

G = modulus of elasticity for torsion; d = diameter or side of bar; D = mean diameter of spring; n = number of coils in spring

Similar formulas may be developed for stresses produced by shocks in beams or other members subjected to bending, and supported in various ways. The accompanying Table 1 gives the unit stress p in beams of length L produced by a weight Q falling a distance h. Only the simplest cases have been considered. It is interesting to note that the approximate value of the stress produced by the shock is the same, irrespective of how the beam is supported. This again shows how the effects of shocks and the static load differ. As a matter of fact, the expression for the approximate value of p will be the same for beams supported on both ends and subjected to a shock at any point between the supports.

Effect of Shocks on Helical Springs made from Round or Square Bars

A load suddenly applied on a spring will produce the same deflection, and therefore also the same unit stress as a static load twice as great. If, however, the load Q falls from a height h before striking the spring, it will produce a stress equal to that of static load P, according to the formula:

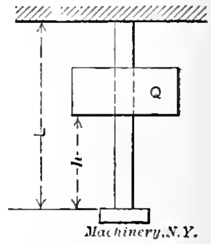
$$P = Q\left(1 + \sqrt{1 + \frac{2\,h\,G\,d^4}{C\,Q\,D^3\,n}}\right) \qquad (4)$$

in which G = modulus of elasticity for torsion,
d = diameter of round spring or side of square spring,
C = a constant, which is 8 for round bar, and $1.8\,\pi$ for square bar,
D = mean diameter of spring,
n = number of coils in spring.

If the deflection y of the spring is small compared to h, an approximate formula may be written

$$P = \sqrt{\frac{2\,Q\,h\,G\,d^4}{C\,D^3\,n}} \qquad (5)$$

Table II gives the fiber stress f produced by weight Q dropped a distance h before striking a helical spring. The main conclusion arrived at in these formulas is that the fiber stress for a given shock will be greater in a spring made from square bar, than in one made from a round bar, if the diameter of coil be the same, and the side of the square bar equal the diameter of the round bar. It is, therefore, decidedly more economical to use round stock for springs which must withstand shocks.



Stress due to Shock

This is due to the fact that the deflection for the same fiber stress for a square bar spring is smaller than that for round bar spring, the ratio being as 4 to 5. The round bar spring is therefore capable of storing more energy than a square bar spring for the same stress.

Shocks from Bodies in Motion

The formulas previously given can be applied, in general, to shocks from bodies in motion. A body of the weight W moving horizontally with the velocity of v feet per second, has a stored up energy

$$A = \frac{1}{2}\,\frac{W\,v^2}{g} \text{ foot-pounds, or } \frac{6\,W\,v^2}{g} \text{ inch-pounds.}$$

This expression may be substituted for $Q\,h$ in the previous equations for unit stresses containing this quantity, and the stresses produced by the energy of the moving body thereby determined. The formulas in this case are no longer approximate, but correct, as there is no work corresponding to $Q\,y$.

It will be noticed that in all these formulas, the stress is directly proportional to the square root of the energy consumed. Therefore, if it is assumed that only a certain percentage, as p per cent of the energy developed, is consumed, then the stress will be diminished from the first value obtained, to the first value multiplied by $\sqrt{\dfrac{p}{100}}$

The writer is fully aware of the limitations of the applications of the formulas given. They give, however, a maximum value of the stresses, thus giving the designer something definite to guide him even in cases where he may be justified in assuming that only a part of the energy of the shock is taken up by the member considered. If the quantity $Q\,h$ be taken as representing the energy consumed by the member in question, then the formulas are perfectly correct. The conclusions drawn, therefore, hold good, as for this purpose, no other significance need be given to the quantity $Q\,h$. The deductions of the formulas given have not been included, as these deductions are rather lengthy. They are, however, all deduced by the simple principle that the work performed by the weight Q acting through a certain distance must equal the work consumed by the internal stresses. The work performed by the weight, of course, is the weight multiplied by the distance through which it falls before striking the body plus the amount of deflection. The work of the internal stresses equals the mean stress produced by the shock times the deflection. This mean stress is ½ of the maximum stress, or the stress P produced by the maximum deflection.

AUTOMOBILE FACTORY PRACTICE*

THE DAYTON MOTOR CAR CO., DAYTON, OHIO

ETHAN VIALL†

The recent hard times, as many in the machine tool line have known them, have as a rule, been regarded as a huge joke by the big automobile builders, for a large majority of them have run full or double time and then could not fill all their orders promptly. So far behind have many of them been that they had to get some of the parts made elsewhere, and the Dayton Motor Car Co., Dayton, Ohio, maker of the Stoddard-Dayton automobiles, has been no exception in this respect. In fact, the company has found it necessary to extend its plant by the erection of an immense steel and concrete structure, now nearing completion, that will nearly double its already tremendous capacity.

This firm actually makes, as the word is understood in the manufacturing world, about 95 per cent of its car, which is a high percentage when one considers the average automobile shop, or even some of those of national reputation, which in many cases are little more than assembling plants. The firms in the same class with the Dayton Motor Car Co., when it comes either to size, methods, quality, or output can be numbered on the fingers, with several to spare. The forging department alone is as large as some good-sized factories. Here everything in the nature of a forging which is used on the automobiles, with the exception of the crank-shaft, is made; even the big elliptical side springs are made up complete in this department from the plain steel strips to the finished article which is tested out in actual service.

This firm is also one of the few which has its own foundry, thus insuring a more nearly uniform product than can be obtained from a jobber. Then, too, the body tops are cut, sewed and finished and cushions are made in their respective departments. Wood is bent into shape for the bodies and top braces and, of course, all painting and finishing is done in the plant. There is, besides the complete line of manufacturing departments, a big garage and repair shop maintained especially for the quick repairing of disabled machines of their own make that may be shipped or brought in.

Crowded as are the conditions in the factory just at present, the shop practice itself stands out clear and strong, the equal of anything in the country. This does not mean that every machine is original or built especially for the work to be done, for at the present stage of the automobile business this is no longer necessary, but where special machines or tools have been needed they have been built, and built in a way that speaks well for their efficiency and length of usefulness.

The most vital part of an automobile is the motor and it is around this part of the machine that the interest of a mechanic usually centers. Many of the parts cannot, for lack of space, be followed through the various routes they take in the shop, but the practice of different factories varies to such an extent regarding piston rings, pistons and cylinders, that these parts will be taken up pretty much in detail, and a few other more or less important or interesting points will also be touched upon.

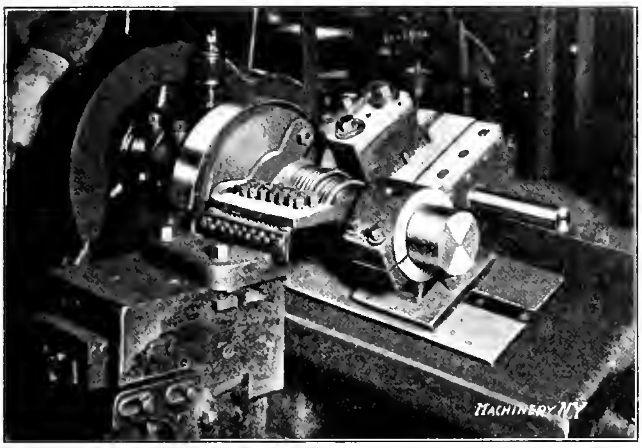


Fig. 1. Turning, Boring and Cutting-off Piston Rings in a Gridley Machine

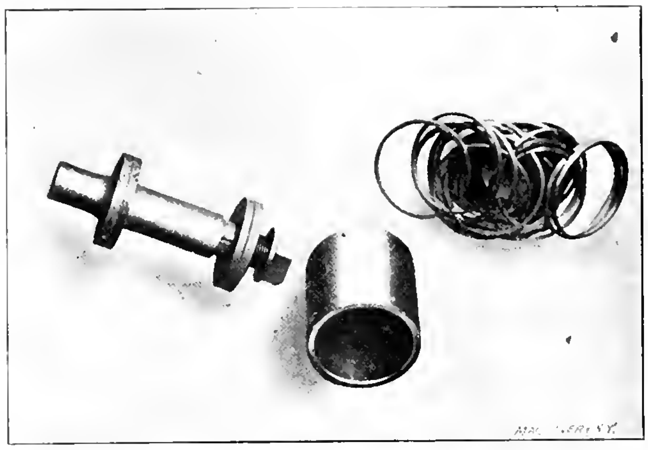

Fig. 2. Mandrel for Holding Rings when Grinding the Outside

Fig. 3. Facing the End, breaking the Inside Edge and boring out the Piston

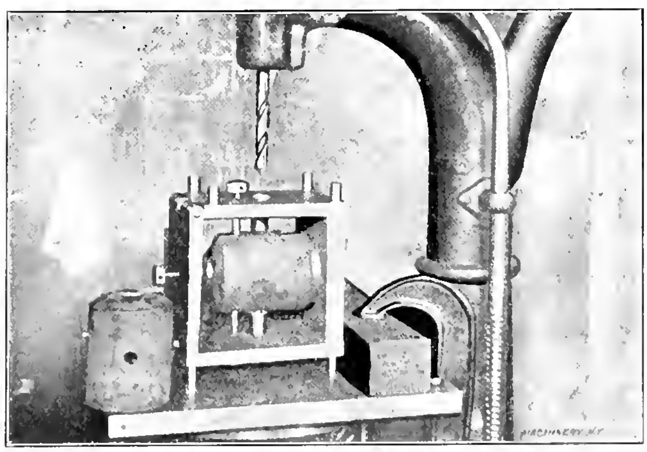

Fig. 4. Jig for Drilling the Wrist-pin Hole in the Piston

Making Piston Rings

Piston rings go through comparatively few separate operations, as three of the operations are done simultaneously on one machine. The piston-ring casting is made with three large flanges or lugs on one end for the purpose of bolting it to the face-plate. The holes in these lugs are laid out by hand and drilled in a drill press and the casting is then bolted to the face-plate of a Gridley semi-automatic piston ring machine which is shown in Fig. 1. This machine bores out, turns eccentric and cuts off the rings, all the operations going on at once. The motion of the turning-tool carriage which turns the outside of the casting eccentric while the inside is bored concentric, is obtained by a cam on the back of the face-plate. After leaving this machine, the rings are taken to the grinding department which is in charge of Mr. C. A. Smith, and placed one at a time on the magnetic chuck of a Heald grinder, and the sides are ground. They are next split with a milling saw and are then ready for the finishing of the outside, which is done by filling the cast-iron sleeve,

* For additional information on this subject, see "Machines and Tools for Automobile Manufacture," June, 1909, and articles there referred to.

† Associate Editor of MACHINERY.

shown in Fig. 2, with the split rings, placing it over the mandrel, putting on the loose flange and screwing on the nut. The sleeve is then removed, the mandrel placed on centers and the outside of the rings ground. The rings are now ready for the final inspection from which they are passed to the assembling department.

All of the operations on piston rings which have been just described, as well as the following ones on pistons, except the grinding operations, are done in what is known as the screw and turret department, in charge of W. F. Hittle.

The Piston Processes

The first machining operation done on a piston, is to place it in a four-jawed lathe chuck as in Fig. 3, with the open end outward, and true it up by the cored hole. The outer end is then faced off, the inside edge broken or beveled slightly with the same tool and the inside bored out to the wrist-pin bosses by the boring head shown in the tail spindle. The casting is next placed in the drilling jig, Fig. 4, and the wrist-pin hole is drilled. The work is located in the jig by means of a plug which fits the hole just made by the boring tool. Next, the piston is placed in a Gridley automatic and

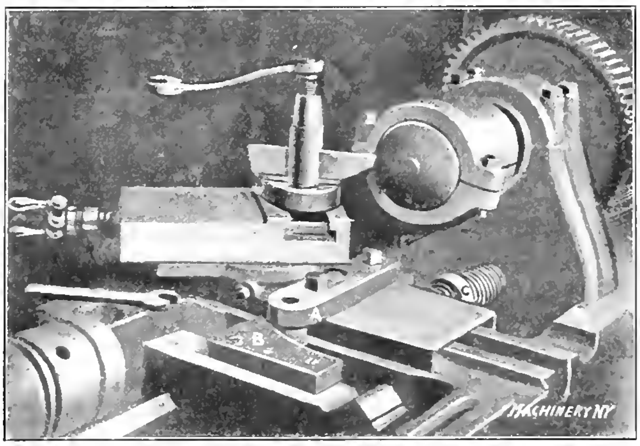

Fig 5 Lathe equipped with Forming Slide for Turning Spherical End of Piston

the outside, the piston ring grooves, and body clearance are turned. The piston is held in the machine by means of a stub mandrel, on the nose of the spindle, to which it is fastened by a long eye-bolt running through the spindle and tightened by a hand-wheel at the back. A short piece of heavy iron rod is also inserted through the wrist-pin hole in the piston and the loop of the eye-bolt. The piston is steadied on the cut by a follow rest.

From the automatic, the piston is taken and placed in the hollow chuck shown in Fig. 5, and the closed end rounded. The cross-slide of this lathe is especially fitted with a bracket *A* carrying a roller which is pressed against the former *B* by the heavy spring *C*. On being taken from this lathe, the piston is placed in another and held in the same way as on the automatic, while the end is centered and the ring grooves

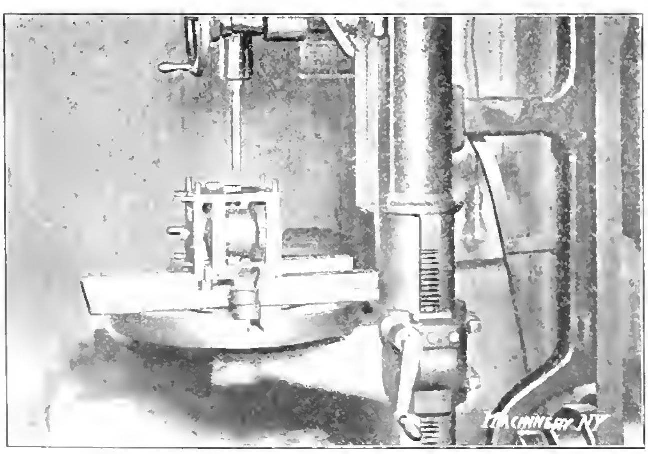

Fig. 6. Jig in which Wrist-pin Holes are Reamed

are carefully trued and sized. The piston is then placed in a Brown & Sharpe grinder, between a large and a small center and the outside ground to size; then it is inserted in the jig shown in Fig. 6 and the wrist-pin hole is reamed out. The final machining operation is to place the piston in the special machine Fig. 7, for the purpose of milling out the space between the wrist-pin bosses for the end of the connecting-rod. In this machine the work is held and located

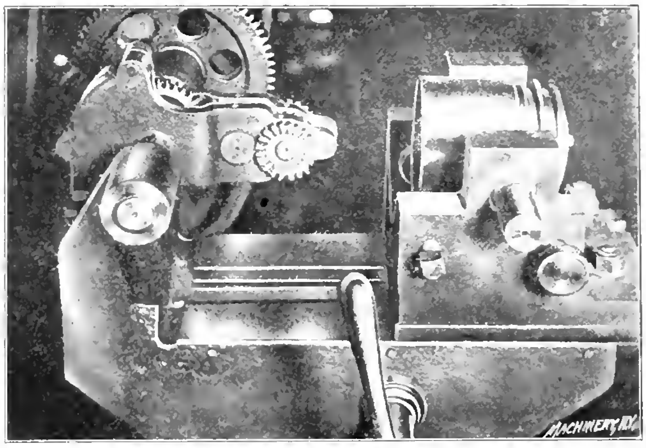

Fig. 7. Special Machine for Milling the Space between the Wrist-pin Bosses

between V-jaws with plugs inserted in each end of the reamed wrist-pin hole. The mechanism operating the mills is too plainly indicated to need further explanation. Just before the last inspection, the pistons are placed in the jig shown at *B*, Fig. 8, and the wrist-pin hole is carefully hand-reamed with a pilot reamer.

Machining Cylinders

Cylinders of the several types used on the different models of Stoddard-Dayton motors, are all machined in the machine shop which is in charge of Mr. Walter Sigler. These cylinders are of two general types: One having the water jacket cast in one piece around the cylinder with no openings other than the pipe openings, while the other type has a large opening fitted with a removable cover, both types being cast in units of two cylinders each, so made that they may be easily

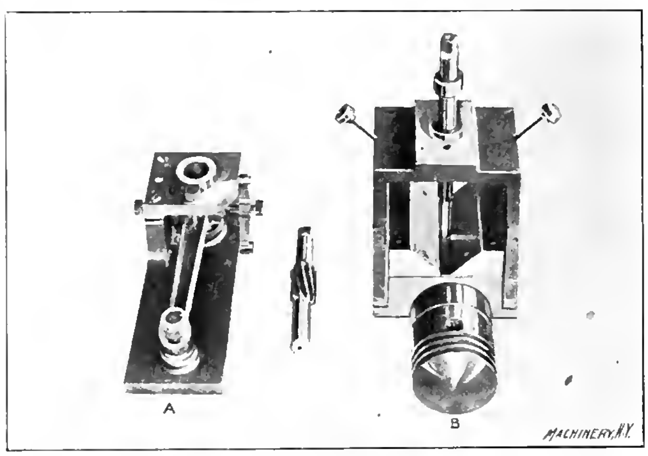

Fig. 8. Reaming Jigs for the Crank End of the Connecting-rod, and the Wrist-pin Hole in the Piston

grouped in multiples. The first machining operation on the first-mentioned type, consists in boring out the cylinders on a regular Beaman & Smith cylinder boring machine Fig. 9. This machine is arranged to hold four two-cylinder units at a time; two of the units being in position for boring while the other two are being set into the fixture. After one set has been bored, the fixture is reversed and in this way no time is lost in setting up the work. The second operation consists of drilling and reaming the valve holes in a turret-head drill press Fig. 10, the cylinder unit being held in a jig as shown. In the third operation, the water-pipe holes are drilled and tapped, and then the cylinders are strapped onto an angle-plate and the spots for the exhaust pipe flanges are surfaced off in a vertical mill. They now pass through several minor drilling operations before they are ground and given their final inspection.

The second mentioned type of cylinders, having the water-jacket covers on the sides, are bored out on the Beaman & Smith machine in the same way as the first type. The cover seats are then surfaced off in a mill and the cover holes

drilled and tapped using the jig shown in Fig. 11. The work is next placed in the indexing or tilting jig, Fig. 12, and the valve holes drilled, bored and reamed. In all, ten holes are finished in this jig. Instead of using an angle-plate to hold these cylinders while surfacing the exhaust pipe flange spots, as in the first instance, they are placed in a special fixture shown in Fig. 14.

leather padded cover, being clamped over the two large ones, then filling the jacket with water, attaching a pressure gage, connecting to an air hose and running the pressure slowly up to seventy pounds, all the time watching for any indication of a leak from a crack or a flaw. A similar preliminary test is also made in the machine shop on all cylinder water-jackets before machining and after boring out the cylinders.

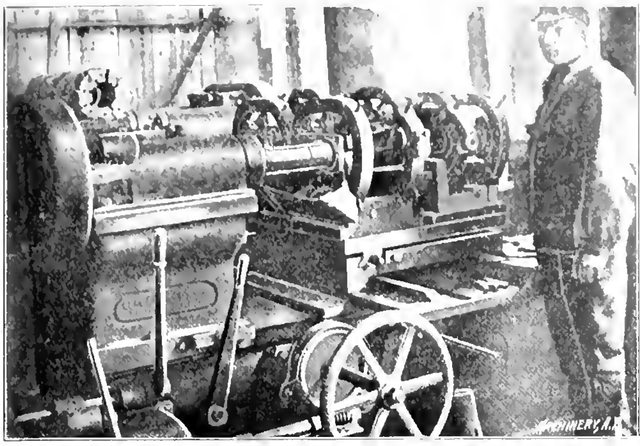

Fig. 9. Boring out Cylinders on a Beaman & Smith Machine

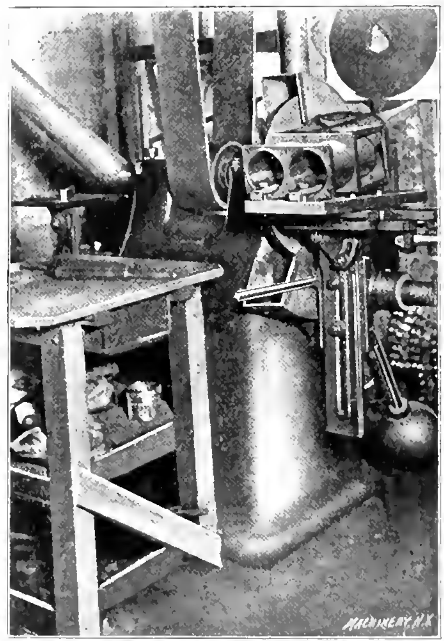

Fig. 13. Finishing Seats for Water Jacket Cover on a Besly Disk Grinder

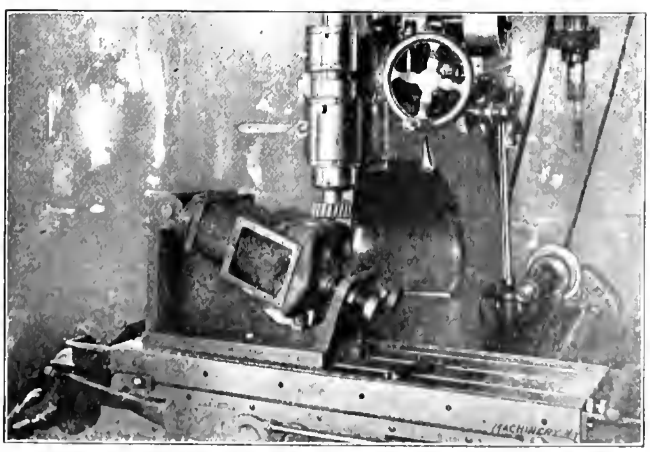

Fig. 14. Fixture for Holding Cylinder while facing Exhaust Pipe Flange Bosses

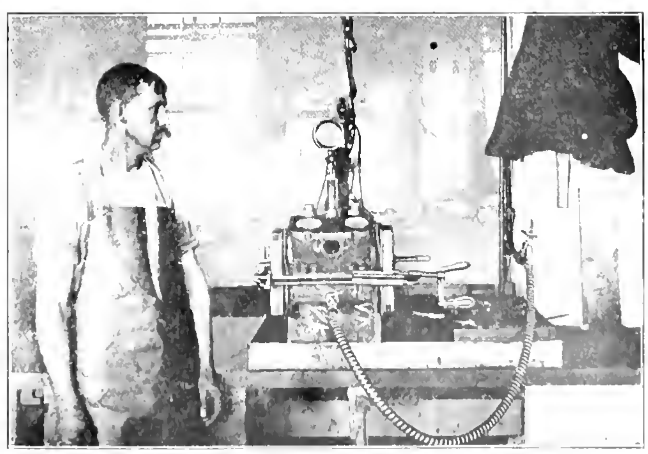

Fig. 15. Testing the Water Jackets

After all the machining operations are finished, these cylinders are sent to the grinding room and the water-jacket cover-seats finished smooth and true on a Besly disk grinder, as shown in Fig. 13. The cylinder bores are ground on a Heald grinder.

Before being assembled in the motor, the cylinder water-jackets are tested under seventy pounds water pressure, as shown in Fig. 15. This is done by stopping up all openings,

After the connecting-rods are drilled and reamed in a box jig, the final reaming is done in the motor part assembling department, the jig shown at A, Fig. 8, being used for this purpose.

Cover-seats on the differential cases, are surfaced off on a Becker-Brainard vertical milling machine as shown in Fig. 16, only the cross and table feeds being used to mill the almost circular rim of the cover seat.

Push-rod fork-ends are milled with a gang mill, eight at a time, on a Le Blond milling machine as in Fig. 17, the clamps of the jig being arranged so that the tightening of one nut clamps two rods as shown.

Milling Drive-gear Clutch Teeth

In Fig. 19 is shown the way the three clutch-teeth are milled in the gear-clutch end of the drive-gear sleeve, using a three-spaced indexing jig. Fig. 20 shows the same sleeve reversed for milling the teeth in the drive-shaft end, while Fig. 21 shows the way the clearance is milled on the teeth. A wedge is inserted under the bottom of the fixture so as to give it the proper angle, and a wider mill is used. It will be noted that clearance is shown on the teeth in all three engravings. This is because a finished sleeve was used while taking the pictures, no partly finished ones being available, but of course in actual work the clearance is milled in the order given.

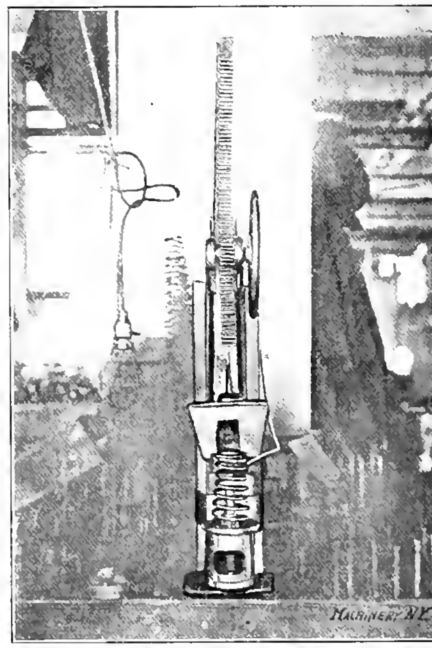

Fig. 18. Device for Compressing Valve Springs when Assembling Cages

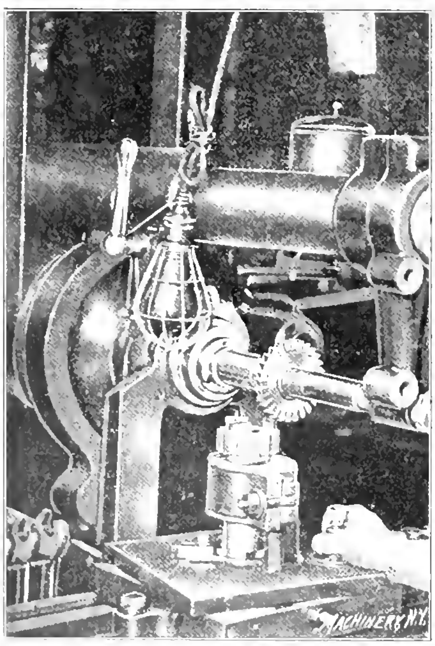

Fig 19. Milling Clutch Teeth in Gear-clutch End of a Drive-gear Sleeve

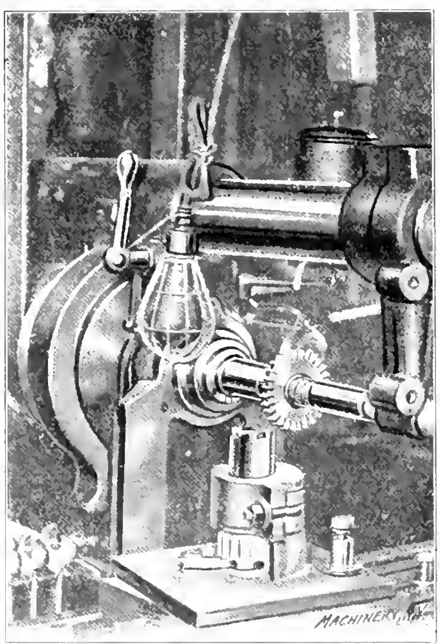

Fig 20. Milling Clutch Teeth in the Drive-shaft End of the Sleeve

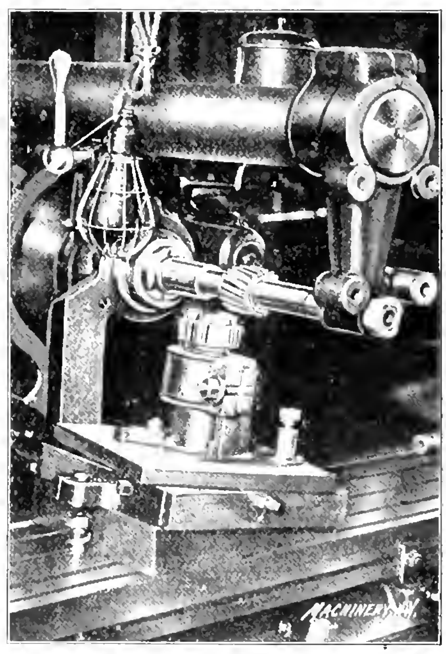

Fig. 21. Milling the Clearance on the Clutch Teeth of a Drive-gear Sleeve

Small valve cams are milled on a Garvin milling machine fitted with a Brown & Sharpe cam attachment (Fig. 22); they are then ground on a special grinder. On the new models, however, the cams and shaft are forged in one solid piece and are to be ground on a new, special grinder, now almost completed.

Crank-shaft bearings are bored out and then hand reamed in the reaming jig shown in Fig. 23; they are then broached out on a La Pointe broaching machine, the broach and guides shown lying on top of the crank-case in Fig. 24 being used. This unusual way of finishing the bearings, saves hand scraping and does a better job in far less time.

In the motor parts assembly department, in charge of Mr. L. C. Miller, there are a number of interesting things devised to expedite assembling; one of them, shown in Fig. 18, is an old paint-press made over to compress the valve springs so that the retaining washer and cotter-pin can be easily placed on the end of the valve stem, when assembling the valve-cage parts. The engraving shows a lower valve-cage and parts in position in the press ready for the compression of the spring and the placing of the washer and cotter-pin.

Crankshafts are held as shown in Fig. 25, while fitting the connecting-rods, which is much better than the usual method of holding them in a vise.

The adjustable motor assembling stands Fig. 26, are as convenient as any I have seen in use anywhere. As the engraving shows, the bed of the motor is bolted to the stand top which may be placed in a horizontal, 45-degree or vertical position on either side, as desired.

The forging department or steel shop as it is called, in charge of Mr. F. E. Sellars, is one of the most complete of any similar department of an automobile factory in the country. It is fitted with big steam hammers, board drops, forging machines, punch presses, bulldozers, special benders and

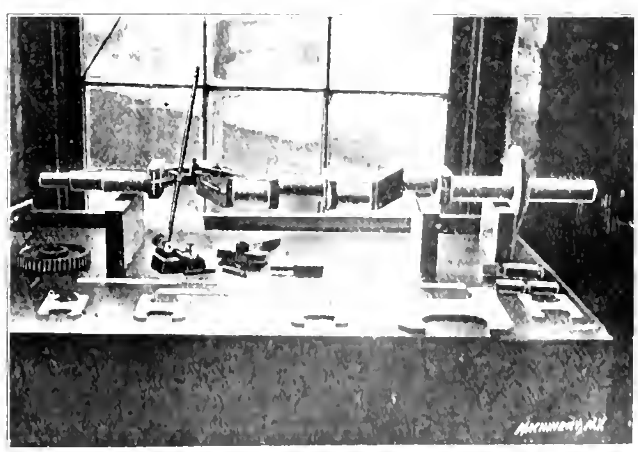

Fig. 29. Various Gauges used for Testing Crank-shafts

heating furnaces, and everything that is used that is a forging, as was previously stated, except crankshafts, is made here. Even the long, channeled frame-slides are formed out of the heavy steel bands in which form they come from the steel mills, and the holes in them are punched, using a big templet as a guide instead of laying out the holes and drilling as fre-

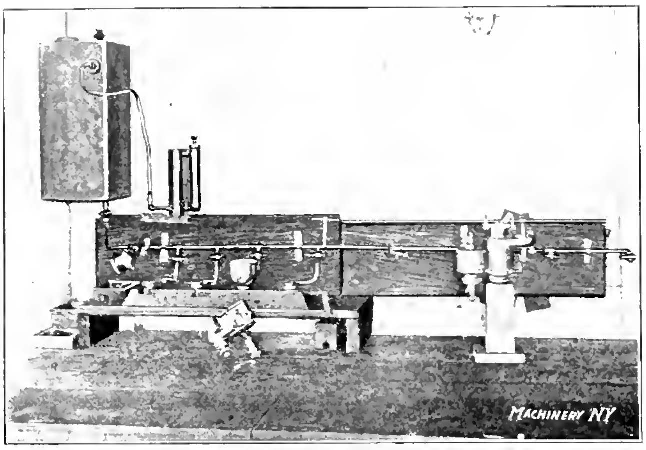

Fig. 30. Apparatus for Testing Carbureters

quently is the case. This department also contains the most complete barium-chloride tool-hardening plant in the West, with the possible exception of that of the Firth-Sterling Steel Co., in Chicago. A partial view of this department, showing the oil heated crucible furnaces used for melting the barium chloride, is shown in Fig. 27.

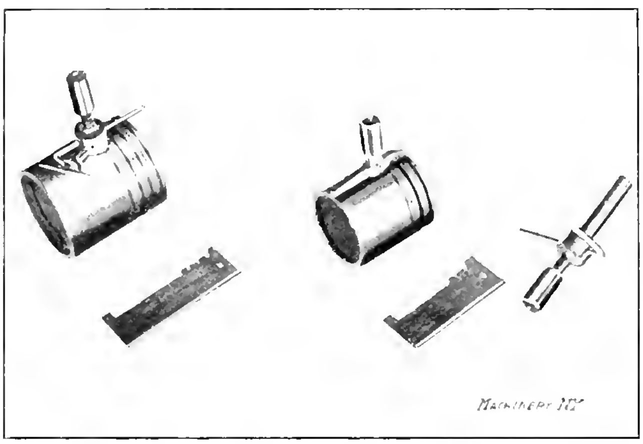

Fig 32. Piston Gages

The motor testing department, in charge of Mr. George Gorton, is also very complete, being fitted with all the necessary testing apparatus and a French manograph. As in all factories doing high class work, the testing and inspecting departments are the ones on which the reputation of the product depends, for no matter how good the design is, if

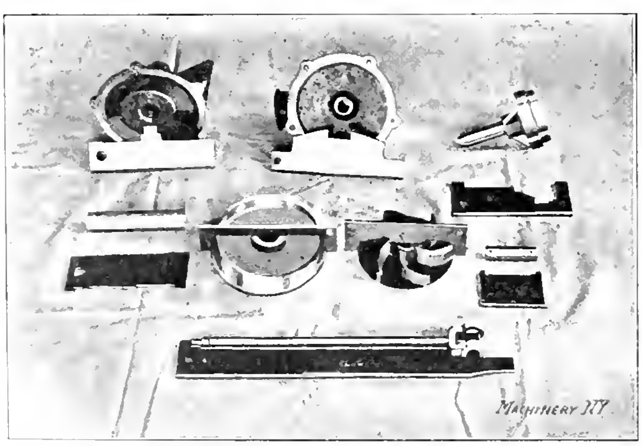

Fig. 34. Some of the Parts which are tested by the Templet Gages

the testing or inspecting is not thorough, the good designing soon is lost sight of by dissatisfied users. Recognizing this, the most rigid inspection is given all parts between each operation and before they are used or sent out. Of all the inspecting departments, that of the motor parts inspection in charge of Mr. M. Manny will probably be of the most interest to readers of MACHINERY. In this department, purchased parts are given an especially careful test as to material, workmanship and efficiency. Magnetos and their timers are carefully tested as shown in Fig. 28. This apparatus consists principally of a board with spark-plugs numbered to corre-

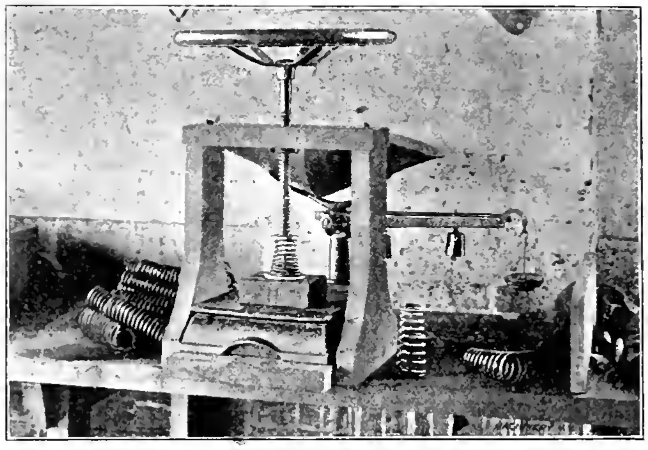

Fig. 31. Spring Testing Device

spond to the number of cylinders to be operated. These plugs are joined to the timer by suitable connections and a crank is fastened to the spindle of the magneto, so that by turning this crank and watching the resulting sparks, the tester can easily see if the spark-plugs respond in the correct order and with a spark of the proper "fatness."

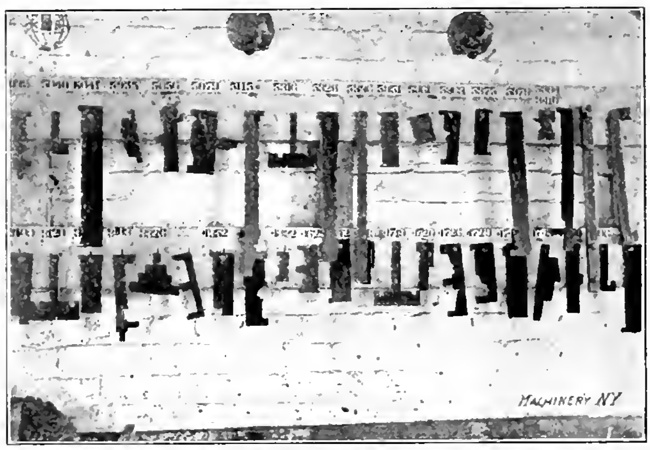

Fig. 33. Group of Miscellaneous Templet Gages

Crankshafts are tested on the large surface-plate shown in Fig. 29, the parallels, limit gages, indicators, scales and parts shown being used.

Carbureters are tested for leakage as shown in Fig. 30, a gasoline tank and pump to give the proper pressure together with a pressure gage and suitable fittings making up the

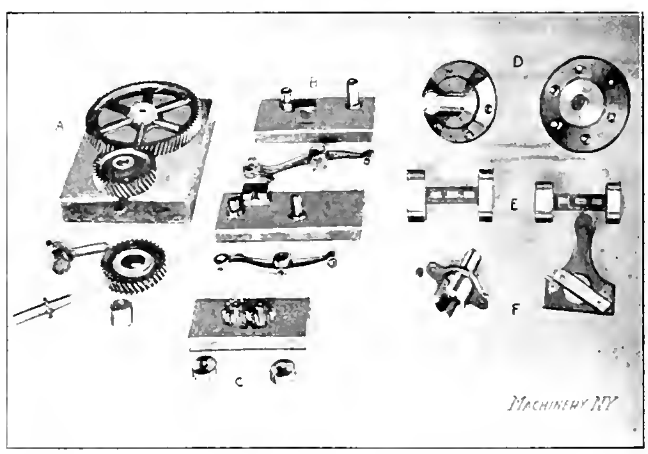

Fig. 35. A Number of Gages used in Testing Motor Parts

apparatus. Schebler carbureters are tested at $\frac{3}{4}$ pound pressure, and Stromberg's at 2 pounds.

Valve and push-rod springs, are tested as shown in Fig. 31. These springs are tested according to certain tabulated data. For instance, the spring shown must give a pressure of 60

pounds when compressed to $2\frac{1}{8}$ inches, a slight variation being, of course, allowable.

Pistons are measured for diameter, and the angularity and size of the wrist-pin hole, the length of the piston, the depth, spacing and size of the grooves are tested with the gages and templets shown in Fig. 32.

A group of flat metal templets, used for various purposes is shown in Fig. 33, and the way some of them are used for testing pump and other parts is shown in Fig. 34.

At *A*, Fig. 35, is a device for testing the center distance and proper meshing of the timing gears, the small gear being mounted on an eccentric pin with a small lever attached, and the center distance being obtained by calipering the centers when the gears are properly meshed. At *B* are two rocker-arm contact gages; *C* is for testing small pump gears, the disks being used to test the accuracy of the pins from time to time; at *D* are two flywheel bore and drilled hole gages; at *E* are two Brown & Sharpe limit plug-gages and at *F* is a valve plunger guide and gage.

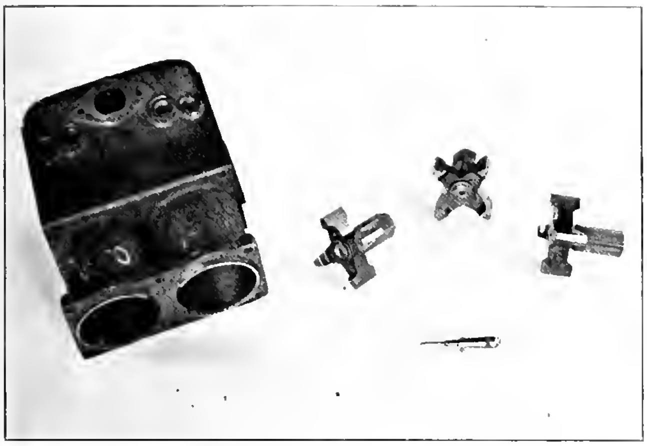

Fig. 36. Cylinder Bore Limit Gages

Fig. 36 shows a cylinder and three bore gages. The middle one is standard, the one at the left is 0.002 inch small, and the one at the right is 0.002 inch large, while in case of doubt the inside micrometer is used.

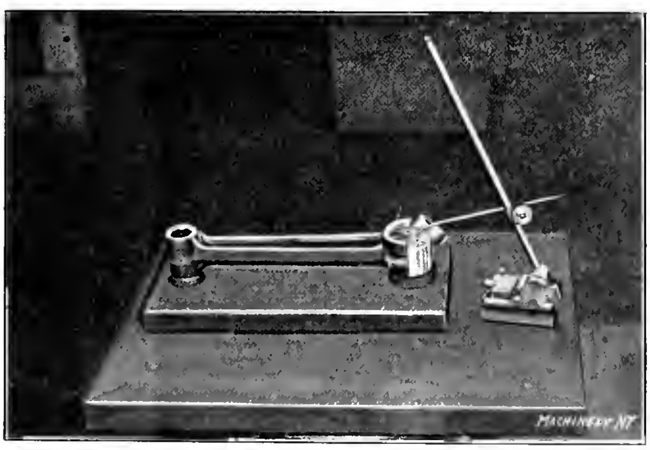

Fig. 37. Method of Testing Connecting-rods

Connecting-rods are tested as in Fig. 37, the pins in the plate being exactly the proper distance apart and of the correct diameter. The surface gage is used to test the amount of offset at the large or crank end.

In preparing this brief description of a few of the interesting things to be found at the Dayton Motor Car Co.'s plant I am especially indebted to Mr. Harry Tuttle, Chief Engineer Edwards, Supt. Houk, and also to Mr. A. C. Miller, the well-known racing man, who acted as guide.

* * *

According to the *London Financial Times* a new patent law was enacted in Austria last December which came into force in June this year. This law contains a section similar to that of the new British patents act by which patents in Austria will be revocable at the expiration three years from the date of publication, without any notice, if the patent is not worked in Austria to an adequate extent.

FACE-PLATE FOR ECCENTRIC PISTON RINGS

CONTRIBUTOR

The design of a special plate to be secured to an ordinary face-plate for holding any work to be either bored or turned eccentric, is shown in Fig. 1. When turning eccentric piston rings, for example, any degree of eccentricity can be obtained from zero to the maximum amount that the plate is designed to give, and, in addition, all the operations such as boring, turning and cutting off the rings can be performed at one setting of the casting.

The construction of the plate is clearly shown in Fig. 1. The outer part *C*, to which the work is attached, is secured to a plate *D* by the bolts *E* and *F*. The bolt *F* acts as a fulcrum for the plate *C*, which swings upon it to either of the extreme positions of eccentricity indicated by the dotted lines *B*. The hole in the part *D*, for the bolt *E*, is elongated as shown in the elevation so that the bolt is free to move when the plate is being set over for eccentric turning or boring. The spring *H* serves to keep the faces of the two plates in contact when the nuts are slacked off to permit the plate *C* to be moved. This prevents the possibility of any dirt getting between the plates. Assuming that it is first

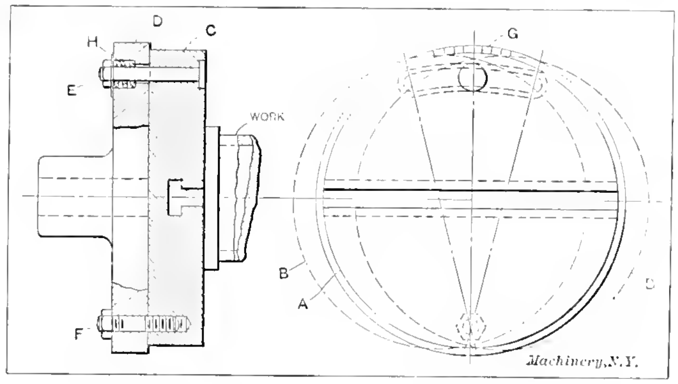

Fig. 1. Special Lathe Face-plate for Turning Eccentric Rings, etc.

necessary to turn a piece of work, the casting would be set true by the outside, with the locating plate *C* in its central position *A*, in which it runs true with the face-plate proper. After the turning operation, the two nuts on bolts *E* and *F* would be slacked off slightly, and the locating plate pushed over the required amount. The nuts would then be tightened and the inside bored to the size required; the outside, of

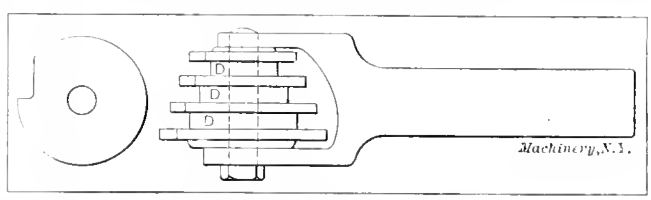

Fig. 2. Cutting-off Tool for Piston Rings

course, would be running eccentric. By graduating the plate as shown at *G*, it can be quickly set to any desired amount of eccentricity.

The tool-holder shown in Fig. 2, which is equipped with circular cutters, may be used to part the rings to the correct width. As will be seen in the illustration, the distance pieces *D* determine the width of the rings. These distance pieces should be made of mild steel as it affords a better surface grip than if hardened steel were used. The shape of the cutters is shown by the outline to the left of the engraving.

* * *

The number of automobiles in use in Germany slightly exceeds 20,000. The number in use in the United States has been estimated to be 160,000, or twice the number of the automobiles in use in the whole of Europe. There are 69,000 automobiles registered in New York state alone. In a statement recently published by the American Motor Car Manufacturing Association, the number of concerns building automobiles in the United States is given as 253, and the capital invested in the automobile industry, including that of kindred trades, sales-rooms, garages, etc., is nearly $200,000,000.

SUGGESTIONS FOR A MODEL BLACKSMITH SHOP*

JAMES CRAN†

Buildings for manufacturing purposes are as a rule constructed more or less in accordance with recognized standards that have been adopted on account of their adaptability for the particular class of work they are to be used for. In plants of the larger machine-building concerns and similar industries usually all buildings are of the same general style throughout with the exception of the blacksmith or forge shop, which is often entirely different. Why this should be, no good reason is apparent from a practical point of view, as the style adopted is often less suitable for the purpose than that of the other buildings, and the result is that very often blacksmiths and forge men have of necessity to work under conditions that are anything but an incentive to the best results. Workmen, no matter what the nature of their occupation may be, will do more and better work under pleasant and attractive conditions than they can be expected to do in a gloomy atmosphere. In this respect blacksmiths are no exception to the rule. As their art is indispensable to all other industries, a few practical suggestions that would have a tendency, if adopted, to reduce cost, increase and improve production for the employer, and bring about better conditions for the blacksmith, may not be out of place.

The principal essentials of a blacksmith shop where maximum production at minimum cost is expected are light, ventilation, sanitary arrangements and sufficient space to accommodate a full equipment of machinery and appliances systematically arranged and installed. What the writer considers a basis that could be worked from in constructing, equipping and arranging blacksmith shops from a few forges capacity to the largest is shown and described in the following:

Foundations and Walls

To begin with, the foundation has first to be considered. Where a rock bottom can be had very little preparation for building is necessary, but where building has to be done upon sand, clay or swampy ground it is important that the foundation be made thoroughly solid, otherwise the jar from steam hammers and other machinery will have a tendency to warp and crack the walls. The construction, in general, like buildings used for other purposes, should be governed to a certain extent by the class, size and weight of the work that has to be done. If used for light forging exclusively, the walls need neither be as high nor as heavy as where the work is varied or of large proportions. For light and medium weight work walls need not be more than from 15 to 20 feet in height, but for heavy work or where it is of a wide variety as in railroad or heavy machine building shops the walls should be from 20 to 25 feet in height so that there would be sufficient space between the tops of large steam hammers and the roof trusses for the free use of jib cranes or other overhead lifting and conveying devices.

Very little can be said regarding the foundation specifically, as general conditions and the nature of the site would have to be taken into account before any authentic information could be given, other than that it should be made as solid as possible. The walls, preferably of brick or reinforced concrete, should be of a more substantial nature than is generally required for other purposes. The piers between windows may be supported either with pilasters or buttresses or a combination of both. For the admission of plenty of fresh air which is essential in all manufacturing buildings, especially in blacksmith shops where more or less heat is radiated from forges and furnaces, the windows should not be over 36 inches above the level of the floor. If placed higher in the walls, which is often done to save their being broken by flying pieces of iron or steel, or to conform with a pet theory of protecting the men employed from drafts, they are too high to be of much benefit other than admitting light, as the greater portion of the air admitted enters at a point too high to benefit the workman or to keep the lower portion of the shop where heat is generated cool enough to be comfortable. Plain sash windows that can be raised from the bottom and lowered from the top are the best type to use and can be protected inside and out with wire screen. In locating doors it is well to have one in each end of the building large enough for the admittance or removal of any kind of work or material and to have others in the side walls where they may be required.

Forge Space and Arrangement

The next thing that calls for attention is the amount of space that is necessary for each forge. This depends very much upon their arrangement. If they are grouped as is customary in some shops, a saving of space is effected, but work in general cannot be so conveniently or economically handled as when they are arranged in rows, for the reason that in groups men from some of the forges will either have to pass between other men and their forges or anvils or take a long roundabout way to and from steam hammers; not only this, but work is often of a shape that can only be handled to advantage on forges with at least three sides accessible. It is therefore advisable that they be arranged in rows sufficient distance from the walls to allow of portable vise benches, surface plates, etc., being used where the light is best and moved from place to place as they are required without necessarily taking them into the center of the floor or between blacksmiths and steam hammers. With forges installed from 5 to 6 feet from the walls and 16 feet of space allowed for each as shown in Fig. 1 there would just be sufficient space around them for the tools generally used at the anvil and the convenient handling of all ordinary blacksmith work. For light work they may be placed a little closer than 16 feet, but more difficulty is experienced in trying to do work in limited space than where there is sufficient room. Wherever conditions will permit it is preferable to have blacksmith shops, if they exceed the capacity of 10 forges, wide enough for a row on each side with corresponding rows of steam and power hammers facing the forges on the side of the shop in which they are installed.

Forges used for the average range of blacksmithing are from 36 to 48 inches in width. With these placed 5 feet from the walls and anvils from 18 to 24 inches out from the line of forges the distance from wall to anvil will be approximately 11 feet. At least 12 feet of clear space should be allowed between the line of anvils and steam or belt-driven hammers, the bases of which are anywhere from 5½ to 8 feet in length. As a certain amount of space behind the hammers is necessary, 10 feet more may be added. Thus a shop of approximately 40 feet in width is required for single rows of forges and hammers and 80 feet for double rows. The advantages of a short wide shop over a long narrow one are obvious. It is more compact and better under the observation of the man in charge. The space back of the steam hammers is doubled, making the center of the shop wide enough for a line of car tracks which may be standard or narrow gage, and the handling of work too long or of a shape that could not be advantageously handled by ordinary means. Not only this, but the saving in actual construction, which would amount to about one-third, is an item too important to be overlooked.

There are, however, certain elements to be contended with in the construction of a wide building that can be entirely dispensed with in a narrow one. When a building exceeds a certain width some supports for the roof other than the walls are necessary if cost, which is a prime factor, is to be kept at the lowest margin. These roof supports are generally in the form of columns so arranged that the weight is evenly divided. In blacksmith shops columns or supports should be located where they would offer the least obstruction to the handling of work which is almost invariably hot, and the success of the various operations of shaping it depends upon reaching a steam hammer in the least possible time after it is removed from the fire. It is therefore obvious that the fewer obstructions there are to be avoided the greater the probability of the work being successfully accomplished. Just behind the line of steam hammers, columns would be entirely out of the way and would serve the double purpose of supporting the roof and traveling cranes or trolleys.

* For data previously published on this subject, see MACHINERY, February, 1904, "Machine Shop Equipment—Equipment of the Forge Shop."

† Address: 916 West Third St., Plainfield, N. J.

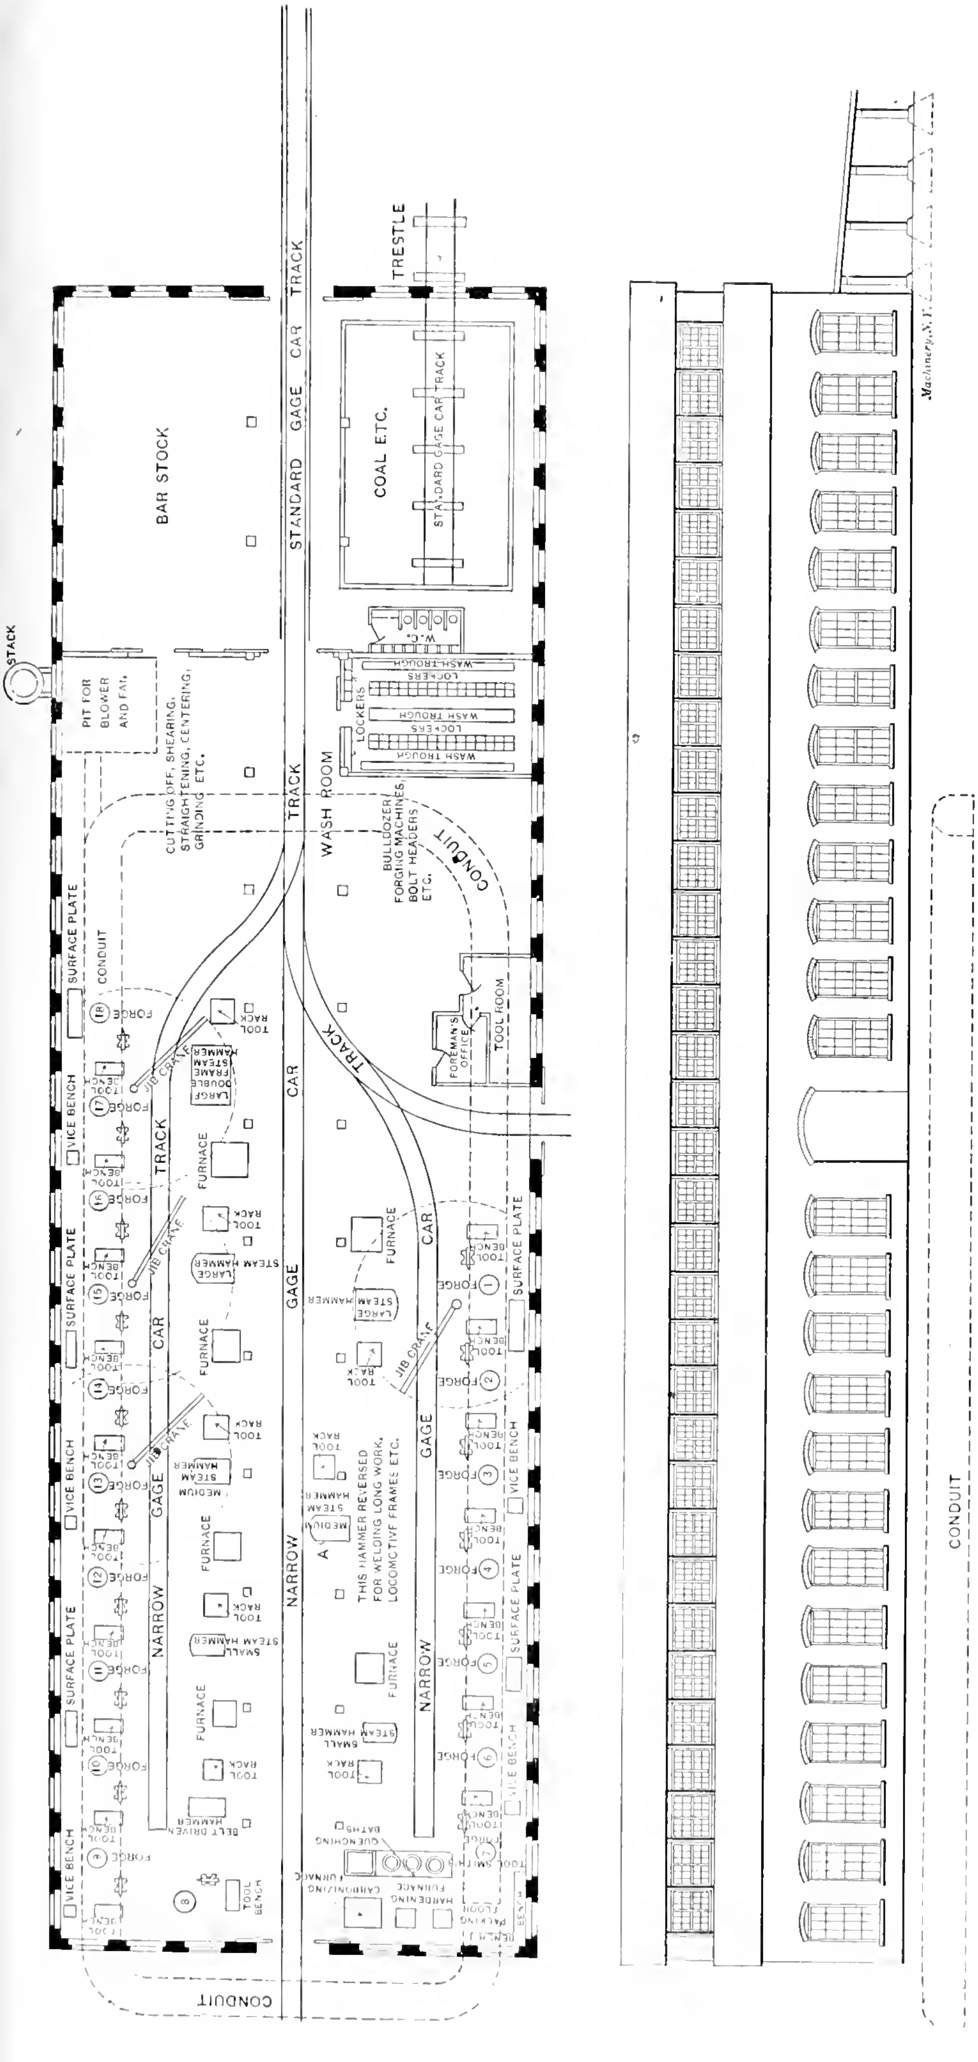

Fig. 1. General Layout and Side Elevation of Blacksmith Shop

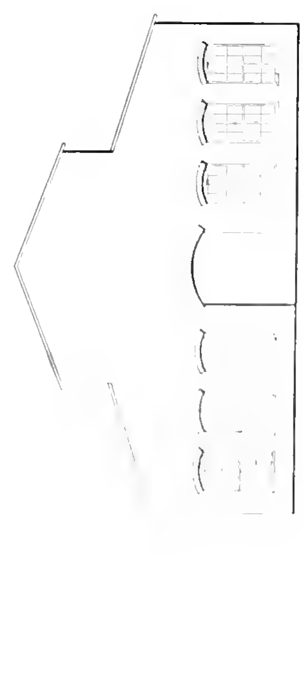

Fig. 2. End View of Blacksmith Shop

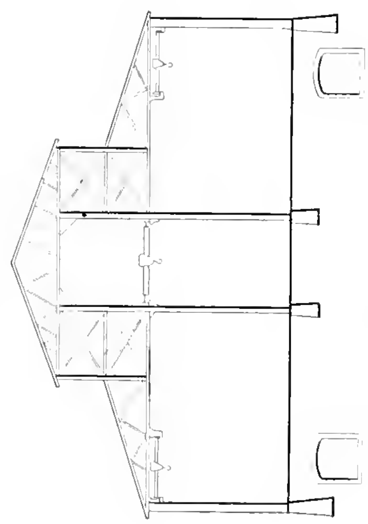

Fig. 3. Cross-section, showing Travelers

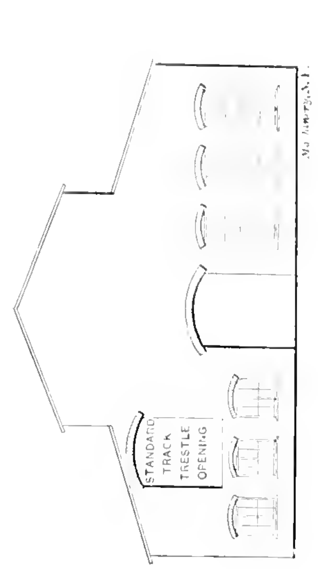

Fig. 4. End View, showing Car Trestle Opening for Discharging Fuel

These points considered and provision made for the storing of bar stock, coal and other materials used in blacksmithing in the same building or adjacent to it constitute the most important features of an ideal blacksmith shop, which may be constructed, laid out and arranged as follows, or the general idea used as a basis to work from.

The general arrangements of a shop of 18 forges in which provision has been made for a full equipment of appliances generally used in a shop of that capacity are shown in Fig. 1. One end is assigned to material, as bar stock, coal, etc., and space for cutting off and centering machines, in short all that is required for putting work in proper condition to be work that can be heated in them and have them as near to steam hammers as is practicable. In most of the blacksmith shops connected with manufacturing plants one or more toolsmiths are employed and more or less carbonizing, heat treating, annealing, hardening and tempering has to be done. This class of work should be as much concentrated as possible, located in the shop where it would be least likely to conflict with other work and be under the charge of a sub-foreman. Saws, shears, cutting-off, straightening and centering machines, together with any other machine tool that may be used, should be located near the stock supply and if possible near the point from which finished work is forwarded

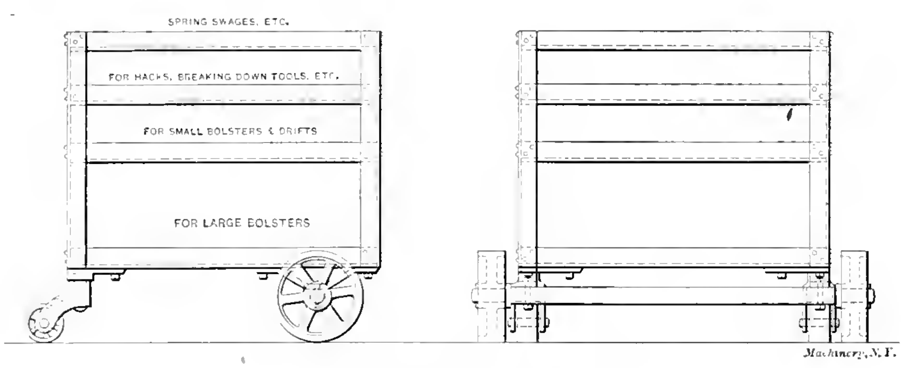

Fig. 5. Portable Rack for Steam Hammer Tools

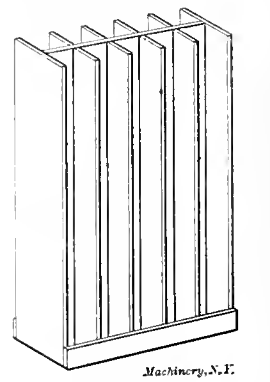

Fig. 6. Upright Rack for Light Bars

turned over to the machine shop without workmen having of necessity to go outside the building. Forges are arranged in rows 5 feet from the side walls, with those intended for the largest and heaviest work nearest to the stock supply for which one end of the building is exclusively assigned. All forges are served by an overhead trolley system, one cross section of which is assigned to each forge for lifting and supporting work at the anvil. Forges for the larger work are further supplied with jib cranes so arranged that the column is well out of the way of work so that one can be used for conveying to and supporting at the steam hammer the work of two forges, the furnace being located near the hammer that it serves.

Arrangement of Steam and Belt-driven Hammers

All power hammers, steam and belt-driven, with the exception of one, which will be referred to later, are installed in rows facing the forges at a distance of 12 feet from the line of anvils, which is just sufficient space for the general range of blacksmith work being done at steam hammers without conflicting with that being done at forges. The steam hammer *A* which is reversed and out of alignment with other hammers can be used for such work as welding long shafts, leadscrews for long lathes, locomotive frames or any other work too long or of a shape that could not be advantageously handled by ordinary means. This class of work is supported by hooks from an overhead trolley and heated in a portable forge so arranged that it drops clear of the work when it is ready to be conveyed to the hammer by turning a lever. This forge was shown and described in MACHINERY, December, 1908, in connection with an article on welding. No definite information can be given upon the number of steam or power hammers necessary for any given number of forges, as that would depend very much upon the class of work to be done. Sometimes three or more blacksmiths could use the same hammer to block out their work without wasting time in waiting for turns or one man's work conflicting with another's, while on other kinds of work one man may monopolize one hammer for a time. In any case the equipment of hammers and other power appliances should be ample for the requirements, otherwise much time may be wasted in men having to wait after their stock is heated before they can have access to a hammer or in having to leave it before an operation is completed. In a shop of 18 forges where work is of a wide variety of shape and size, from 6 to 9 hammers will be required. Generally a great part of machine blacksmithing, especially blocking out, can be much more economically heated in furnaces than is possible when forges are used exclusively. It is therefore advisable to use furnaces for all

to the various departments where it is wanted. These machines and all bar stock would constitute a department that could be attended to by a sub-foreman.

Location of Blowers—Conduits—Piping

The blower for supplying forges and furnaces with blast and the fan for mechanical draft, if a down-draft system of carrying off smoke and gases is to be used, may be installed as near to each other as is practicable and operated by the same mechanism, preferably motor drive. Common practice is to elevate blowers and fans above the level of forges; sometimes they are placed upon a platform in the roof trusses to save floor space. This practice is not to be com-

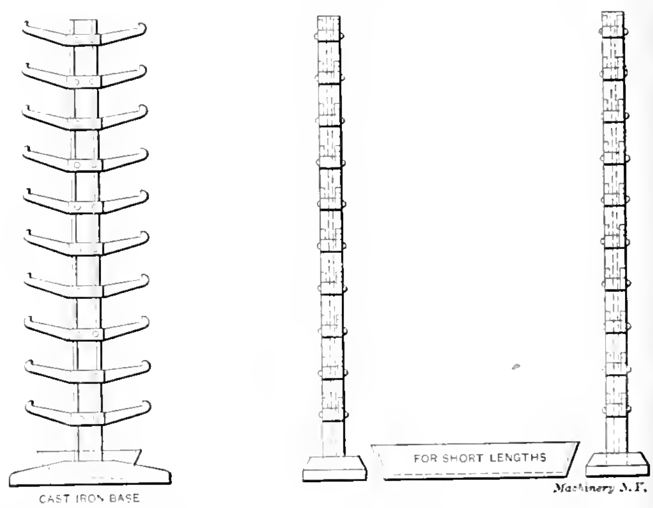

Fig. 7. Rack for Round or Square Bar Stock up to Four Inches

mended for the reason that when the wind gate of a forge or furnace happens to be left open when the blower is closed gas generated by the still ignited fuel upon the forge enters the pipes and naturally rises. It may escape through the blower unless it happens to be started up before the fire upon the forge has died out. When this happens the gas is forced back upon the still burning fuel where it is ignited, causing an explosion which may ruin pipes and damage the blower. If blowers and fans are installed in a pit below the level of the floor they are more accessible and the danger of being damaged by explosions is minimized from the fact that gas will not descend except when forced. Generally blast is conducted from the blower to forges and furnaces through a main pipe which is reduced in size as it passes the various branch pipes which connect with the forges. This has a tendency to make the pressure greatest near the terminal

of the main pipe. To equalize the blast pressure at all points the main pipe should be in the shape of a loop, both sides of which may be of equal capacity to the discharge of the blower so that it would act as a reservoir permitting of branch pipes being connected with it at right angles instead of the more acute angles generally used, and should it be necessary to increase the blowing facilities or enlarge the capacity of the shop this could be done without changing the blast pipe. In an ideal blacksmith shop all piping should be where it is least likely to be in the way and still be accessible. For this purpose an underground conduit in the shape of a loop directly under the line of forges as shown by dotted lines in Fig. 1 and in cross-section in Fig. 3 of a size sufficient to accommodate the entire piping system including blast, steam, water, gas, oil, compressed air, heat for warming

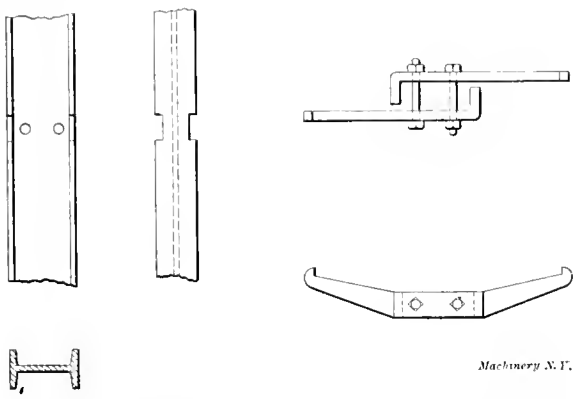

Fig. 8. Detail of Upright and Arms for Rack shown in Fig. 7

the shop in cold weather, smoke, sewer or any other piping or wiring that may be necessary and to which access may be had through openings in the floor between forges. These openings should be lined with concrete covered with slatted platforms upon which blacksmiths could stand at their work and through which heat could be admitted in cold weather and cool air in warm weather either through the heating system or openings in the walls fitted with gratings and shutters that could be opened and closed at will. The water supply which is essential in all blacksmith shops is more important than is generally supposed; each forge ought to be provided with a slake tub, the water in which should be kept fresh. If this has to be carried from a general supply pipe as is customary in most shops, much time is wasted both in emptying and refilling the tubs that could be turned to good account if a faucet and sewer connection is located near each forge and elsewhere about the shop where they may be required.

steam and power hammer there should be a tool rack, preferably portable, of which Fig. 5 is an example, that would accommodate a full set of spring swages, fullers, breaking down tools, hacks, bolsters or any other appliances that may be used in connection with hammers, each tool as far as possible being assigned to its own place upon the rack. This would overcome the disadvantage of having to turn over a miscellaneous heap of tools usually stacked upon the floor to find the one that is wanted and to move them individually should the space they occupy be temporarily wanted for some other purpose.

To get the greatest efficiency from steam power hammers the foundations upon which they are mounted must be solid. Concrete resting upon hard pan has given better results than the combination of heavy wooden beams and concrete commonly used. In installing solid concrete foundations there should be several inches of cement placed over the concrete and a cushion of wood at least three inches in thickness placed between the cement and the base of the anvil to give the necessary resiliency and prevent the concrete being pulverized by the impact of the blows. Back and front of the hammers there should be openings down to the level of the anvil base so that it could be leveled or adjusted by wedging up and grouting with cement if for any reason it should get sagged or out of alignment with the upper parts of the hammer. These openings should be covered with hatches level with the floor.

By conducting steam to hammers from the main steam pipes in the underground conduit through branch pipes provided with traps the disadvantages and annoyance caused by condensation are practically obviated, providing the supply pipes are enclosed in non-conductive casing until they are connected with cylinders. The exhaust and all other pipes leading from hammers may be accommodated in the same casing down to the floor level, where they may be conducted outside the building through conduits and allowed to discharge in the usual manner or be turned into a condenser and ultimately into the sewer.

Foreman's Office, Wash Room, Lockers, Etc.

The foreman's office and the room used for special tools, fixtures, formers, welding compounds, etc., should be connected, if possible, and located centrally in a position from which the whole or the greater part of the shop could be easily seen and if possible near the door that is used the most. If that happened to be a side door, office and toolroom may be as shown in Fig. 1. Should an end door be more convenient the office and tool-room may occupy the space assigned to forge No. 8. For convenience as well as

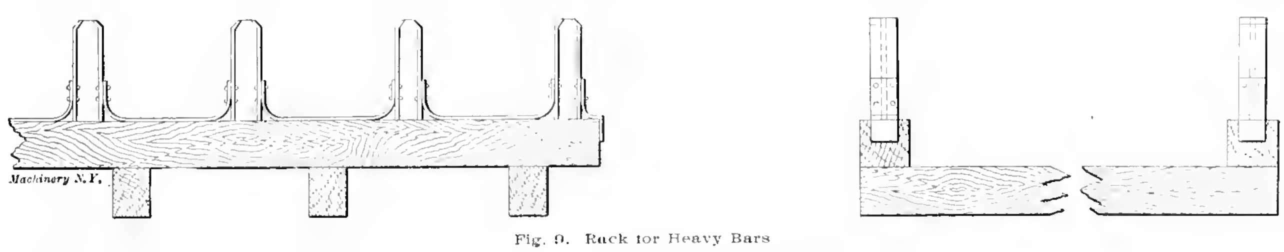

Fig. 9. Rack for Heavy Bars

These connections should not be made directly with the tubs, except at forges used by tool-smiths or where hardening has to be done, as it is often necessary to move tubs and other appliances at forges used for regular forging to make room for work of unusual shape.

Furnaces—Tool Racks Hammer Foundations and Piping

Furnaces to be used for heating work that is to be blocked to shape in quantities at steam hammers and those used for heating material to be drop-forged or shaped in forging machines, bolt-headers or bulldozers may be heated either with solid fuel or oil. Oil is preferable for several reasons. It is conducted from the supply tank to where it is to be used automatically through pipes. Once ignited the supply can be regulated and the heat maintained at an even temperature for any length of time. There is practically no refuse to be removed and no time is wasted in waiting for a fresh supply of fuel reaching the proper temperature for the work to be done as is the case with any kind of solid fuel. For each

economy blacksmith shops should be provided with washing accommodation, locker rooms and lavatories, which would not only add to the comfort of the men employed, but would be the means of saving the time that is wasted in going to other buildings. In a shop of 18 forges there should be locker and washing accommodations for at least 60 men. This at a conservative estimate would occupy at least 650 square feet of floor space. The lavatory for obvious reasons should be separate from the locker and washroom, but in close proximity, and is therefore shown in the floor plan just beyond the partition that separates the shop from the coal storage.

Flooring

There is much difference of opinion as to the material that is best adapted for the flooring of blacksmith shops. Wood is too inflammable, bricks crack and break from the heat and impact of work being laid upon them, cement or concrete is poorly adapted for the same reason, and asphalt is out of the

question. Nothing that has been tried so far has given better satisfaction or can be installed at less cost than dirt mixed with ashes. If kept moist by being watered at least once every day it is more comfortable to stand upon than anything else that can be used for the purpose. It is easily repaired and leveled should holes or irregularities get worn in it, and it is not affected in the least by hot or heavy pieces of work or material being dropped or laid upon it. The space between walls and forges, however, may be covered with concrete and cement to facilitate the handling of such appliances as portable surface-plates and vises, and the floor of wash-rooms and lavatories may be of asphalt, while the foreman's office and tool-room may be of wood.

The spaces assigned to cutting-off machinery, etc., and that for drop-hammers and other machines used in making die forgings has not been laid out in detail for the reason that machines for that class of work vary so much in general outline and in size that it would be difficult to arrange them satisfactorily except by knowing their makes and the size of work they are to be used for.

Bar Stock Racks and Storage

In storing bar stock several things have to be considered if time is to be saved and the chances of making mistakes in using wrong material minimized. Racks are necessary for the purpose and should be constructed in a manner best suited for the accommodation of the various kinds of material and so that bars can be lifted from the sides instead of having to be pulled from the end, as must be done when the common lattice pattern rack is used. For tool steel or any other special material racks of the type shown in Fig. 6 will be found to be the most convenient, as bars can be stood on end irrespective of length, and short pieces kept in the enclosed portion at the bottom. For the more ordinary grades of stock up to a certain size a rack of the type shown in Figs. 7 and 8 will be found to be very convenient, as bars can be removed from the sides, which is much more expedient than pulling them from the ends. Lengths too short to be supported by the arms can be placed in the box-shaped receptacle at the base. For bars too heavy to be stored upon racks of the types already shown a platform raised a little above the level of the floor and divided into sections by upright stakes, which may either be of cast iron or steel of structural shapes as shown in Fig. 9, may be used. All material to be designated by colors on the ends of the bars to correspond with the colors of the racks in which they are stored.

Communication between the stock-room and cutting-off department should be through sliding doors that would permit of bars too heavy to be lifted by hand, being lifted and conveyed between the two places by an overhead trolley system, to pass through the sliding doors at the point where they come together.

Fuel Storage—Roof Construction

On the opposite side of the building from the bar stock store are the pockets for storing coal, coke, charcoal or any of the other solid fuels that may be used. The approach to these pockets is a line of standard gage car tracks elevated upon trestle work and entering the building through a door in the end wall above the level of the pockets as shown in Fig. 4, this door to be large enough to admit locomotive and cars so that coal, etc., could be dumped directly into the pockets from which it could be supplied to forges or furnaces by hand cars.

The roofing of a building as here depicted apart from general outlines is a subject upon which the constructing engineer ought to be left with a free hand, as stresses must be calculated and tension and compression members of the trusses arranged accordingly. The sides of the ventilating monitor, however, should be at least 6 feet in height to admit of the windows used being of a size sufficient to throw good light upon the anvils at the opposite sides of the shop. These windows should be balanced upon horizontal trunnions so that they could be opened and closed by means of cords or rods operated from the floor.

* * *

The value of the present output of automobiles is estimated to be about $130,000,000 yearly.

HOW OLD SI WAS NEARLY "OSLERIZED"

A. S. ATKINSON*

Native ability is something that is quite scarce in the average machine shop, or at least if it is there it is smothered up or held in check or choked by too much rule-by-measurement practice. Of course I don't mean the ability to run a machine, cut after a pattern, or do any of the other routine work that must make up most of the day's labor in nine cases out of ten. Old Si Smith used to define native ability as "the knack of making something out of nothing." Si had this kind of ability. He was of the old school, hadn't been trained and schooled in an industrial college, and when he served his apprenticeship in the shop there weren't one hundredth as many machines to do your work as there are to-day. A man then had to get out and be his own boring machine, lathe, and planer. There wasn't any monotony about a machinist's job then. Likely as not one day you'd have to weld together a broken rod in the blacksmith's shop or hammer a new point onto a broken bit, and the next you'd be patching up a boiler plate or riveting a steam box to keep it from bursting, or you'd be doing almost anything from filing and scraping down a rough piston to making a new sheet-iron box. There was no standing before a huge machine and watching its rhythmic cutting and pounding, hour after hour.

The old school developed native ability, if one had it in him, and sometimes it knocked a little into one who didn't inherit any from birth. It may be the new method is better for turning out great quantities of exact work, but the day of the man with the knack for doing things has gone for good. Not entirely though—at least one such man is essential to the success of every shop. Just to prove this I will recall some little experiences in which old Si figured. The old superintendent understood Si, and instead of looking upon him as a back number who ought to be "Oslerized," he valued his services for all they were worth. He was always sure of his position in that shop. But the old superintendent died, and another, a stranger to most of us, came to take his place, and with him a new foreman who was about as much a stranger as the head boss. They were both younger than their predecessors, and they believed in hustle and bustle, and method and system. They put everything and everybody to checking off everything and everybody else. They said they wanted to know how much each man was doing, and how much each article cost. I suppose it was all right, as it was modern and progressive. Most of us were young enough to adapt ourselves to the new way and not let it bother us. But it came rather hard on old Si Smith. Si couldn't understand it. He didn't know why he had to be watched and why he had to jot down on a paper everything he did—the time, date, and number of minutes. He protested in vain. "I've been here forty years, an' I never cheated the boss out of an hour of time. I do my work honestly." But this was of no use. "I believe you're honest, Si," the foreman replied not unkindly, "but how do we know whether you're doing your share of the work. It's not so much a question of good intentions as of capacity and efficiency." That stumped Si, and he only stared back stupidly. "What does he mean?" he asked appealingly of us at the noon hour. "Does he mean I don't understand my job or that I ain't up to date, or—or—or—"

Poor Si! We tried to relieve his mind, but it was a dismal failure. Si's particular specialty was fine, careful work. He was not a fast worker, but nothing left his bench until it was perfect. He loved it, and when he did a bit of welding or polishing or cutting with hand tools, it was a pleasure to look at it. He had the machines beat to a standstill. If a machine could cut out a die to a hundredth of an inch, Si could cut another by hand that would come within a thousandth of an inch of perfection. Why, tools in his hands took life and precision that made the work of the rest of us clumsy and bungling. Of course that didn't count in a shop where a new and unsympathetic foreman and superintendent had taken charge. Si couldn't keep up with the pace. His time cards soon showed that. He was slow in his fine work, and at the end of each week the record went against him. You

* Address: P. O. Box 1189, New York City.

see, by their new system, they could tell just how much work each man was doing, and if one was loafing on his job he was told to hustle. It was all intended to increase the speed and weed out the slow ones. The most of the trouble fell upon Si, and within a few months we began to feel sorry for the old fellow. The constant prodding and reprimanding was getting onto his nerves, and that made him slower than ever. This increased his disgrace, and then one day the crisis was reached. Old Si was to be "Oslerized," but owing to his long service in the shop it was only a modified process. He was given a month's vacation on full wages, and at the end of that period he was to return as watchman at a big reduction in wages. We didn't hear the words of the interview. Si was too surprised and dumbfounded to say much; he had to get out and think it over. Then he exploded before us. "They make me watchman on half pay," he said angrily. "Me a watchman, an' too old an' slow to do anything else. I'll go an' drown myself first. No, I'll go to another shop an' get work."

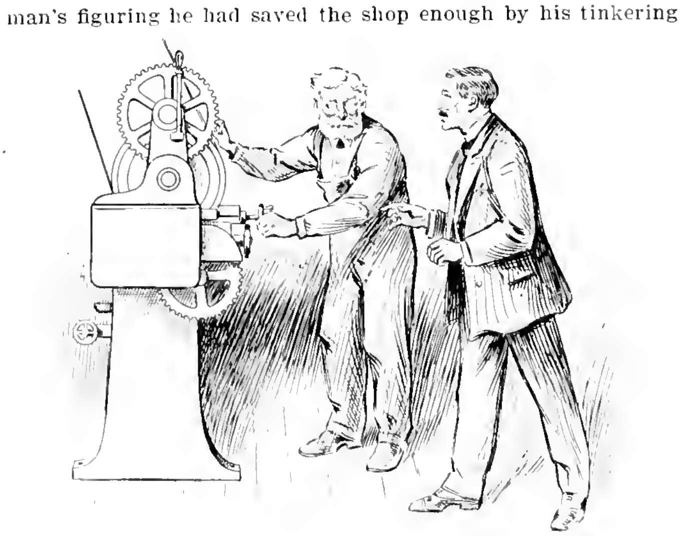
"Does he mean I don't understand my job, or that I ain't up to date?"

This determination we tried to combat, advising Si to think it over and not decide too hastily. He had a month to decide. But he was angry, and he spent a week going from shop to shop for work. But nobody wanted a machinist of Si's age, and they knew nothing about his skill. The following Monday morning Si returned to the shop. He was crestfallen and quiet; he knew now that he had little chance in the new industrial work. "But, Si," we protested, "you have three weeks more of vacation. What are you doing here?" "Vacation?" he stammered. "Oh, yes, I'm having a vacation; I'll spend it here roun' the old shop. There ain't nothing to do but sit aroun' an' look on. I get homesick when I'm away, but I'll have my vacation all right." This, in substance, he repeated to the foreman when he asked Si why he was back. The foreman smiled, and let the old fellow have his way. He was harmless, and so long as he didn't interfere with the work of the others he could hang around and look on. Probably he wanted to get some points from the younger men about increasing his capacity and efficiency.

Now Si's method of looking on was quite different from that of most men. If anything went wrong with a machine he would jump up and look for the trouble. He had an ear tuned so exactly that he could almost anticipate trouble with a machine. The lineshaft couldn't miss a revolution or a gas engine skip once in the most distant part of the building without Si knew it. Once a belt slipped so near the edge of its pulley that it came into contact with a loose guide and bent it out of position. The operator didn't notice it, but Si did. In another minute there would have been trouble, but old Si jumped up and stopped the machine just as the belt slipped off and landed where it would have been caught in another machine. The foreman came up frowning and Si offered only as an explanation: "I saw that belt slipping and stopped it. Them guides ain't no good anyway." The foreman understood the importance of this sudden interference, but said nothing. Si disappeared then into the forge shop. That night after work hours he appeared with a new set of guides which he proceeded to put up. They were so strong and good that they are doing service to-day. Si had forged them out of old metal, and they cost the firm nothing.

On the third day of Si's vacation in the shop a big turret lathe snapped one of its back gears and put it instantly out of commission. We had rush orders on hand, and the crippling of this machine put us in a bad position, as there were no duplicate parts on hand. The foreman was upset, and the superintendent, too. Orders were telegraphed to the manufacturers, but it would mean a loss of several days at least. While the others were bemoaning the fact that the turret lathe would shut down a good deal of the work, old Si was peering into the machine and taking mental notes. When the old thing was abandoned, Si took the fractured parts into the blacksmith's shop, and for several hours was busy. Toward night he returned, black with dirt and grime, and the perspiration running in streaks down his face. He carried something in his hands. Nobody noticed him particularly, but just before the hour for shutting down arrived we were all surprised by hearing the old turret lathe start up and begin rhythmic operations again. The foreman rushed to the place, and there he found old Si beaming happily. "I guess she'll run all right for a few days," he said, pushing his spectacles up on his greasy forehead.

The foreman could hardly believe his senses. He had to stop the machine and get Si to show him what he had done. Oh, it was simple. He had brazed the broken gear until it was almost as strong as a new one—certainly good enough for an emergency. That night a volunteer crew ran the old turret lathe and caught up with the rest of the work. It was nearly a week before the manufacturers' expert appeared on the scene with new back gears, and it took him two days to put them in and finish his job. The foreman after watching the repairs, took a pencil from his pocket and began to do some figuring. We could only guess what it was about. Si didn't know either, but the next day the foreman and superintendent had a conference, the result of which was that old Si was called in the office for a short talk. They had decided that they couldn't afford to lose Si. According to the foreman's figuring he had saved the shop enough by his tinkering



"The foreman could hardly believe his senses"

to pay for his salary several months. There had been danger of losing an important order through the mishap, and Si saved that for them. Si was put back into the machine shop, and he is there now. The Lord knows how old he is; he must be long past the sixty mark, and yet he's as useful as ever. He can't hold his end upon piece work to-day, and nearly every youngster in the shop can beat him. But when they want some very fine piece of work done it is turned over to old Si, and when there's trouble with the machines Si is the expert called in, and its a pretty bad case of breakdown that he can't fix up. He can turn his abilities to almost anything, and when he prescribes medicine the patient generally recovers in a short time.

We called him "old saw bones," for he was a surgeon—more than a physician. He could fix up a broken leg or rod or weld together any fracture so that you would hardly see a scar. That is what I call native ability. Si had it, and it certainly was "the knack of making something out of noth-

ing." If he didn't have the right piece of metal to fix a thing he'd make a piece out of old scrap or anything else handy. A shop that doesn't have an "old saw bones" in it is minus one of the most important factors. Give me one of the old school machinists who knows how to handle tools for mending anything, and in the end he will save more than his salary is worth twice over. There are a good many such old men tinkering around, but unfortunately their breed is dying out, and I suppose in time there will be none left. Then we'll have to depend upon the experts from the manufacturers, who will charge a big price and hold up operations for several days or a week every time something goes wrong.

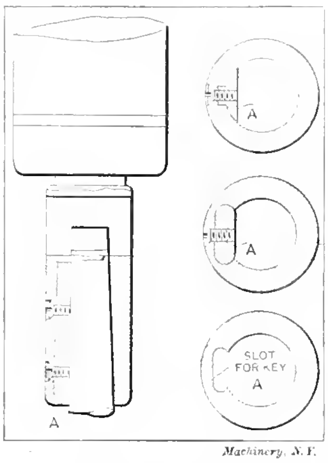
DRILL SOCKET

Harold E. Bradley has assigned to the Morse Twist Drill Co., New Bedford, Mass., his patented drill socket described in U. S. patent No. 926,845, July 6, 1909. The object of this invention is to provide a drill socket or collet which in addition to its regular function of driving the drill by the tang or flattened end, is also adapted to receive and drive a drill with a broken tang, thus utilizing drills which would otherwise be worthless. The illustration shows a vertical section of the improved socket, and also horizontal sections of alternative designs. The novel feature is the key A, which can be readily inserted in grooves in the socket and held in position by screws. After one side of the drill shank is ground or flattened off to correspond with the flat of the key, the drill may be again inserted and driven by the socket.



Drill Socket adapted for driving Reguler Teper Shank Twist Drills and Drills with Broken Tangs

DIES AND PUNCHES FOR MAKING NUTS

One of the latest improvements for automatically making nuts from a bar of metal by dies and punches was patented by George Dunham, Unionville, Conn. (U. S. patent No. 928,509, July 20, 1909). The dies and punches are adapted for an ordinary double crank machine having two horizontally moving punch slides.

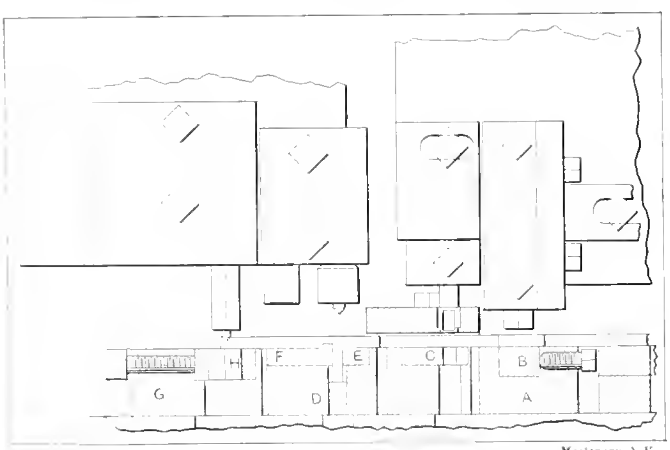

Fig. 1. Sectional View of Dies and Punches for Making Nuts

Fig. 1 is a vertical section of the dies on the bed plate with the punches above. At the right is a die holder A with a die B having two V-shaped cutting edges, the apices of which face each other. This die cuts V-shaped notches in the opposite edges of the bar and is called the notching die. While each notching punch has four cutting edges, only two of the edges can be used at one time. Adjacent to the notching die is a die C with a die block; this die has a round hole for punching the center hole of the nut blanks. The next die holder D has a crowning die E and a flattening die F, the two preferably being made in one piece. The fourth and last die holder G has a die H for cutting the nut from the bar.

Fig. 2 is a bar illustrating the various steps taken in making the nuts. The notches d and the round hole in the nut blank are made by one blow of the right-hand slide. The blank b is crowned and the blank c flattened by one blow of the left-hand slide. The nut blank a is then cut off and trimmed. The next blow of the two slides will form one more pair of notches and perform the previous operations on the blanks f, g, h and k. By changing the dies and punches any desired form of nut may be obtained. Square nuts may be made by omitting the notching punches and substituting a trimming die and punch of a square form for the hexagonal one shown.

BORING ELLIPTICAL HOLES

A lathe attachment for boring elliptical holes is described by James Shaw, Dauphin, Manitoba, in U. S. patent No. 928,404, July 20, 1909. The attachment as fitted to a lathe is shown in Fig. 1, and consists essentially of movable supports A and B, and a boring bar C with eccentric end bearings. Fig. 2 is a longitudinal section through the bearing brackets showing boring bar C. The ends D and E are eccentric to C and are in alignment longitudinally the one with the other. It will be noticed that D and E are carried by bearings which can be raised vertically in guideways at the rear face of the supports, while at the other face the main shaft has bearings with horizontal guideways. When the device is in operation the sliding bearings are free to move in their respective ways. In the main shaft is a hole for the cutting tool (see Fig. 2), and in Fig. 1 the tool is shown in position boring an elliptical hole in the work on the lathe carriage.

* * *

The chief item of expense in the maintenance of automobiles is generally the tires. Mr. Charles Clifton, president of the Association of Licensed Automobile Manufacturers, says that there are three prime factors responsible for short tire life: First, excessive speed, especially in hot weather; second, rounding curves at a high rate of speed; and third, unnecessary use of mechanical brakes.

MAKING PISTON PACKING RINGS

E. B

The accompanying engravings illustrate a cheap and rapid method of making expansion rings. This method has been used for some time by a certain gas engine company, and has done much toward reducing the costs of this class of work. Referring to Fig. 1, the dotted lines *A* indicate the shape of the casting from which the rings are made. This consists of a cast-iron cylinder with a flange on one end to facilitate clamping in the chuck for turning and boring. Having chucked the casting in the lathe, the rings are then turned and bored in one operation by means of the tool shown. This tool consists of a frame *D*, which is rigidly connected to the tool carriage and is fed along in the same manner as any other tool. Through this frame passes a spindle *C*, which turns freely in the frame and is held from moving lengthwise by means of a pin *K*, which fits into a recess cut in the spindle. On one end of this spindle there is an eccentric collar *D* which is rigidly held by a pin, thus turning with the spindle. The other end of the spindle is cut square or to some other shape to fit a block with a hole of the same shape, which is fastened to the chuck head. Therefore when the tool is fed along, this spindle slides into the chuck head, and at the same time revolves with it, as does the casting *A*.

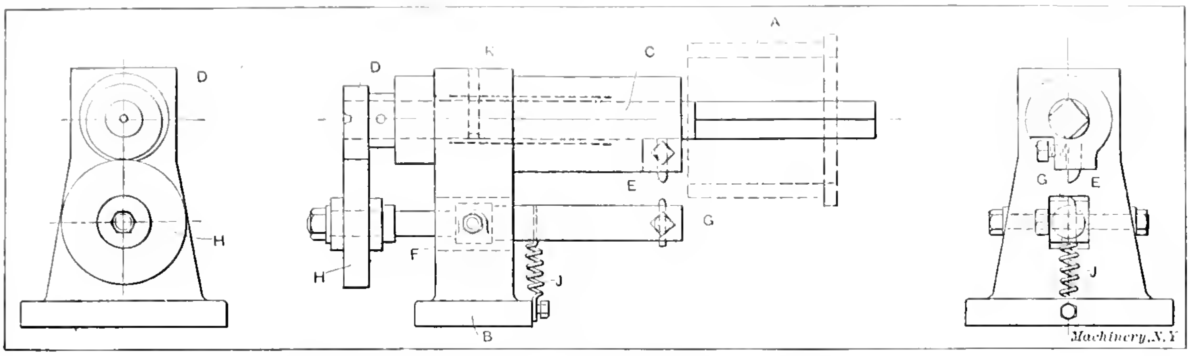

Fig. 1. Tool for Boring and Turning Eccentric Rings simultaneously

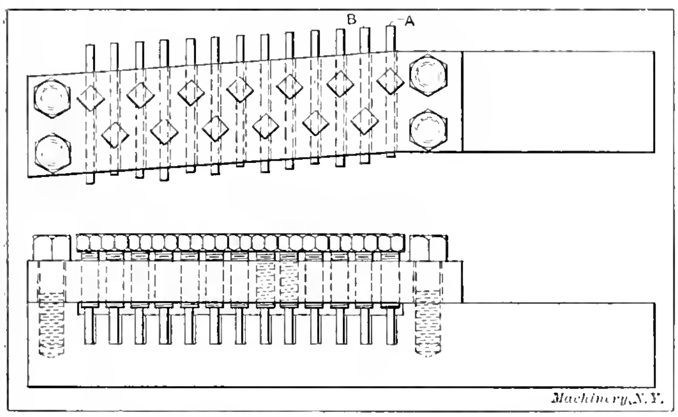

Fig. 2. Cutting-off Tool for Severing the Rings successively

When the casting makes one revolution, the spindle and eccentric also make one revolution. In the frame is set a tool *E* which bores the casting. Through the lower part of the frame passes another spindle or lever which is hinged at *F* and has a tool *G* on one end and a roller *H* on the other end which turns freely on this lever. A spring *J* holds the roller *H* up against the eccentric *D*. As stated before, the eccentric makes one revolution to each revolution of the casting, therefore the lever and tool *G* perform one complete oscillation to every turn of the casting. The tool therefore turns the casting eccentric to an amount depending on the location of the fulcrum *F* and the eccentricity of the cam *D*. This can be better understood if we assume the casting *A*, spindle *C*, and eccentric *D* to be stationary, and the frame *B* to revolve about the spindle. The path of the turning tool would then be in a circle eccentric with the axis of *C*. Therefore, if the frame *B* is stationary and the work *A* revolves, then the outer surface of the cylinder will be cut eccentric to its axis. In this way the casting is turned and bored in one operation.

The next operation is to cut off the rings, and this is done by means of the tool shown in Fig. 2. This tool consists of a bar in which are mounted a number of cut-off tools spaced the proper distance apart to give the desired width of ring. The holder is bent and the tools are set successively at greater distances from the axis of the work. Therefore the tool *A* gets through first and the first ring drops off, and the other rings, throughout the entire length of the casting, are severed in succession.

The next step is to split the rings on the thin side; they are then ready to be ground on the outside. To facilitate this operation a casting, Fig. 3, is bored to such a diameter as will allow for the amount to be ground off. The rings are then sprung into this cylinder as shown by the dotted lines.

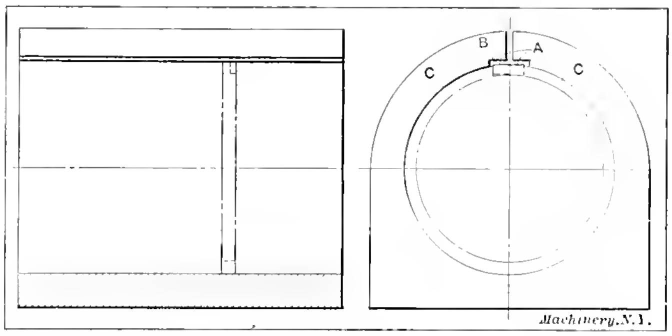

Fig. 3. Fixture for Holding the Rings while they are being secured in the Grinding Arbor

In springing the rings together the points *A* move outside the circle of the bore and the slot *B* is cut in the casting to allow them to do so. This is an important point because if this slot were not provided the points *A* would be forced in and ground to a true circle with the remainder of the ring, with the result that when the rings were placed on the piston and inserted in the engine cylinder the points *A* would rub on the cylinder walls and a part of the ring, say from *A* to *C*, would be held away and the fit would not be perfect. But if these corners are allowed to project as shown, they will be ground away and will therefore not rub afterward.

Having placed a number of rings in this assembler, an arbor, Fig. 4, is inserted and the rings clamped together between the collars *A* and *B*. The arbor is then placed in the grinding machine and a light cut is taken off the rings. These collars *A* and *B* just fit the cylinder, Fig. 3, and the rings are therefore accurately centered at once. The collars are cut away at *C* to allow the grinding wheel to pass over the rings without cutting away the collars and destroying their usefulness as a centering device.

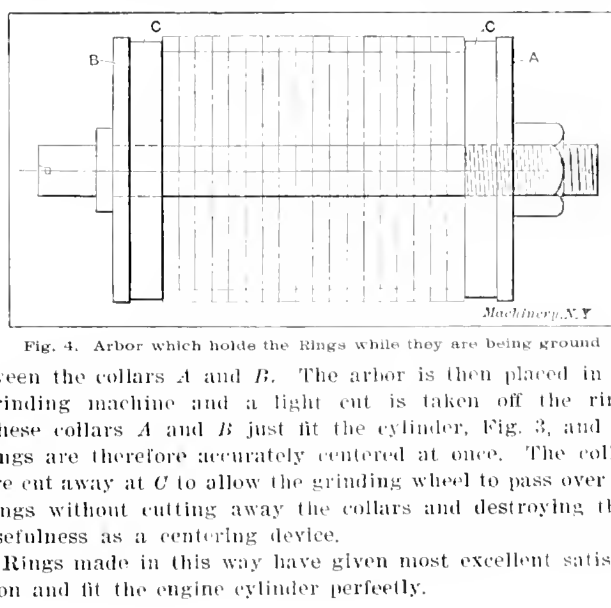

Fig. 4. Arbor which holds the Rings while they are being ground

Rings made in this way have given most excellent satisfaction and fit the engine cylinder perfectly.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD, NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall, Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month, give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

OCTOBER, 1909

PAID CIRCULATION FOR SEPT., 1909, 20,449 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

HEAT TREATMENT OF ALLOY STEEL

The rapid development of the automobile industry in America has awakened a quick, keen appreciation of the great importance of proper heat treatment of steel. It is pointed out by Mr. Henry Souther that scientific heat treatment is quite as essential as the quality of steel. Ordinary steel may acquire good physical qualities with proper heat treatment, and the best of steel can be ruined by defective methods. There must be thoroughness in the various operations of annealing, hardening and tempering, for treatment carried on with care only makes uniformity of product possible. This is particularly true in the production of drop forgings.

The difference between ordinary steel and the best is great. For example, the elastic limit of ordinary steel is about 40,000 pounds per square inch with a reduction of area of, say, 50 per cent. Nickel steel properly heat treated has an elastic limit of 80,000 to 100,000 pounds per square inch of section, with a reduction of area of 50 per cent, or more. Brittleness does not follow proper heat treatment, the enduring quality being increased in a greater ratio than the elastic limit. Consequently crystallization, fatigue, or whatever we name the cause of breakage, is less likely to develop in a properly heat-treated and tempered material than in an annealed and soft material. This fact, discovered in the laboratory and established in actual practice, is now commonly accepted by metallurgical experts, notwithstanding that it completely overturns previous general belief. Another commonly accepted belief disproved is that strength and stiffness are coordinate, or "the stronger a piece of steel, the stiffer it is." To illustrate, it was thought if one piece of steel were twice as strong as another, it would bend only one-half as much under a given weight. But actual test has shown that a chrome-nickel steel having an elastic limit of 150,000 pounds or more per square inch of section, bends under a given load the same amount as a carbon steel specimen, and this condition holds true as long as the load is within the elastic limit of the weaker material. The elastic limit of a well-tempered steel spring is about 150,000 pounds per square inch, but a spring can be made of soft steel. If it is not loaded beyond its elastic limit, the spring will return to its original shape after every deflection, but the deflection would not be sufficient to make a good spring. In fact, it would be hardly noticeable, and of course, would be of little value.

Between these extremes lie the steels used by the spring makers in the past. Not only has the automobile industry forced the spring makers to depart from their old materials and methods, but the "shake-up" extends all along the line. Assume that a 0.20 carbon steel has been used with advantage for a given design of crank-shaft, neither bending nor breaking through long continued use, and that the bearing surfaces are as small in area as can be used without heating or excessive wear. A crank-shaft of properly treated chrome-nickel steel, having an elastic limit four or five times as high as the 0.20 carbon steel would be no stiffer, but would have greatly increased life and reliability. The steel makers must be prepared to meet these new conditions. Sound knowledge of steel has spread fast among intelligent manufacturers; from the knowledge obtained in the laboratories established where all materials are physically and chemically tested they have learned to discriminate in selection. With known characteristics, heat treatment scientifically conducted is sure of results that make high-grade steels comparable with ordinary steels in about the ratio they, in turn, bear to cast iron.

THE VALUE OF THE TRADE PRESS

The following quotation from the *Journal of Commerce*, New York, is an unprejudiced statement of the functions of the trade press:

In the very nature of things the man of affairs, with multitudinous and various cares pressing sorely on his time and attention, necessarily becomes self-centered and preoccupied. This is the man for whom the trade press stands as an invaluable ally. While he digs and delves in his own tasks, the trade press is his reliance for more basic information than he imagines. The ordinary press gives him the products of its daily observations in the doings and misdoings of the big round world of politics and society, but what it brings is only a diversion; a stepping aside from his grind. It may refresh him, but it does not aid him in his money-making slavery. But the trade press has an entirely different function in his life. While he toils in his office or warehouse the trade press is performing for him the task of confidential messenger to the rest of the commercial world. Its human machinery is finely tempered and carefully adjusted. Its men are trained, not merely in the collection of interesting facts of ordinary happenings, but in the observation of those events and developments which have a direct bearing on the commercial side of life. The trade press is his organ of communication outward as well as inward. Circulating, as it does, both in a local field and throughout the country, he has but to say the word and his message is disseminated among the very men most interested in his ideas. No man who has ever watched the development of any great trade movement can deny that, without an intelligent, trustworthy trade press, it would have been impossible.

Especially applicable is the description, "an intelligent, trustworthy trade press." The value of the trade journal to the industry it represents is based almost entirely on its trustworthiness. The same carelessness in regard to fact and the tendency to exaggeration which characterize the daily press, would so affect the influence of a trade journal with its readers as to materially reduce its value as a property in a short time. Trustworthiness, accuracy and the qualities which make for reliability, are demanded by the readers of the technical press; and the smallest mistake in a figure or calculation seldom escapes attention.

It is a noteworthy fact that no house organ, or publication issued in the interests of a manufacturer or dealer, has yet developed into a great trade journal. The publications to which the latter term may be applied, we believe, without exception, have started as independent journals, and their development has been strictly along that line. The stronger they grew, the more truly independent they became.

* * *

The growth of the automobile industry is one of the most amazing features of modern manufacturing industry. About 75,000 cars were built in 1909, and, according to the statement of Mr. Alfred Reeves, general manager of the American Motor Car Manufacturers' Association, manufacturers plan to place 200,000 automobiles on the market in 1910.

THE PNEUMATIC TIRE AND THE AEROPLANE

It seems a far cry from the bicycle tire to the aeroplane in the sense that the former is to any degree concerned with the development of the latter, but, according to one who has given the matter some serious thought, it appears that the connection between the pneumatic tire and the flying machine can be logically established. The fact that the automobile is an intermediary in the evolution that has made the latest mechanical triumph possible is interesting now, and it will not be unprofitable to briefly trace the evolutionary process that has made flight actually possible under favorable conditions, and which has aroused high hopes of ultimately making it a practicable means of travel.

The early bicycles of the high-wheel variety were facetiously named "bone-shakers," and bone-shakers they were in truth. The bicycle was only moderately popular in favored places having smooth roads and specially constructed tracks, until the advent of the "safety" and pneumatic tire. The new tire transformed the bicycle from a hard-riding machine, extremely fatiguing to all but those of strong physique, to a vehicle of business and pleasure for young and old of both sexes.

The wonderful improvement in riding quality made in the bicycle by the pneumatic tire stimulated the efforts of inventors and designers to produce a practicable four-wheel carriage driven by power to replace the horse-drawn wagon, and the "tires of air" literally smoothed away some of the great difficulties that had made the horseless wagon impracticable before.

When the running-gear problem was in a fair state of development, attention was concentrated on the motive power, and after a few years of strenuous competition the steam engine gave way to the internal combustion motor which won out because of its simpler control, higher efficiency and greater power per unit of weight. To-day the automobile gas engine is the world's wonder for concentration of power and simplicity of construction. In the space occupied by a Saratoga trunk can be placed a motor capable of generating 40 to 50 H. P. and weighing only from 8 to 10 pounds per horse-power.

Observers of birds and bird flight long ago took note of the strength of their wing muscles and apparent ability to exert great muscular effort in proportion to weight. Whether birds actually exert much power to sustain themselves when once in flight is a mooted question, but it is easily proved that they must expend great effort in the first few moments when rising in the air and getting in motion.

The heavier-than-air flying machine requires a powerful, light motor to launch it into the atmosphere and to sustain motion. The gas motor developed to meet the needs of the automobile required only further development to fit the special needs of aviation. As a matter of fact that development has been going on simultaneously in automobile, motor-cycle and aeroplane motors, and the leaders in mechanical flight might well contend that their share in the development of the gas engine is by no means small. Whether the chain of events thus outlined actually put the aeroplane in debt to the pneumatic tire, we shall leave to our readers to decide for themselves; but whatever the conclusion, the tracing of mechanical developments to imagined or real sources leads to some curious discoveries. One is forced to believe that many of the apparently trivial devices, in their infancy, have been the germs from which the most important developments have come.

* * *

THE COST OF SPECIAL TOOLS

Before deciding upon the design of special tools for manufacturing purposes, it is very important to compare the saving expected to result from the use of the new tool, with the cost of building the tool itself. A writer in MACHINERY in a recent series of articles on jigs and fixtures refers to this matter as follows: "Before planning the design of a tool, compare the cost of production, using present tools, with the expected cost of production using the tools to be made, and see that the cost of building the new tool is not in excess of the expected gain." This rule seems so simple and elementary that it is difficult to explain why it is so often disregarded.

As a concrete example of the meaning of the rule laid down above and the results produced when it is disregarded, the following occurrence in a prominent machine tool building shop may be of interest: A certain machine detail was produced in a slotting machine by means of a fixture costing $35. Ten pieces were produced per hour, the price per piece, including over-head expense, but not interest and depreciation of the fixture, being eight cents. The head tool-designer of the concern conceived the idea of a special fixture for producing these parts much more rapidly on a milling machine. Considerable experimenting, however, was necessary, and the total cost of the new fixture when completed was $518. This fixture made it possible to produce twenty pieces per hour, or double the number made by the old fixture. Consequently the price per piece is only four cents when the new fixture is used, interest and depreciation of the fixture itself not being considered, and a saving of four cents a piece is made possible. This would be a considerable saving if the fixture were constantly in use, but only 300 of these parts are required each year, so that the total saving resulting from the use of the fixture amounts to only $12 a year, and the fixture is in use for only fifteen hours during the whole year. Five per cent interest on $518 is $25.90, and if the manufacturing company expects this rate of interest, at least, on its investment, it will be seen that the use of the new fixture actually entails a loss of $13.90 per year, not considering depreciation and the fact that the labor necessary to build it could have been used to better advantage for other purposes. The depreciation may perhaps be considered as practically eliminated, because the fixture is used only for a few hours during the whole year.

This incident plainly illustrates the importance of determining closely the cost of a tool before it is designed and built, and the saving to be effected by its use. The designer, however, is not always directly responsible for the waste entailed when this cardinal principle of economical tool designing is overlooked. As is well known, the designer is often not permitted free access to the cost accounts, and this policy is largely responsible for some misdirected efforts of his energy. Often he does not know the present cost of doing certain work, and is given no opportunity to find out; yet he is expected to design tools for improved methods of performing the work. In such cases the designer cannot be held wholly responsible for inefficient and uneconomical results. That responsibility then falls on the man "higher up," who considers that anything relating to the economics of the concern should be strictly confined within the four walls of the cost-keeping department.

PRIZE FOR A SAFETY AUTOMOBILE CRANK

A French association for the prevention of accidents in industrial work has offered $300 in prizes for a crank or safety device for hoists, cranes, and all forms of lifting apparatus, and also for explosion motors, which shall, in the first case automatically stop the descent of the load, or in the second case, throw out of gear the driving action when not required. The invention remains the property of the competitor, who must himself be responsible for its due protection by patents. Drawings of competitive devices should be sent to the office of the Association des Industriels de France contre les Accidents du Travail, 4, Boulevard Saint-André, Paris, France. A non-return starting crank for gas engines, of simple design, was illustrated in the January, 1906, issue of MACHINERY; prospective competitors may be interested in studying this design in order to see what has already been done along these lines.

* * *

"John Brown, Practical Plumber," "James Smith, Practical Horseshoer," "Robert Jones, Practical Gunsmith," etc., are samples of signs found wherever we go that show a misunderstanding of the word "practical" or a deliberate misuse of the word for which there is no good excuse. If a man is a plumber, or a horseshoer or a gunsmith, he must be practical and follow practicable methods. Who ever heard of a theoretical plumber, or a horseshoer who shod horses by absent treatment, or a gunsmith who took dents out of gun barrels by suggestion? Drop the misused word "practical" from signs and see if they are not just as strong and comprehensive as before.

EFFICIENT SYSTEM FOR THE RAPID ASSEMBLY OF MOTOR CARS*

HAROLD WHITING SLAUSON†

From a mere corner in the machine shop in the days when the automobile was built in lots of but two or three at a time, the assembling room has grown to such an extent that, in many factories where the output is large, it occupies an entire floor of the main building, and has come to be considered as one of the three or four most important departments of a modern motor car factory. A corresponding increase in responsibility has attended the growth in size and importance of the assembling room, and today, unless well managed and equipped with the most up-to-date devices for the convenient and rapid handling of parts, it can easily "eat up" the profits on a whole year's output of low or medium-priced cars. Without requiring the services of an excessive number of men, it must take care of the parts from the machine shop and the parts-assembling room as they are turned out, and not allow a great number of finished pieces to accumulate at any time in the stock room. The work of assembling must also be done thoroughly, so that, when tested, the complete car need not be sent back for overhauling and readjustment of parts. In short, the assembling room must work in harmony with each of the other departments in doing its share toward producing a car of maximum quality at minimum cost of production—and that share is by no means small. But not alone are the best systems and business management, proper interior arrangement and most up-to-date devices necessary, but the highest class of skilled mechanics must be employed as well. A motor and transmission may be composed of the best of materials and have bestowed upon them the most skilled workmanship available, but unless they are placed together in the completed car with each shaft lined up, each bearing scraped and fitted and each gear in position to mesh properly, all this expensive material and labor may count for naught. The assembling room cannot, to any great extent, compensate for poor machining, but it *can* absolutely ruin the best products of the machine shop.

That the leading automobile manufacturers have been brought to a realization of the importance of the use of the best systems, equipment and labor in their assembling rooms is particularly well exemplified in the factory of the Chalmers-Detroit Motor Car Company at Detroit, Mich. Probably the most convincing proof of this statement will be fouud in the fact that, for the 3,000 complete cars turned out by this company last year, not more than 30 men were employed at any one time on the assembling room floor. More remarkable than this, however, is the high record established for a day's work. In ten hours, the 30 men in this department assembled 35 complete cars! Of course this does not include the assembling of the various small parts of the motor, transmission and rear axle, as these are taken care of in other departments, but when it is remembered that the chassis assembly *does* include the installation of all these parts in the frame, the adjustment of each to its new position, the attaching of all springs, wheels, running-boards, foot-rests, steering gear, and the wiring and piping of the motor, it will be realized that the system and equipment employed in this department of the Chalmers-Detroit factory must be perfect in every respect in order to turn out this amount of completed work.

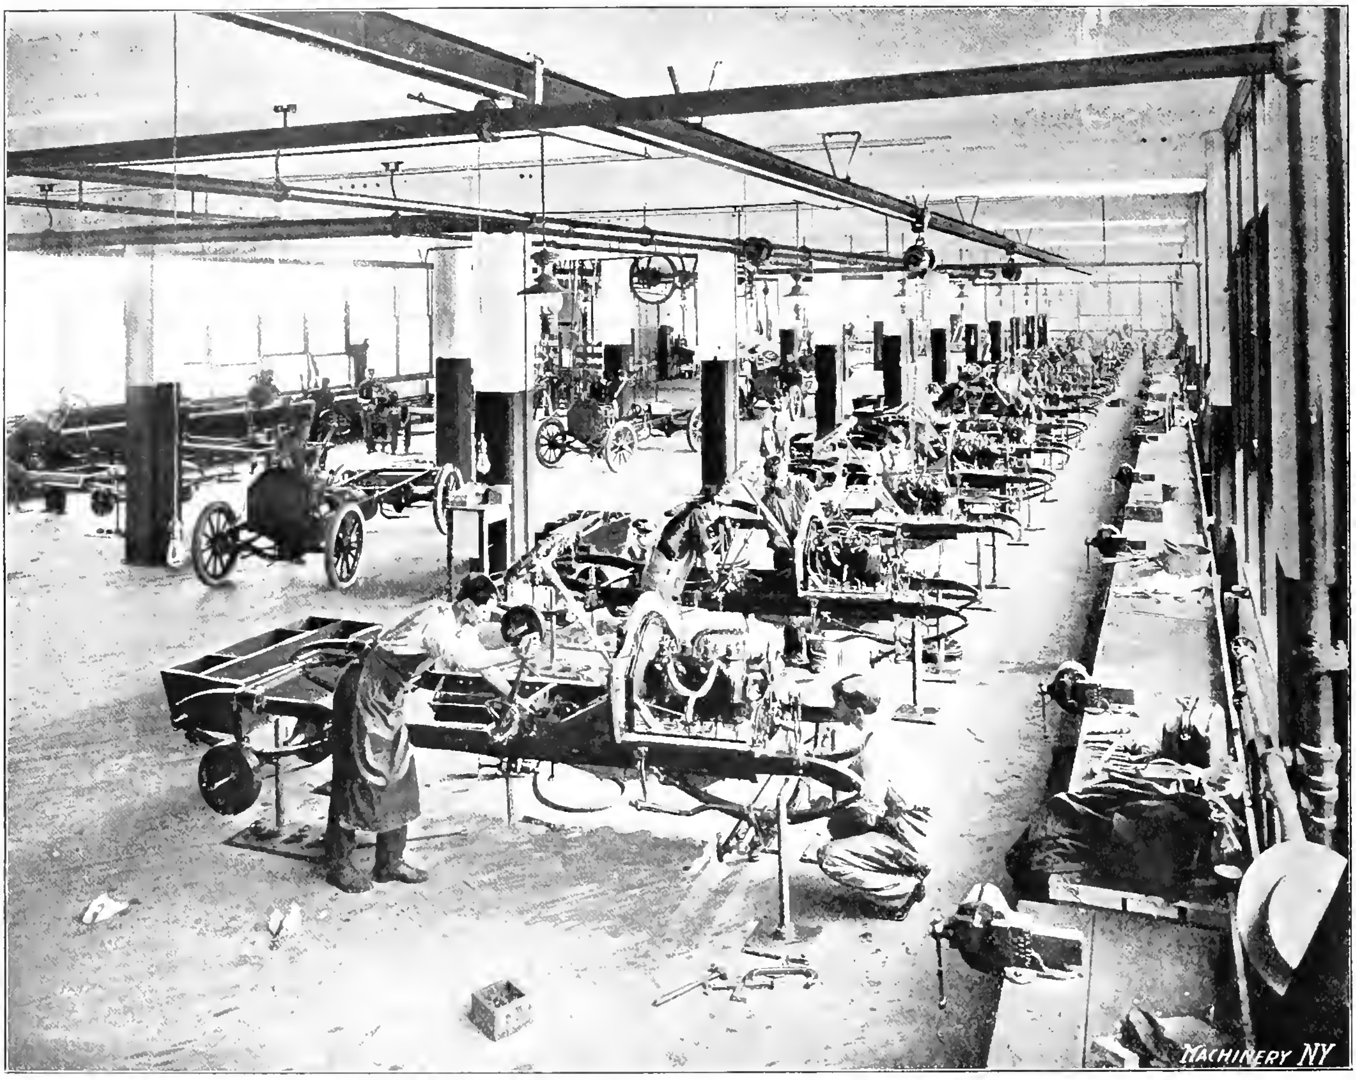

Fig. 1. View of the Assembling Room, showing Arrangement of Overhead Track and Differential Hoists; the Trucks, each of which holds the Parts for Two Cars, and the Adjustable Frame Supports

The headquarters of the assembling department may be said to lie in the finished stock room, which occupies a large section of the floor of the main factory on which the assembling room proper is located. To this finished stock room come all finished parts such as nuts, bolts, screws, front axles, springs, and wheels, and the previously assembled motors.

* For further information on this subject, see "Machines and Tools for Automobile Manufacture," June, 1909, and articles there referred to.
† Address: Box 27, Times Square Station, New York.

transmissions, steering gears, and rear axles. These are all classified and placed by themselves, the smaller parts being kept in bins which extend in long rows down one end of the room. Lists pasted in conspicuous places along these bins show the exact number of each size and kind of bolts, nuts and other pieces required for the various models of cars made here, and hand trucks having bodies divided into compartments are drawn down past the bins and filled with the necessary number of small parts for two cars. In the larger divisions of the truck box or body are placed the axles, steering gear, running boards, foot rests, and other bulky parts of the car. Each truck is filled with a sufficient number of the

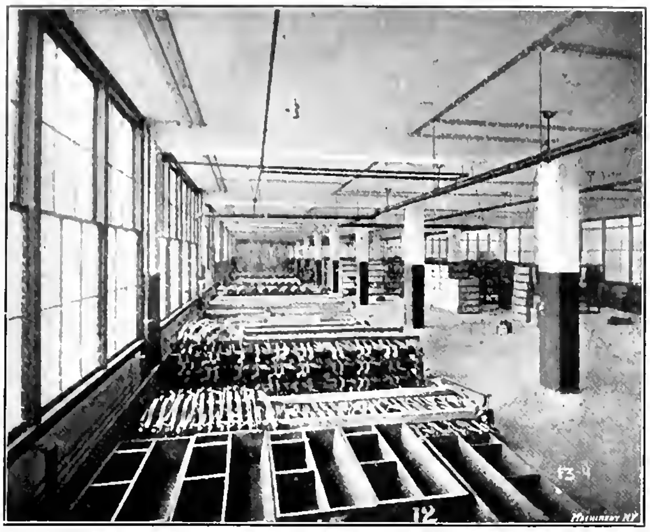

Fig. 2. View of Stock Room, showing Trucks in which Parts are taken to the Assembling Room, Assembled Parts, and Bins in which Smaller Parts are Stored

proper parts for the complete assembly of two cars and is then rolled into the assembling room, adjoining the stock room, and placed between two pressed steel frames which form the foundations, as it were, of the two chasses to be assembled. Having received the required number of parts of the proper kind, three men now devote their entire time to assembling the two chasses—and it is here that the advantages of "team work" are exhibited. Having become accustomed to this method of assembling, each man knows just what he is to do, and always has the other chassis at hand to which he can turn his attention when he is liable to interfere with the work of his two companions. It is highly specialized work, each team of three men devoting their whole time and energy to the installation and adjustment of the various parts of two cars until they are ready for the road test. As three men finish the first two chasses, another truck is brought in containing parts for two additional cars, and the team then devotes its attention to cars three and four. The motors are not included in the quota of parts comprising the truck load, but are carried in separately on differential hoists which travel on overhead tracks and pass in two lines down the sides of the assembling room in front of the two rows of chasses. When the frame is ready for the installation of its motor, the latter is lowered in place. This system renders each car independent of the stock room after the truck load of parts has been received, and the work bench, vise and kit of tools near every chassis reduce to a minimum the number of steps necessary to be taken by each workman.

The arrangement of the rests for holding the frames rigidly in place is very ingenious and entirely does away with the use of saw-horses or other movable and bulky supports. There are four of these supports for each frame, as shown in Fig. 1, and when not in use, one or all may be let down into the floor. Each of these supports consists merely of a vertical iron rod, bent at right angles at its upper end and forged into the shape of a hook. A corner of the frame rests on this horizontal portion of the rod, while the hooked-shaped ends of the two opposite supports prevent lateral motion in either direction. Each rod is supported by a pin passing through it at the proper distance from the end, which rests across the top of the base-plate which is bolted to the floor and through which the end of the rod passes. By giving a partial turn to the rod, the pin is allowed to pass through a slot in the base-plate, and the whole support is thus dropped until its top is flush with the floor. In order that the supports may accommodate themselves to various lengths of frames, the rear pair of every set of four base-plates is made with four sets of holes, in any of which the rods may be placed. The sets of supports are placed at such intervals along the floor that sufficient space between the frames is allowed to enable two teams of men to work on adjoining cars without interference. While it may seem a small matter, the facility with which these supports may be put in place, adjusted or removed from the floor, helps to make possible, in no uncertain degree, the record for the rapid assembly of cars of which this factory can boast.

Although not a part of the assembling room proper, the department in which the pressed-steel frames of channel-section are prepared for the chassis, has an important part in facilitating quick assembling. When the frames arrive at the factory, forty or fifty holes must be drilled for the various parts which are to be attached, such as the gear shift, brake levers and their supports, the motor, transmission, running boards, fenders, lamp brackets, springs, and the like. Most of these, with the exception of the motor and transmission, are riveted in place before the frames reach the assembling room. These operations are performed in the frame riveting room, which contains several unique and ingenious arrangements that, so far as efficiency is concerned, bring this department on a par with the assembling room. The frame is first placed on a set of supports similar to those used in the assembling room, except that a tension rod and turnbuckle connect both pair of rods for the purpose of holding the frame more rigidly in place. A single track over this set of supports carries a differential hoist, from which is suspended a large jig (see Fig. 3) containing a guide hole corresponding to every hole necessary to be drilled in the sub-frame, which carries the motor and transmission. This jig is clamped securely in place and the holes drilled by means of pneumatic drills connected to flexible piping. When all the

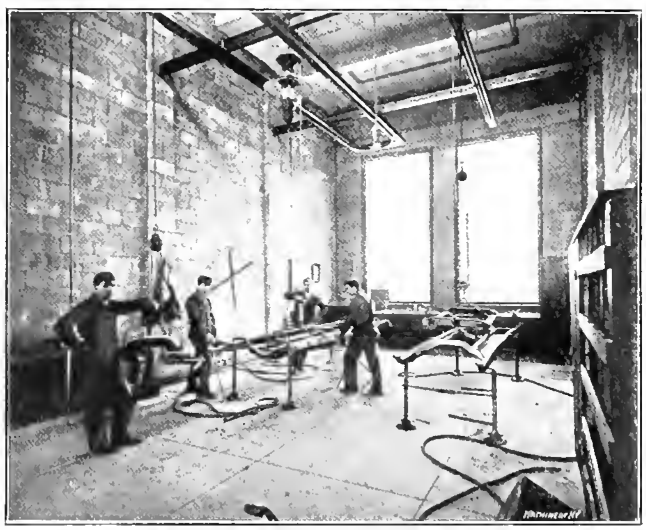

Fig. 3. Room in which the Frames are drilled and riveted by Pneumatic Tools

holes are drilled in this manner, the frame is removed to another set of supports a few feet distant where it is held rigidly in place in the same manner as that before described. Above this second set of supports is an oval track of the same length and width as the frame. From the traveler on this track is suspended a cable terminating in a single pulley through which passes a chain. On one end of this chain is a heavy, pneumatic riveter, which is counterbalanced by an iron weight attached to the other end of the chain. This enables the tool to be placed at any height desired without unnecessary exertion. A small forge (not shown in the illustration) in one corner of this room heats the rivets before they are driven into the frame. By means of the oval track and pulley, any vertical or horizontal plane bounded by the frame may be reached with the riveter, and four or five men

in this department are usually able to keep the assembling room supplied with the required number of frames. After being finished in this department, however, the frames in all cases are taken directly to the finished stock room, from which they are drawn out to the assembling room as needed. This stock room, in fact, acts as a sort of clearing house for the whole factory, and no part ever reaches the complete car until it has been inspected, checked and entered in the stock room records.

The keynote of this system is specialization. Every man knows what he has to do—and he does it. There is no overlapping of departments. It is scarcely ever necessary for the men in the assembling room to step into the stock room, and the men in the stock room are supposed to keep the men in the assembling department supplied with the necessary parts for the cars that have been ordered to be finished that day. Each team in the assembling room follows its two cars through until they are ready for the road test, and it is then easy to place the responsibility for any defect, where it belongs. When this system is supplemented with such labor and space saving devices as are used in the assembling and frame riveting rooms, and when, at the head of it all, is able, efficient and experienced management, one can begin to understand the conditions which allow the immense increase in production and the reduction in cost of the American-made motor car of today.

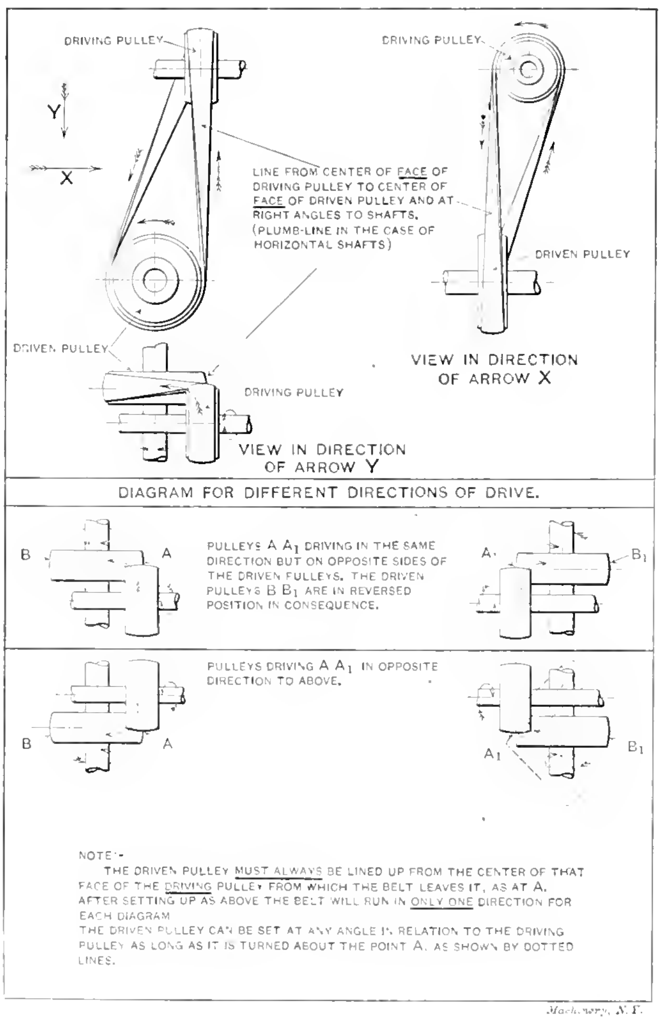
LOCATING ANGLE BELT DRIVES

GLASGOW

In answer to C. A. H.'s article in the August number, under the heading "What Would Jim Have Said," I submit herewith a data sheet of angular belt drives which was issued to



Locating Belt Drives when Shafts are not Parallel

the men here some twelve months ago. These diagrams show all the different positions of the pulleys for different directions of rotation of the shafts, and are also applicable to shafts in any position, vertical or horizontal.

ASSEMBLING MACHINE TOOL UNITS*

ALFRED SPANGENBERG†

In an article on "Elements of Assembling Operations" appearing in the September issue of MACHINERY, the writer laid down some fundamental principles relative to the methods and processes employed in manufacturing, and advanced the proposition that accurate drawings, accurate machine work and the use of jigs and gages are at the fonndation of economical assembling. Interchangeability, standardization, and duplication in quantities were also discussed. The present

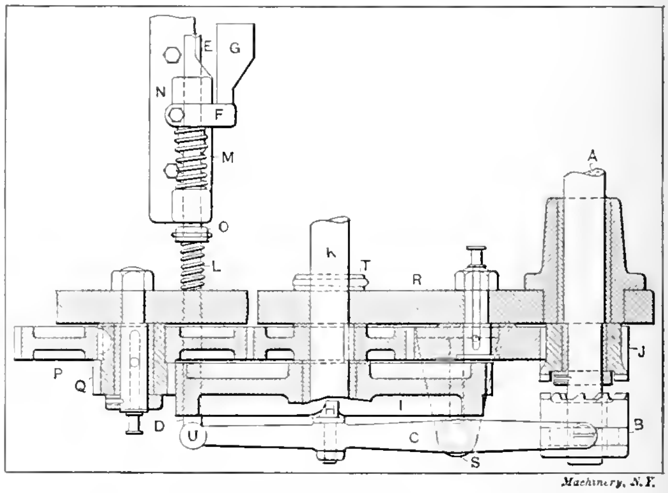


Fig. 1. Turret Lathe Indexing Mechanism to be assembled

article will deal with concrete examples illustrating the application of these principles in actual shop practice.

Assembling a Turret Lathe Indexing Mechanism

The turret lathe indexing mechanism shown in the line engraving Fig. 1 is presented to bring out clearly the necessity for analyzing the purpose of every part of a machine in order to machine and assemble the members so that they will function properly. In operation, the driving shaft *A* is constantly revolving in a certain direction. Keyed to this shaft is the sliding clutch member *B* operated by the forked lever *C*, link *D*, rod *E* and stop *F*. The dog *G* is bolted to the turret carriage and when the carriage is run back this dog strikes the stop *F*, thus withdrawing the indexing pin *H* from its slot in the index gear *I* and engaging the driven clutch member *J*. This starts the train of gears that revolves the turret by means of the worm shaft *K*, the worm-gear being bolted to the turret. An automatic knockout (not shown) stops the power traverse of the carriage the moment clutch *J* is engaged.

Fig. 2. Turret Lathe Indexing Mechanism shown in Detail in Fig. 1, Assembled

The turret continues to revolve until the carriage is run forward by throwing in the rapid power traverse mechanism which allows the indexing pin *H* to enter the slot in the index gear, and the turret stops revolving by virtue of the springs disengaging the clutch member *B*. The ratio of the back-gears is such that the index gear makes one revolution for each station on the turret. Spring *L* is for releasing the clutch and spring *M* keeps the stop *F* in position when the bracket *N* is moved along the bed in its T-slot. It is obvious that the springs should be as light as possible in order to avoid unnecessary wear on the indexing pin and face of the index gear and also to prevent a heavy pound when in

* For additional information on this subject, see MACHINERY, September, 1909, "Elements of Assembling Operations," and articles there referred to.

† Address: 951 W. Fifth St., Plainfield, N. J.

operation, but the springs must have sufficient power to always bring the index pin to the bottom of its slot in the index gear.

The length of the springs, their stiffness, and the position of the collar *O* on the rod are determined in the beginning by experiment, and when found to be correct, their dimensions are marked on the drawing so as to provide for standardization. To permit the use of light springs, it is absolutely essential that the clutch-operating members be fitted perfectly free so that the mechanism will index properly. The function of these members requires no rigidity in fit and the looseness desired is provided for by limits on the detail drawings, so that when the work, properly inspected, comes to the assembler no special fitting is required. As a general rule such parts receive little or no oil when the machine is in the hands of the operator, and if the parts are naturally stiff, trouble will arise. It must not be inferred that the writer is advocating such looseness in fits as to indicate poor workmanship, but many similar mechanisms have failed to work properly because of being too stiff, which shows lack of judgment and experience on the part of the assembler. The trouble in some cases, however, was due to the parts not being in proper alignment.

Before starting to describe any of the assembling operations, it will be well to bear in mind that while the description necessarily gives the operations in sequence, it is probable that in actual practice a number of different operations will be carried on at the same time, depending on the number of men working on the job. The gear plate and its cover, the latter being shown at *A*, Fig. 2, come to the assemblers with all the holes jig drilled and reamed except the taper dowel pin holes *B*. All the oil grooves are machine cut except those for the worm-shaft in the gear plate and cover.

Assuming that the turret lathe beds are in process, the operations of assembling the mechanism complete will include bench and vise work, and also floor work, since some of the members are interdependent with others on the lathe bed. The bench work consists of assembling the three independent groups, *viz:* the back gear members *P* and *Q*, Fig. 1; the fork lever members, including the sliding clutch *B;* and the operating rod bracket members *D*, *E*, *F*, *M*, *N*, and *O*.

The floor work consists of lining up the gear plate *R* on the lathe bed and assembling the entire mechanism. The operation of lining up is accomplished by means of two special arbors, one of which fits the worm-shaft bearings in the turret carriage and the other fits the holes in the operating rod bracket *N*, the arbors being long enough to pass through corresponding holes in the gear plate. The arbors are placed in position, with the turret carriage and operating rod bracket moved as close to the gear plate as possible, the latter now being bolted to the lathe bed. For obvious reasons the lining up is done with special reference to the operating rod and worm-shaft holes, since the adjacent bearing on the bed for the driving shaft *A* is some four feet away from that on the gear plate. Alignment of the driving shaft is tested by surface gage measurements taken from the top and side of the V on the bed, a few thousandths "off" being permissible.

Referring to Fig. 2, the bolt holes *C* have 1/32 inch clearance in the gear plate to allow it to be shifted slightly, and when properly set, the taper dowel pin holes are drilled in the bed by means of a pneumatic drill, then hand reamed, and the taper pins driven in place. The subsequent operations consist of assembling the shafts, studs and gears in their places, the process being so simple that no explanation is necessary. Next, the operating rod bracket members are put in place and then, after setting the index gear, the fork lever bracket *S* (Fig. 1), with its members already assembled, is bolted on and the connection with the link *D* made by inserting its pin.

Setting the index gear is accomplished in the following manner: The worm-shaft is set so that one-quarter of its total amount of back-lash is on the driving side, *i. e.*, if a line is placed on the periphery of collar *T*, and the total amount of backlash in the worm between its bearings in the turret carriage allows the line on this collar to travel ½ inch, then the worm-shaft is turned so that the line on collar *T* moves back ⅛ inch from the side towards which the shaft revolves when in operation. Now, with the fork lever members in place, excepting the pin *U*, the index gear is set so that when the indexing pin *H* is in position in its slot, the pin *U* will enter freely in its holes by virtue of their being in line.

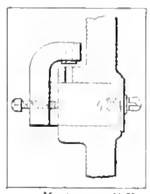

Fig. 4 Jig for Set-screw Holes

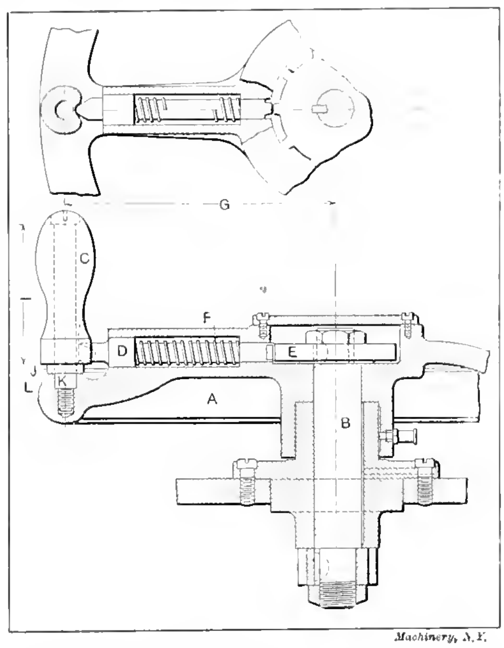

Fig. 5. Example of Device Difficult to assemble if Parts are not made in Jigs insuring Interchangeability

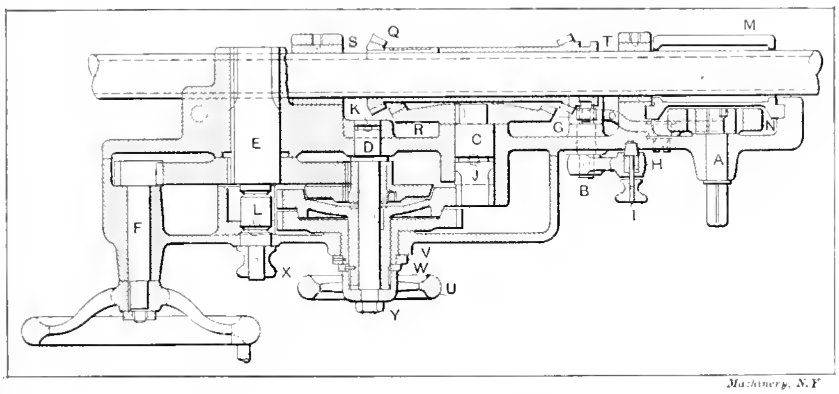

Fig. 3. Engine Lathe Apron to be assembled

The setting of the index gear to accomplish this is done by keeping the teeth of the index gear in mesh with its pinion and changing the teeth in the large back gear *P* in relation to those in its driving gear. Smaller adjustment of the index gear is obtained in this manner than by changing its teeth in relation to the teeth on the pinion *Q*, which fact is due to the ratio of the gears. Bolting on the cover is the final operation.

Assembling an Engine Lathe Apron

The engine lathe apron illustrated in the line engraving Fig. 3 is presented to show how machine tool units of this character are assembled on a manufacturing basis. Lathe makers, as a rule, build their lathe parts such as head-stocks, tail-stocks, rests and aprons in large lots so as to take advantage of the economy to be gained from carrying on the same operations on a large number of similar pieces in succession, both in machining and assembling; this has already been referred to.

It will be observed that the various shaft members are entirely independent of each other as far as their separate assembling is concerned, so that it is highly advisable to group these units to permit their being assembled at the bench as opportunity offers, which in most cases is while the aprons and covers are being bored and drilled. There are six distinct groups consisting, respectively, of the shafts *A* to *F* and their members. The assembling of these groups at the bench merely involves ordinary vise work so that little explanation is necessary. It will be well to state here that

when these parts are machined, particular attention is paid to the inspection of the length over shoulders, so that when the groups are assembled and put in place in the apron and cover no occasion will arise for any fitting or adjusting.

The method of testing shoulders on the friction gear shaft members, group *D*, in Fig. 3, is clearly shown at the right in Fig. 6; *A* represents a surface plate having a hole to receive the bearing end of the shaft. The double friction gear *B* when in its place in the apron has a lateral movement of 1/16 inch, the movement being controlled by the hand-wheel *C*. The dimension *D*, when all the friction surfaces are tight, being known, it is tested with a surface gage as indicated. The dimensions *E* and *F* are tested with ordinary length gages. A running fit is allowed on all shoulders while the length of the bearings in the apron and cover are made standard.

At the left in Fig. 6 is shown a jig for locating the levers *G* and *H* (Fig. 3) at the proper angle on their shaft while drilling and reaming the taper pin holes. This operation is done on a sensitive drill press to permit machine reaming.

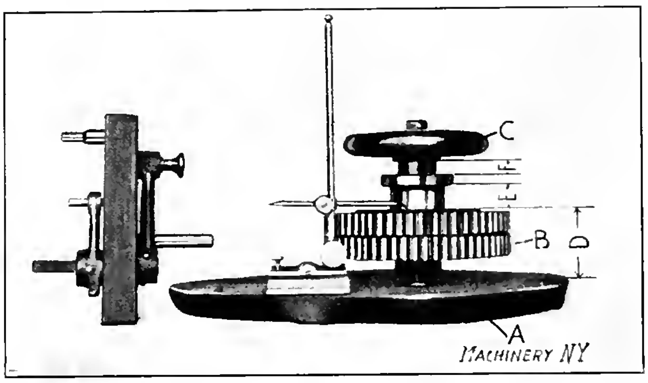

Fig. 6. Special Devices used in Assembling the Lathe Apron shown in Fig. 3

The jig is shown standing on end for the purpose of illustration, and its being used for two different sizes of levers accounts for the extra locating pins.

Referring now to Fig. 7, the method of testing the lead-screw nuts *M*, cam *N*, safety lever *O*, trunion lever *G* and the bevel gears *Q* and *R* is clearly indicated, the reference letters corresponding to those in Fig. 3. At *D* is shown a testing fixture in the form of an apron casting which is bored and reamed in the apron jig and is provided with supports at the back for holding it in the position shown. A short arbor representing the lead-screw is placed in the bearings *S* and *J* and holds the double bevel pinion *Q* (not in place in the engraving) in position.

It will be observed that the function of the safety lever is to prevent the double bevel pinion and the lead-screw nuts from accidentally becoming engaged at the same time, which

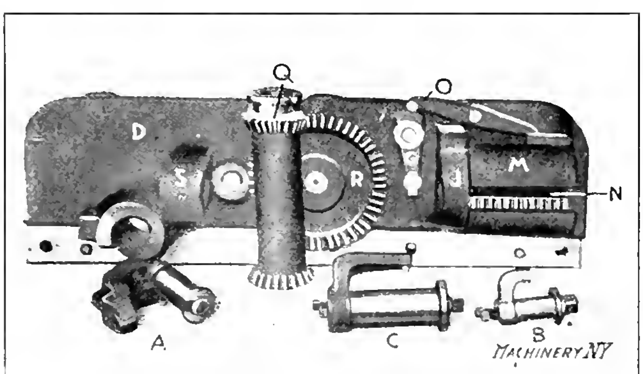

Fig. 7. Testing Fixture for Parts of Lathe Apron

would cause a breakage. Special milling fixtures are provided for milling the ends of the safety lever and the slot in cam *N* and lever *G*.

A babbitting jig is provided for the lead-screw nuts so that it is not necessary to babbitt them in place on a threaded arbor. The cam pin holes in the nuts are jig drilled. This has the advantage of making the nuts interchangeable besides avoiding the necessity for carrying hot babbitt any distance through the shop. If any of the members fail to function properly, the faulty member is, of course, replaced.

All the drilling, boring, and machine reaming on the aprons and covers is completed in the drilling department except the holes for the oil pipe (not shown) spring pin *I* and set-screws *J* and *K* (Fig. 3). Small holes such as these can be

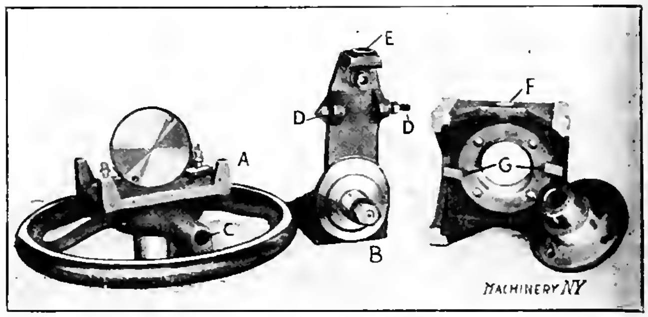

Fig. 8. Jigs for Drilling Parts of Device shown in Fig. 5

drilled cheaper with an air drill, due to the fact that the oil holes are comparatively short and are on an angle, while the spring pin hole *I* cannot be drilled until some of the assembling operations are completed.

When the aprons and covers are received in the assembling department, they are placed on special trestles for convenience in assembling. The castings are now painted, all of the chipping and cleaning having been done in the foundry. The next operation consists in drilling the oil holes and the holes for the set-screws *J* and *K*. Jigs for drilling the latter are shown at *A* and *B* in Fig. 7. Jig *C* drills the spring pin hole *L* in the apron cover which is machine drilled. The hole is at right angles to the top of the cover and the jig is easily set up as is evident by referring to Fig. 4 which shows jig *B* in position in the apron. It will be observed that these jigs permit the groove in the shafts to be cut standard size and the shafts made interchangeable.

After chipping the oil grooves and tapping the screw holes, the covers are bolted on for the purpose of hand reaming

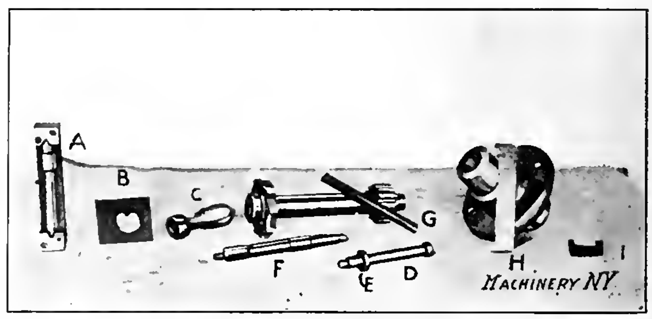

Fig. 9. Gages for Testing the Parts of the Device shown in Fig. 5

all shaft holes to standard size. The covers are then removed and the aprons laid face down for the purpose of fitting the lead-screw nuts *M* (Figs. 3 and 7). The nuts, babbitting jig and grinding ways in the apron being machined to gage, it is only necessary to smooth the surfaces on the nuts and apron to make the nuts slide freely.

When all of the members shown in Fig. 7 fitting the back of the apron have been fitted and tested at the bench, they are put in place in the aprons. In performing this operation the corresponding pieces are placed in each apron in succession. With the lead-screw nuts closed by means of the cam, a special tap, mounted on an arbor fitting the lead-screw bearings, is run through the nuts to clean out the threads.

The aprons are now turned face up for the purpose of fitting the oil pipes and drilling the holes for spring pin *I* (Fig. 3). There are three holes to be drilled in the apron for this pin to enter, one for the central position of lever *H* which operates the double bevel pinion, and one for each extreme position. A special center punch which fits the hole in lever *H* is used to lay out these. The central position is determined by the safety lever fitting into the notch in lever *G*; while the bevel pinion mounted on an arbor and alternately brought into mesh with the bevel gear, determines the extreme positions. After the holes are drilled by means

of a pneumatic drill, a reamer is substituted for the center punch in lever *H* and the holes reamed taper to fit the spring pin *I*. A collar on the reamer acts as a depth gage. It would, of course, be possible to drill these holes in the jig that drills and bores the aprons, but this is hardly deemed advisable as there are a number of elements that must be taken into consideration, an error in any one of which would prevent the bevel gears from meshing properly. Placing the spring pins *I* in position completes the work on the feed reversing mechanism.

The rack pinions *E* and gears are now put in place, then the friction gear shafts *D* and their members, except the hand-wheel *U* and collars *V* and *W*. After driving in the studs for the intermediate cross-feed gears (not shown because of the sectional view) the aprons are ready to receive the covers.

Work on the covers consists in placing the hand-wheel pinions and hand-wheel members in position and fitting the rack pinion spring pin members after which the covers are bolted onto the aprons. The rack pinion knob *X* is now put on and then the collars *V* and *W* are fastened onto the friction gears as shown in the line engraving Fig. 3. Screwing on the hand-wheel *U* and nut *Y* completes the apron and it is ready to be sent to the store room.

Assembling an Automatically-releasing Hand-wheel Mechanism

Unless jigs and gages are used in the machining process, the peculiar conditions encountered in assembling a mechanism such as shown in the line engraving Fig. 5 would call for a high degree of skill on the part of the assembler besides involving excessive cost. The half-tones Figs. 8 and 9 illustrate a set of jigs and gages for producing this mechanism, which enables the assembling to be done without any filing or fitting, the object being to illustrate that *interchangeable* manufacture is really *economical* manufacture.

It will be seen that the function of the device is to automatically engage and disengage the hand-wheel member *A* with its shaft *B*, the action being as follows: Turning the hand-wheel in either direction by means of the handle *C*, so that the latter does not rotate in the hand, engages the pawl *D* with the ratchet *E* which is keyed to the shaft *B*; on releasing the handle, spring *F* disengages the pawl.

The requirements are that the handle and pawl must work perfectly free so that no effort to grip the handle hard will be necessary; the axis of the handle and pawl must intersect so that each cam face will work equally well; when the pawl is fully engaged with the ratchet, the handle end of the pawl must still be on the cam face of the handle; the contour of the cam, length of the pawl, diameter of ratchet and center distance *G* must be within close limits. Referring to Fig. 8, *A* is a jig for drilling the hand-wheel cover and its screw holes in the hand-wheel. The jig is shown in position for drilling the latter, being located in the counterbore of the hand-wheel. Resting on top of the jig is the hand-wheel cover which fits into the recess shown and is held by the two straps and bolts. The hand-wheel and its cover are, of course, drilled separately.

At *B*, in the same figure, is shown a jig for drilling the handle stud hole and the pawl hole *C*. The hand-wheel is located on a stud through its bore, and clamped to the jig by passing a bolt through the stud, this bolt being provided with a split washer on the end. To bring the pawl hole central with its hub, two set-screws are provided at *D* which hold the hand-wheel in position while being drilled by clamping against the sides of the spoke. The jig is fastened on the edge of the drill press table, so that the table does not interfere with the wheel. The vertical hole, with the drill guided by bushing *E*, is now drilled and reamed in all the hand-wheels, this hole being the pawl hole. For drilling and reaming the small diameter, a long bushing is used in the large diameter of the hole to guide the tools. When this hole is drilled, the jig is then clamped to the side of the box table and the hole for the handle stud is drilled in all the wheels.

The jig shown at *F* in the same engraving is for drilling the shaft bearing which is seen to the right. The hub on the bearing fits into the jig, the straps *G* holding the work in place. Both this jig and the one at *A* are provided with complete sets of clearance and tap bushings so as to permit their being used on a multiple spindle drilling machine.

In Fig. 9 will be seen a set of gages for testing the component parts of the mechanism shown in Fig. 5. Gage *A* is for testing the length of the pawl which is shown in position in the gage. The ends of the pawl are milled with forming cutters. At *B* is shown a gage for testing the cam surface on the handle *C*. This cam is also milled with a forming cutter and when milled to the proper depth will just pass through the gage. The gage *D* is used to test the handle for length *I* (Fig. 5), the collar *J*, the depth of counterbore *K*. This gage represents a standard handle stud except that it is provided with a groove to fit the U-shaped collar *E* which is of the same diameter and thickness as the collar *J* in Fig. 5. To test the handle, the gage is inserted into the hole and the U-collars slipped into the groove; the collar *J* is tested for thickness by fitting the groove in the gage; to test the depth of the counterbore *K*, the gage is screwed into the hand-wheel and the collar *E* tried as before.

The tool shown at *F* is the counterbore used in connection with jig *B*, Fig. 8, for finishing the counterbore *K* and surface *L* in Fig. 5. At *G*, Fig. 9, is a length gage for the shoulders on the hand-wheel shaft against which the gage is seen resting. In the same engraving, *H* is a gage for testing the length through the bearing hole, while to the extreme right at *I* is shown a length gage for the hand-wheel shaft hole.

It will be observed that all of these gages, with one exception, that of the cam gage *B*, are length gages. Their use was found imperative for interchangeable work. This is due to the fact that errors in length are far more likely to occur and cause trouble in assembling than errors in diameter. All of the essential measurements of diameter on the component parts of the mechanism shown in Fig. 5, *i. e.*, the running and driving fits, are tested with ordinary limit and plug gages, while the threaded members are tested with male and female thread gages.

In assembling the mechanism, the pawl, its spring, and the handle members are first assembled. After fitting the Woodruff keys and the shaft members, the ratchet wheel is removed for the purpose of assembling the bearing and hand-wheel. The ratchet wheel is then replaced and the nut screwed down tightly with a socket wrench, the shaft being held from turning by engaging the pawl. Fastening on the cover and screwing in the oil cup finish the assembling operations. There is no adjusting or fitting to be done since the proper allowances for all fits are provided for on the detail drawings and the accuracy of the machine work is insured by a thorough system of inspection. Thus it will be seen that the work of assembling in this case merely consists in combining the separate elements in their logical order.

Summary of Principles of Assembling Operations

Summarizing the principles referred to in the previous discussion, we may state the following rules as being the main points to be considered in assembling work.

1. To secure economical results we must have accurate drawings, accurate machine work, and use jigs and gages.
2. The use of limits on detail drawings is valuable especially when supplemented with a thorough system of inspection.
3. Inspection, both in the machine and assembling departments, is absolutely necessary.
4. Before assembling any part of a machine, its function should be thoroughly understood in order to have the parts work properly and to avoid any unnecessary refinement.
5. Study carefully the question of rigidity in fits.
6. Plan quick and efficient methods of lining up.
7. Always follow the drawings. In no case should deviations be permitted.
8. Anticipate any extra chipping for clearance that may be necessary, and so avoid having to take the work apart.
9. Analyze the elements carefully, and see if it will not pay to substitute the machining process on pieces that are sometimes fitted by hand.
10. Standardization is one of the cardinal principles of economical assembling. Therefore, do not leave stock for adjustment when the pieces can be machined to standard size.

11. Provide for the duplication of parts in quantities so as to take advantage of the saving to be gained from performing the same operation on a number of pieces in succession.

12. Separate the assembling operations for any particular job so as to provide for a subdivision of labor.

13. Follow the unit system of assembling in order to permit a large number of workmen to be employed on a job.

14. The operations involved in assembling the units should be separated from the erecting process.

15. All chipping should be done before the parts are scraped.

16. Where it would be necessary to take the work apart to line up the brackets or bearings, perform the lining-up operation first.

17. Plan methods and processes so that the work can be assembled with the least amount of handling.

18. Provide ample handling facilities.

19. Make the laborious operations in scraping as easy as possible by providing efficient pulling devices.

20. Before sending the units to store or to the erectors see that the operations are completed as far as possible.

* * *

FORMULAS FOR CONE CLUTCHES*

There appears to be considerable misunderstanding, or perhaps rather, lack of understanding, of the formulas for cone clutches. A number of formulas are given in various handbooks and treatises on design, but at first sight they do not agree, and if the designer has not deduced any of the formulas for himself, he will naturally doubt the source from which he obtains them because of finding discrepancy between final results. However, the various authorities in general give correct formulas, and the difficulty met is caused by the fact that in cone clutch design different formulas are developed according to whether the clutch surfaces are considered to engage with or without some slip. In the following a set of formulas are deduced for both conditions, and a summary of these formulas is given in the accompanying Data Sheet Supplement:

Assume that:

H.P. = horse-power transmitted.

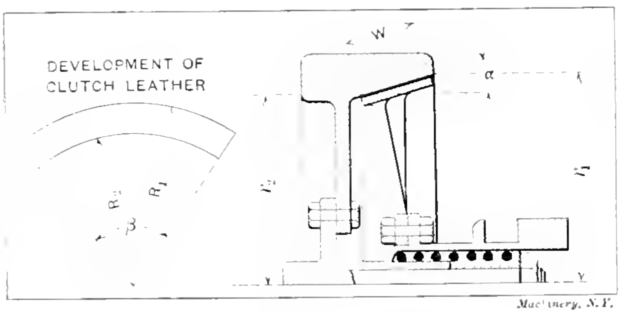

Fig. 1. Diagram of Cone Clutch

N = revolutions of crank-shaft per minute,

r = mean radius of friction cone, in inches,

r_1 = large radius of friction cone, in inches,

r_2 = small radius of friction cone, in inches,

R_1 = outside radius of leather band, in inches,

R_2 = inside radius of leather band, in inches,

v = velocity of a point at distance r from the center, in feet per minute,

F = tangential force acting at radius r, in pounds,

P_n = total normal pressure between cone surfaces, in pounds,

P_s = spring pressure, in pounds,

α = angle of clutch surface with axis of shaft = 7 to 13 degrees,

β = included angle of clutch leather, when developed,

μ = coefficient of friction = 0.20 to 0.25 for greasy leather on iron,

p = allowable pressure per square inch of leather band = 7 to 8 pounds,

W = width of clutch leather, in inches.

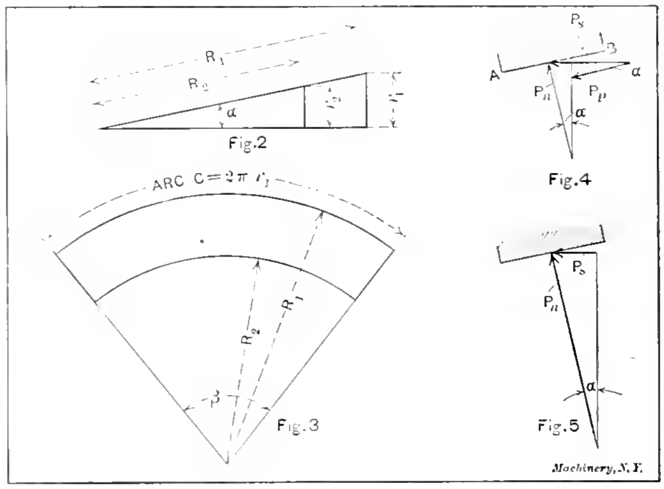
* With Data Sheet Supplement.

The relation between the outside and inside radii R_1 and R_2 of the clutch leather for covering the friction surface and the radii r_1 and r_2 of the friction cone are expressed by the following formulas, the deduction of which are clearly seen from Fig. 2.

$$R_1 = \frac{r_1}{\sin \alpha}$$

$$R_2 = \frac{r_2}{\sin \alpha}$$

The included angle β of the developed clutch leather (see Fig. 3) is found as follows: The length of the outside arc of the developed clutch leather surface equals the largest circumference of the cone clutch, or arc $C = 2 \pi r_1$. (See Figs.



Figs. 2 to 5. Diagrams for Deducing Formulas for Cone Clutches

1 and 3.) Angle β is to 360 degrees as arc C is to the whole circumference of the circle having R_1 for radius. Therefore,

$$\frac{\beta}{360} = \frac{2 \pi r_1}{2 \pi R_1} = \frac{r_1}{R_1}.$$

But it has already been shown that $R_1 = \frac{r_1}{\sin \alpha}$, or $r_1 = R_1 \times \sin \alpha$, and therefore

$$\frac{\beta}{360} = \frac{R_1 \times \sin \alpha}{R_1} = \sin \alpha, \text{ or } \beta = \sin \alpha \times 360.$$

It is obvious that the mean radius r of the friction cone equals the arithmetic mean of the largest and smallest cone radii, or

$$r = \frac{r_1 + r_2}{2}$$

The velocity v of a point on the friction cone at a distance r from the center is found by the well-known formula

$$v = 2 \pi r N$$

in which v and r are supposed to be measured in the same units. If v is in feet, and r in inches, the formula takes the form

$$v = \frac{2 \pi r N}{12}$$

The tangential force acting at radius r, in pounds, is found by the formula

$$F = \frac{\text{H.P.} \times 33{,}000}{v}$$

which is deduced directly from the familiar formula for horse-power when the torque is given in foot-pounds.

If the width of the clutch surface is W, the area of this surface is $W \times 2 \pi r$. The total pressure on the surface, P_n, must equal the pressure per square inch multiplied by the area, or

$$P_n = W \times 2 \pi r p.$$

From this we deduce the formula

$$W = \frac{P_n}{2 \pi r p}.$$

The horse-power transmitted equals

$$H.P. = \frac{P_n f \times 2 \pi r \times N}{12 \times 33{,}000}$$

in which r is given in inches. By inserting the value of π in this formula, and dividing numerator and denominator in the fraction by 2π, we get

$$H.P. = \frac{P_n f r N}{63{,}025}$$

In Fig. 4 let it be assumed that the clutch surfaces engage without slip. Assume further that the spring pressure is represented by line P_s, the pressure normal to the clutch surface AB by P_n, and the force tending to bring the clutch surfaces in closer engagement by P_p; this last force, of course, is parallel to AB. The force P_s is partly used for producing the normal pressure P_n and partly used for bringing the clutch surfaces in closer contact; consequently

$P_s = P_n \times \sin a + P_p \times \cos a.$

But $P_p = P_n \times f.$

Therefore

$P_s = P_n (\sin a + f \cos a)$

$$\text{and } P_n = \frac{P_s}{\sin a + f \cos a}$$

If we substitute this value of P_n in the horse-power formula just deduced, we have

$$H.P. = \frac{P_s f r N}{63{,}025 (\sin a + f \cos a)}$$

Transposing, we get

$$P_s = \frac{H.P. \times 63{,}025 (\sin a + f \cos a)}{f r N}$$

If we assume that there is some slip between the clutch surfaces, the force P_p in Fig. 4 becomes zero, and the whole of force P_s is used to produce normal pressure, as shown in Fig. 5. Then

$$P_n = \frac{P_s}{\sin a}$$

and, substituting in the horse-power formula, as before, we have

$$H.P. = \frac{P_s f r N}{63{,}025 \sin a}$$

and

$$P_s = \frac{H.P. \times 63{,}025 \sin a}{f r N}$$

The most important of these formulas have been collected in compact form and are given without their deductions in the Data Sheet Supplement. They will be found very convenient for ready reference when designing cone clutches or checking designs already made.

* * *

The export of automobiles from France, which declined in 1908, has shown a slight increase during the first months of 1909. During the first three months of the year 1907 France exported automobiles valued at approximately $10,300,000. During the first three months of 1908 the exports declined so that the total value of automobiles exported was only $8,700,000. During the first three months of the current year the exports again rose to $9,500,000. England is the best customer of France for automobiles, more than forty per cent of the exports being to Great Britain. The exports of automobiles to the United States are decreasing so that during the first three months of 1909 automobiles to a value of only slightly more than $500,000 were imported, as compared with over $800,000 in 1908, and nearly $800,000 in 1907. The Argentine Republic appears to offer a good field for the automobile trade, the French exports to that country during the first three months of the current year amounting to over $750,000. The imports of automobiles to France are almost negligible when compared with the exports. During the first three months in 1909 the total value of imported automobiles amounted to about $100,000, the United States supplying cars to a value of only $16,000. Germany and Italy supply the largest proportion of cars imported by France.

STANDARD AUTOMOBILE PARTS ADOPTED BY THE A. L. A. M.*

The Association of Licensed Automobile Manufacturers (A. L. A. M.) has, from time to time, standardized some parts which occur in automobile design, and which are likely to require frequent replacement or repairs. The most important of the standards adopted by the association undoubtedly are the standards for fine pitch threads, screws, castle and plain nuts, which were published in MACHINERY'S Data Sheet No. 63, accompanying the November, 1906, issue. In this issue an editorial was also published entitled "Automobile Fine Screw Threads" in which the new standard for screw threads was discussed. A table condensed from the Data Sheet mentioned, giving all the required dimensions, is published herewith.

Since the adoption of the standard A. L. A. M. thread, the association has adopted a standard spark plug, the dimensions and special specifications of which are given in the accompanying supplement. Standard designs for adjustable and solid yoke and eye rod ends have also been adopted, dimensions for which are also given in the supplement, together with dimensions for the pins and washers used with these rods.

The horse-power of automobile engines has always been more or less indefinitely expressed, and until recently there has been no formula giving a satisfactory relation between the horse-power and the diameter of the engine cylinder and the piston speed. The association, therefore, some time ago adopted a standard horse-power formula, assuming a piston speed of 1,000 feet per minute. According to this formula, if

D = diameter of cylinder, and

N = number of cylinders,

$$\text{then } H.P. = \frac{D^2 \times N}{2.5}.$$

The table in the supplement giving horse-power of automobile engines has been calculated from this formula for engines having one, two, four and six cylinders, with the diameter of the cylinder varying from 2½ to 6 inches. It will be understood, of course, that this formula gives only approximate results, as the actual horse-power of any one automobile engine could not be expressed by so simple or general a formula. However, this formula is of great assistance in estimating in a general way the probable horse-power of an automobile engine.

* * *

A commission has been at work for the last two years in Sweden preparing a new schedule for import duties. The new tariff, which has not yet been adopted, proposes increases in the import duties imposed on machinery, the avowed purpose being to protect home industries.

* With Data Sheet Supplement.

TREATMENT OF GEARS FOR AUTOMOBILE MOTORS AND TRANSMISSIONS

HAROLD WHITING SLAUSON*

There is probably no part of an automobile that is subjected to more use or greater abuse than the transmission. Carrying as it does practically all of the power developed by the motor, and, receiving at the hands of a careless driver the strains imparted by a suddenly applied load or a too rapid shifting of the speeds, it is small wonder that the gears of the transmission must be made of the highest grade of materials, and that the care and workmanship bestowed upon each must be of the best. The ordinary automobile transmission consists of a series of different sizes of spur gears mounted on two parallel shafts with means for sliding the gears on one shaft into mesh with those on the other, as desired. In this manner various speed ratios are transmitted from the motor to the main driving shaft, although on the majority of automobiles the high speed drives the car direct, without the interposition of any of the gears of the transmission.

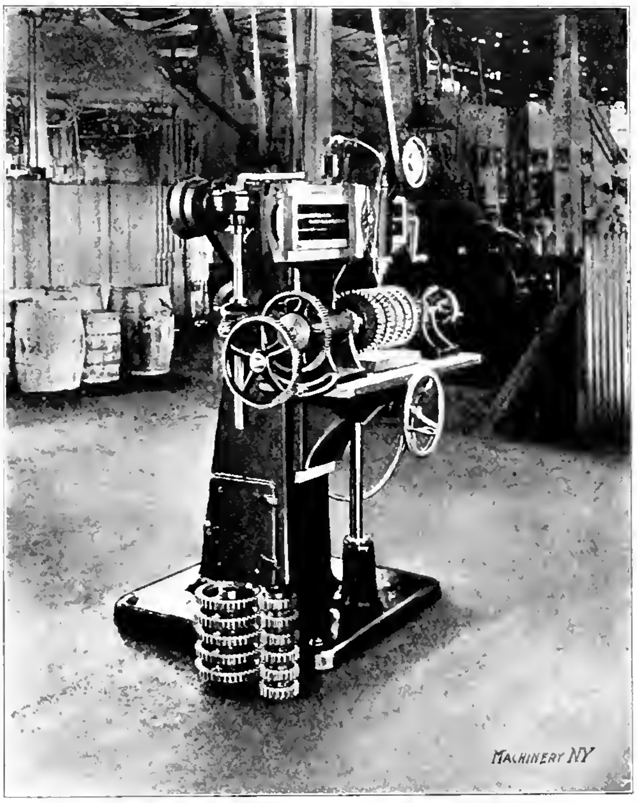

Fig. 1. Chamfering the Teeth of Spur Gears in the Winton Factory

As a saving in weight is an important factor to be considered in the design of a transmission, the gears must be made as small as possible and yet be sufficiently strong to carry suddenly-applied loads with no attendant danger of breaking. Owing to the methods by which the speeds are changed, and the clashing and "bruising" which take place when the gears are shifted, the transmission must also be made of a material which is hard as well as tough. Different kinds of steel have been used and each has been treated by various methods in an effort to discover the perfect gear material, but although this is yet to be found, the transmission of a modern, well-made automobile, when intelligently handled, will last nearly as long as the car itself. Of the various kinds of carbon steel which have been employed for transmission gears, nickel, chrome-nickel and silico-manganese seem to have more adherents among the leading builders than any other materials. In most factories the gears are case-hardened after being cut, and in this manner the combination of toughness with the desired hard surface is obtained. Gears which have been treated in this way have been taken out of cars after having been run many thousands of miles, and in some instances, the original tool marks on the faces of the teeth were still visible.

Methods employed for cutting gears in automobile factories do not differ in any essential features from those used in any well-equipped machine shop or manufacturing concern. Most of the automobile makers purchase their transmission gear blanks outside and cut and finish them in the factory. Many of these blanks of special steel are imported from France, but a few of the leading factories have laboratories of their own in which experiments on high-quality materials for transmission purposes are continually in progress. Six or seven spur gear blanks of the same size are generally placed on the mandrel of the cutter at once. A continuous cut extending throughout the width of all of these blanks is then taken for each tooth, and in this manner six or seven gears are finished at once and are made absolutely uniform.

After the teeth have been cut, the gears are taken to the heat treating room to be case-hardened. In the Middle West, and a few other sections, many of the case-hardening ovens are heated by natural gas obtained from near-by wells. In the Maxwell factory, at Newcastle, Ind., a special machine has been installed for the manufacture of gas from "distillate"—a hydro-carbon obtained from the oil refineries. This machine is set up in the power house connected with the factory, and the gas is stored in a tank located in the same building. It is conducted from here to the heat-treating ovens in which it is used for case-hardening, tempering and annealing. Still another method for obtaining heat for the ovens is in use at the Ford factory, in Detroit. Petroleum, or crude oil, is vaporized and forced by air pressure into a series of special burners located under the ovens. By regulating the amount of air or vapor or both, the ovens can be kept at a uniform temperature, or the amount of heat generated may be varied at will between almost any limits. The temperatures of the ovens are indicated by an electric pyrometer connected with each, and pieces to be case-hardened are kept at a heat of 1,600 degrees F. for a length of time which depends on the depth below the surface to which it is desired to carry the treatment.

In several factories the final operation bestowed upon the gear, before assembly in the transmission or the motor, is the sand blast which serves to scour off any roughness or stains which may have been left on the surface during the cutting or the heat treatment. In the National factory, at Indianapolis, this operation is conducted in a small building separated from the remainder of the shop. The sand is kept in a bin in one corner and is sucked up by a centrifugal blower and forced by the air pressure through a pipe which terminates in a nozzle. The sand, being forced out at high velocity by the air pressure, may be directed at all parts of the pieces to be cleaned. This is one of the most efficient methods of polishing and finishing a gear and does not injure the hard metal surface in any way.

Fig. 2. Gear Case-hardening Room in the Premier Factory

As silence of operation of all moving parts is one of the principal requisites for a motor car of to-day, it is necessary that the teeth of all gears shall be made to mesh perfectly and smoothly with all of those on the other gears with which they come in contact. In order to obtain silence of operation, the gears are run with each other for some time and each tooth is worn to a more perfect fit. The first few weeks of

* Address: Box 27, Times Square Station, New York.

operation by the customer would wear the gears in properly, but, in order to produce a perfect car, this is done before it leaves the factory. Most of this "running in" of the gears can be accomplished by the thorough road test to which the whole car is subjected before leaving the shop, but many of the leading factories supplement this with additional methods for bestowing the required wear on the transmission. A special frame is used in the Marmon factory, in Indianapolis (see Fig. 3), in which the transmission, driving shaft, differential, and rear axle and wheels are set up. An

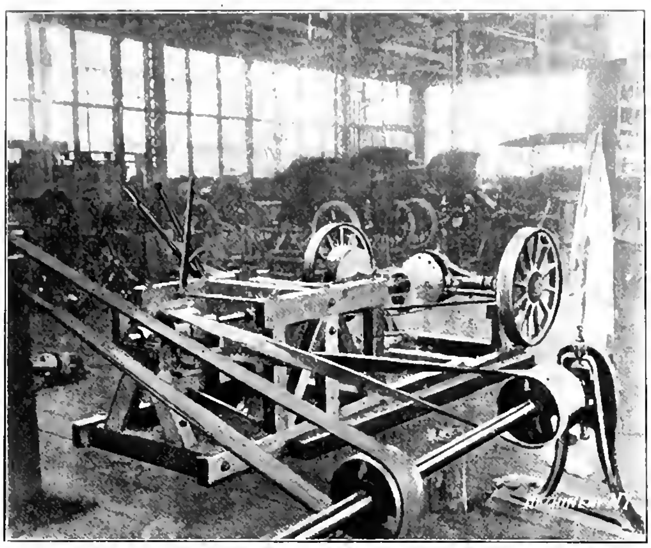

Fig. 3. Running in the Transmission and Differential Gears in the Marmon Factory

idler and a driving pulley, with a belt shifter, are attached to the front end of the transmission shaft and connected by belt to a countershaft driven from the main line shafting. When the power is applied and the different speeds of the transmission are thrown into mesh by the shifting lever, every gear of the whole car, with the exception of those used on the motor, will be set in motion. The gears of the engine are worn in when it is operated under belt power before installation in the chassis. Somewhat the same method is pursued in the Packard factory, in Detroit, the only difference between the two being that here, instead of allowing the wheels to run free, a brake is attached to the end of the driving shaft by means of which a variable load may be applied to the gears in mesh. A section of the testing room is devoted to this purpose, and as the transmission and rear axle are assembled, they are brought in, placed on special

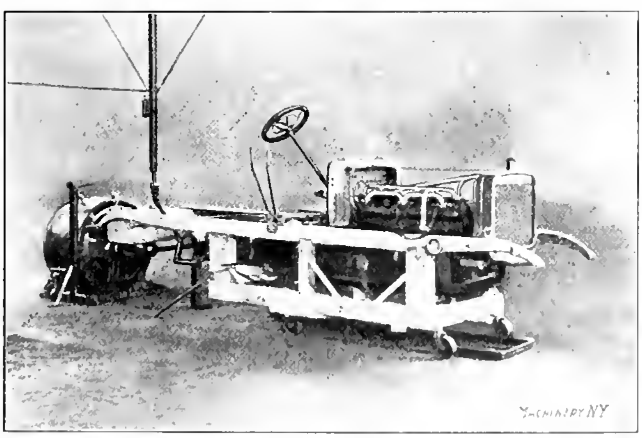

Fig. 4. Preliminary Run of Engine and Transmission to wear in the Parts

frames provided for the purpose and connected by belts to overhead shaftings. As the gears of the transmission and differential are run in, the loads are increased until all are worn perfectly smooth.

Before their final installation in the motor and transmission, all of the spur gears for the Winton cars, made in Cleveland, are set up in a special case and run in under belt power. The bearings in these special cases are set at the proper distances apart to accommodate the various gears of a train, thus wearing in the gears so that all of those for similar parts are absolutely interchangeable. The case is made oil-tight and a mixture of finely powdered emery and lubricating oil is fed through an opening in the top so that this grinding material will come in contact with all the teeth of the gears in mesh in the train. This grinding is continued until each tooth has been worn perfectly smooth and to an accurate fit with the teeth of the other gears with which it comes in mesh. For the gears used in the front of the motor to drive the cam, pump and magneto shafts—gears which always occupy the same relative position in regard to each other—a tooth of each is marked when in the grinding case with the corresponding teeth of the others with which it meshes. This is done so that each gear of the train may be set up in the motor in the same corresponding position as that occupied while being worn to a perfect fit with the others in the case. It is evident that every tooth cannot be of *exactly* the same size and shape, and if each tooth is allowed to mesh with those with which it came in contact while being ground, more perfect rolling contact will take place and less friction and noise will be set up. The marks made on the gears are also useful for timing the magneto and valve cam shafts when the occasion arises necessitating the removal of any of these parts from the motor. Of course, it is impossible to carry this practice to the transmission, for most of the gears on one shaft revolve independently of those on the other, and it is very seldom that the same teeth of two gears will come into mesh on succeeding occasions. This practice, however, may be applied to the bevel gears of the driving shaft and rear axle and the pinions of the differential. As a further means of wearing the gears of the transmission to a perfect fit, the motor, transmission and driving shaft are installed in the chassis as

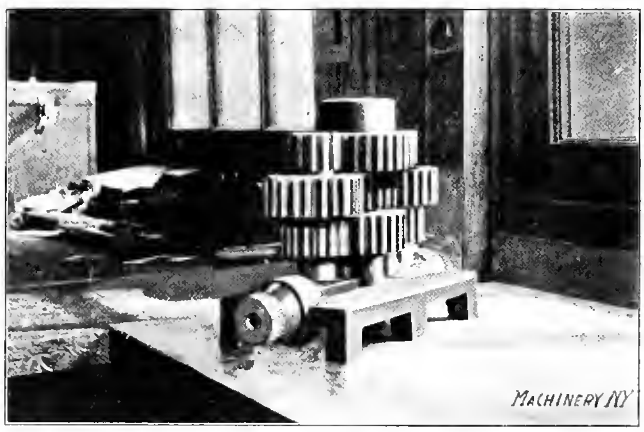

Fig. 5. Device for Testing the Accuracy of Gears

shown in Fig. 4, and the motor is run while the various speeds of the transmission are thrown into mesh in order to wear in every gear thoroughly. During this run an electric dynamometer, by means of which a variable load may be applied, is connected to the end of the driving shaft.

An ingenious device for testing the accuracy of gears is used in the factory of the Grabowsky Power Wagon Co., of Detroit. This consists of a standard having three pins or bearings set in it on which the gears of the transmission are placed as shown in Fig. 5, thus forming a replica of the planetary transmission as used in the car. The middle upright bearing is stationary while each of the other two is movable in a horizontal direction and is connected to a micrometer at either end of the base of the instrument. A master gear is set on one of these bearings, while the pinions to be tested are placed on the other two. When the two movable bearings have been so adjusted that all of the gears mesh perfectly, the readings of the two micrometers may be observed and the amount, in thousandths of an inch, by which the gears are "off" may thus be determined accurately. Certain limits of variation are necessarily allowed, but if any gear is below one or above the other, it is thrown out. Inasmuch as the distance between the centers of the gears must be constant in the transmission case, this instrument is useful in determining just what gears are acceptable without the necessity of installing them in the case.

Many of the gears used in the forward end of the motor for driving the cam, pump and magneto shafts are made of

manganese-bronze. The Premier car, however, made in Indianapolis, employs a laminated gear for the magneto shaft, built up of alternate layers of bronze and fiber. These layers are pinned firmly together and the gear is then cut by the usual methods. This makes an exceedingly quiet-running gear, as the layers of fiber or rawhide cushion the impact of the teeth as they meet, and the whirring or grinding sound familiar in many all-metal gears is practically eliminated. It has been found by means of a series of exhaustive tests conducted in this factory that the silent running of this gear is brought about by a slight rounding or "bulging" of the face of the rawhide sections caused by the absorption of the lubricating oil in the pores of the fiber and the pressure against its sides. This, as mentioned above, effectually cushions the impact of the teeth, but if this bulge becomes too great, the teeth will not mesh properly, there will be a tendency to "jam" and more friction will be set up than would be the case were an all-metal gear used. Of course the wider these fiber sections are, the greater will be the bulge to each, and it has been found as a result of these experiments that laminated gears composed of layers of rawhide about 1/8 of an inch thick, alternating with bronze disks of the same dimensions, give the best service for this purpose. When sections of this thickness are used, a sufficient bulge is formed to cushion the impact satisfactorily, and yet this is not great enough to change the shape of the teeth materially. These experiments are still in progress at the factory in question in order the more accurately to determine other facts and figures concerning the best form of laminated gears, and this is only one of the many instances which give evidence to the fact that the American motor car manufacturer is now fully awake to the importance of paying attention to the most minute detail of design.

* * *

SIMPLIFIED METHODS FOR FLY-WHEEL CALCULATIONS*

R. J. WILLIAMS†‡

In several previous issues of MACHINERY methods and formulas have been given relating to the design of fly-wheels and the size of motor required for giving out a certain amount of energy per stroke of the machine under consideration. In this article a method of calculation will be given whereby the work of finding the desired results may be considerably shortened.

In shears of large size cutting short pieces, where the maximum effort may be required almost continuously it is of great importance that motor and fly-wheel be of sufficient capacity to perform their work properly. Since the amount of energy to be given out by the fly-wheel depends upon the size of the motor, this should always be determined first.

Let

E = total energy required per stroke,
E_1 = energy given up by motor during cut,
E_2 = energy given up by fly-wheel,
T = time in seconds per stroke,
T_1 = time in seconds in which E_1 is given up,
T_2 = time in seconds in which E_2 is restored to fly-wheel,
V_1 = initial velocity of fly-wheel in feet per second,
V_2 = velocity after cut in feet per second,
R_1 = initial revolutions per minute of fly-wheel,
R_2 = revolutions per minute after cut,
R = revolutions per minute after n cuts,
W = weight of fly-wheel rim in pounds,
D = mean diameter of fly-wheel rim in feet,
H_1 = horse-power required to cut every stroke,
H_2 = horse-power actually used,
a = width of fly-wheel rim,
b = depth of fly-wheel rim,
g = 32.16,
n = number of cuts shear will make for a total given reduction in speed.

In the July, 1907, issue of MACHINERY this formula for horse-power was given:

$$\text{H. P.} = H_1 = \frac{EN}{33{,}000}.$$

and since $N = \dfrac{60}{T}$ we have

$$H_1 = \frac{E}{550T} \tag{1}$$

$$H_1 = \frac{E_1}{550T_1}$$

$$E_1 = 550\,T_1\,H_1 = \frac{550\,E\,T_1}{550\,T} = \frac{E\,T_1}{T}$$

$$E_2 = E - \frac{E\,T_1}{T} = E\left(1 - \frac{T_1}{T}\right) \tag{2}$$

Having now the energy that must be given out by the fly-wheel, we can proceed as follows:

We know that $E_2 = \dfrac{W}{2g}(V_1^2 - V_2^2)$ and that

$$V_1^2 = \left(\frac{D \times \pi \times R_1}{60}\right)^2 = 0.00274\,D^2\,R_1^2$$

$$V_2^2 = \left(\frac{D \times \pi \times R_2}{60}\right)^2 = 0.00274\,D^2\,R_2^2$$

$$V_1^2 - V_2^2 = 0.00274\,D^2\,(R_1^2 - R_2^2)$$

$$E_2 = \frac{W}{64.32} \times 0.00274\,D^2\,(R_1^2 - R_2^2)$$

$$E_2 = 0.0000426\,W\,D^2\,(R_1^2 - R_2^2) \tag{3}$$

$$W = \frac{E_2}{0.0000426\,D^2\,(R_1^2 - R_2^2)} \tag{4}$$

Making $0.0000426\,(R_1^2 - R_2^2) = CR_1^2$ we have

$$E_2 = CWD^2R_1^2 \tag{5}$$

$$W = \frac{E_2}{CD^2R_1^2} \tag{6}$$

In cast-iron fly-wheels it is usual not to exceed a speed which represents a fiber stress of more than 1,000 pounds per square inch of rim cross-section. The stress in pounds due to centrifugal force equals $0.0972\,V_1^2$ for cast iron, and for fly-wheels having a maximum stress of 1,000 pounds per square inch we can develop the following formulas:

$0.0972\,V_1^2 = 1{,}000$; $V_1 = 101.5$.

But $V_1 = \dfrac{D\pi R_1}{60}$, therefore we have

$$101.5 = \frac{D\pi R_1}{60}$$

$$R_1 = \frac{101.5 \times 60}{D\pi} = \frac{1940}{D} \tag{7}$$

$$D = \frac{1940}{R_1} \tag{8}$$

Squaring (7) we have $R_1^2 = \dfrac{1940^2}{D^2}$

Substituting this in (6) we have

$$W = \frac{E_2}{C\,D^2\,\dfrac{1940^2}{D^2}} = \frac{E_2}{1940^2\,C}$$

† Address: Wheeling Mold and Foundry Co., Wheeling, W. Va.

‡ Roy J. Williams was born in Syracuse, Ohio, 1884. He received a high school education and became a mechanical draftsman through home study. He has worked as draftsman with the Labelle Iron Works, Steubenville, Ohio; Mutual Electric & Machine Co., Wheeling, W. Va., and the Wheeling Mold & Foundry Co., Wheeling, W. Va. His specialty is rolling mill design.

Making $1940^2 C = C_1$, and $\frac{1}{C_1} = C_2$ we have

$$W = \frac{E_2}{C_1} = C_2 E_2 \qquad (9)$$

The following are the values of C, C_1, and C_2 for different reductions in speed:

Per Cent Reduction	C	C_1	C_2
$2\frac{1}{2}$	0.00000213	8.00	0.1250
5	0.00000426	16.00	0.0625
$7\frac{1}{2}$	0.00000617	23.20	0.0432
10	0.00000810	30.45	0.0328
$12\frac{1}{2}$	0.00001000	37.60	0.0266
15	0.00001180	41.50	0.0225
20	0.00001535	57.70	0.0173

Size of Rim

Let us assume that the depth of rim equals 1.22 times the width. We have then these formulas for size of rim:

$$a = \sqrt{\frac{W}{12D}} \qquad (10)$$

$$b = 1.22\,a \qquad (11)$$

These two formulas can be changed to suit any required ratio of depth to width of rim.

Let y = required ratio.

$$a = \sqrt{\frac{1.22W}{12Dy}} \qquad (12)$$

$$b = ya \qquad (13)$$

Effect of Changing Size of Motor

Let us now suppose that we do not wish to use a motor large enough to cut continuously, and desire to find how many cuts the machine would make continuously without drifting down more than a certain percentage of the original speed. Transposing (3) we have

$$R_1^2 - R_2^2 = \frac{E_2}{0.0000426\,WD^2}$$

$$\text{Let } \frac{E_2}{0.0000426\,WD^2} = K,$$

$K = R_1^2 - R_2^2$, and

$R_2 = \sqrt{R_1^2 - K}$

$$R_3 = \sqrt{R_1^2 - n\,K + (n-1)\,K\frac{H_2}{H_1}} \qquad (14)$$

After several reductions we have

$$n = \frac{\dfrac{H_1\,(R_1^2 - R_3^2)}{K} - H_2}{H_1 - H_2}$$

and since $K = R_1^2 - R_2^2$ we have

$$n = \frac{\dfrac{H_1\,(R_1^2 - R_3^2)}{R_1^2 - R_2^2} - H_2}{H_1 - H_2} \qquad (15)$$

The time now required to bring the fly-wheel up to full speed again after n cuts will be

$$T_2 = \frac{E_2}{550\,H_2} \qquad (16)$$

Examples

We will now work out some examples illustrating the use of these formulas.

Example 1.—A hot slab shear is required to cut a slab 4×15 inches which, at a shearing stress of 6,000 pounds per square inch, gives a pressure between the knives of 360,000 pounds. The total energy required for the cut will then be

$360{,}000 \times \frac{4}{12} = 120{,}000$ foot-pounds. The shear is to make 20 strokes per minute, and with a six-inch stroke the actual cutting time is 0.75 second and the balance of the stroke is 2.25 seconds.

The fly-wheel is to have a mean diameter of 6 feet 6 inches and is to run at a speed of 200 R. P. M.; the reduction in speed to be 10 per cent per stroke when cutting.

$$H_1 = \frac{120{,}000}{3 \times 550} = 72.7 \text{ horse-power.}$$

$$E_2 = 120{,}000 \times \left(1 - \frac{0.75}{3}\right) = 90{,}000 \text{ foot-pounds.}$$

$$W = \frac{90{,}000}{0.0000081 \times 6.5^2 \times 200} = 6570 \text{ pounds.}$$

Assuming a ratio of 1.22 between depth and width of rim.

$$a = \sqrt{\frac{6{,}570}{12 \times 6.5}} = 9.18 \text{ inches,}$$

$b = 1.22 \times 9.18 = 11.2$ inches.

or size of rim, say, $9 \times 11\frac{1}{2}$ inches.

Example 2.—Suppose we wish to make the fly-wheel in Example 1 with a stress of 1,000 pounds, due to centrifugal force per square inch of rim section.

C_2 for 10 per cent = 0.0328,

$W = 0.0328 \times 90{,}000 = 2{,}950$ pounds,

$R_1 = \frac{1{,}940}{D}$. If $D = 6$ feet, $R_1 = \frac{1{,}940}{6} = 323$ R. P. M.

$$a = \sqrt{\frac{2{,}950}{12 \times 6}} = 6.4 \text{ inches,}$$

$b = 1.22 \times 6.4 = 7.8$ inches,

or size of rim, say, $6\frac{1}{4} \times 8$ inches.

Example 3.—Let us now suppose that in Example 1 we wish to use a 50 H. P. motor, and wish to find how many cuts the shear will make continuously without drifting down more than 20 per cent in speed? And what time must be allowed for the motor to restore the fly-wheel to its original speed?

$R_1^2 - R_3^2 = 200^2 - 160^2 = 14400$

$R_1^2 - R_2^2 = 200^2 - 180^2 = 7600$

$$n = \frac{\dfrac{72.7 \times 14400}{7600} - 50}{72.7 - 50} = 3.86 \text{ cuts}$$

Allowing the shear to make 4 cuts we have

$$R_3 = \sqrt{200^2 - 4 \times 7600 + 3 \times 7600 \times \frac{50}{72.7}} = 159 \text{ R. P. M}$$

$E_2 = 0.0000426 \times 6570 \times 6.5^2 \times (200^2 - 159^2) = 175{,}000$ foot-pounds, about.

$$T_2 = \frac{175000}{550 \times 50} = 6.4 \text{ seconds.}$$

Example 4.—Let us now suppose that in Example 2 we wish to use a 50 H. P. motor under the same conditions as in Example 3.

$R_1^2 - R_3^2 = 323^2 - 258^2 = 37750$

$R_1^2 - R_2^2 = 323^2 - 291^2 = 19650$

$$n = \frac{\dfrac{72.7 \times 37750}{19650} - 50}{72.7 - 50} = 4 \text{ cuts, nearly.}$$

$E_2 = 0.0000426 \times 2950 \times 6^2 \times (323^2 - 258^2) = 170{,}000$ foot-pounds, about.

$$T_2 = \frac{170{,}000}{550 \times 50} = 6.2 \text{ seconds.}$$

These examples show the possibilities of the formulas as time-savers for the designer, by reducing the calculations to the smallest possible number, and at the same time reducing the possibility of error.

* * *

Vice-Consul-General Richard Westacott reports that on July 1 there were 3,391 public motor cabs in use in London, this being an increase of 1,886 over the number one year ago. In other words, the number of motor taxicabs has more than doubled in a year, while the number of licensed horse-drawn hansom cabs decreased 1,290 in one year, and the number of four-wheeled horse-drawn cabs decreased by 389. The total number of all kinds of public cabs in London is nearly 11,000.

GLENN H. CURTISS

THE MAN, THE AEROPLANE AND THE MOTOR

Glenn H. Curtiss

Glenn Hammond Curtiss was born May 21, 1878, at Hammondsport, N. Y. Here he received his early education and planned for the future, although he hardly could have dreamed of what he has actually been able to accomplish, namely to go faster on the ground than any other person, and to fly through the air and win in competition over the best aviators of the world.

Mr. Curtiss attended school in Rochester, N. Y., and started in the bicycle business in Hammondsport in 1900. It was at this time that he built one of the first motor cycles ever constructed in this country, and he says that he never since has had such pleasure from any of his successes as came to him when, for the first time, the motor made a few explosions and ran for half a block.

On January 23, 1907, at Ormond Beach, Fla., Mr. Curtiss made a record for the distance of one mile in the extraordinary time of 26 2/5 seconds with a 40-horse-power air-cooled motor cycle which he had built entirely in his own factory. This is the fastest speed ever made with any form of vehicle, and means a speed of about one hundred and thirty-seven miles an hour.

Mr. Curtiss' first interest in aeronautics came from Captain Thomas S. Baldwin who, in seeking a good motor to drive his airships, found the Curtiss the best and most reliable for the purpose. Mr. Curtiss built the first water-cooled motor to be used in the dirigible balloon which Captain Baldwin built for the United States Signal Corps and which made 19.61 miles an hour in its official speed test and flew in its official endurance trial for two hours. Mr. Curtiss operated the engine while Captain Baldwin steered the airship during its flights which were held at Fort Myer, Va., near Washington. These flights, and one made a short time previously, were the first opportunities that Mr. Curtiss had to navigate the air.

In the latter part of 1907 the Aerial Experiment association was formed by Dr. Alexander Graham Bell, the inventor of the telephone, who is greatly interested in the subject of aeronautics, and Mr. Curtiss was appointed the director of experiments. The other members of the association were Mr. F. W. Baldwin, M.E., Toronto University, chief engineer, who made the first public flight in America in a heavier-than-air flying machine, March 12, 1908, in the first machine built by this association, Selfridge's *Red Wing*, which flew over the ice on Lake Keuka, near Hammondsport, N. Y. The treasurer of this association was Mr. J. A. Douglas McCurdy, M. E., Toronto University, who was also assistant engineer and secretary since the death of Lieut. Selfridge. Mr. McCurdy made over three hundred successful flights, averaging nearly nine miles each and covering in the neighborhood of three thousand miles. These flights were made over the ice in Baddeck Bay, Nova Scotia, in his machine the *Silver Dart*, built by the association. The other member of this association was Lieut. Thomas E. Selfridge, military expert in aeronautics detailed by the United States government to observe the experiments of the association, in the interest of the United States Army and acting as secretary of the association. Lieut. Selfridge was killed September 17, 1908, in the accident to Orville Wright's flying machine at Fort Myer, Va., near Washington, D. C. This is the first and only serious accident recorded in the recent* work of aviation, and of many thousands of flights in public in heavier-than-air machines there are only six recorded fatal accidents.

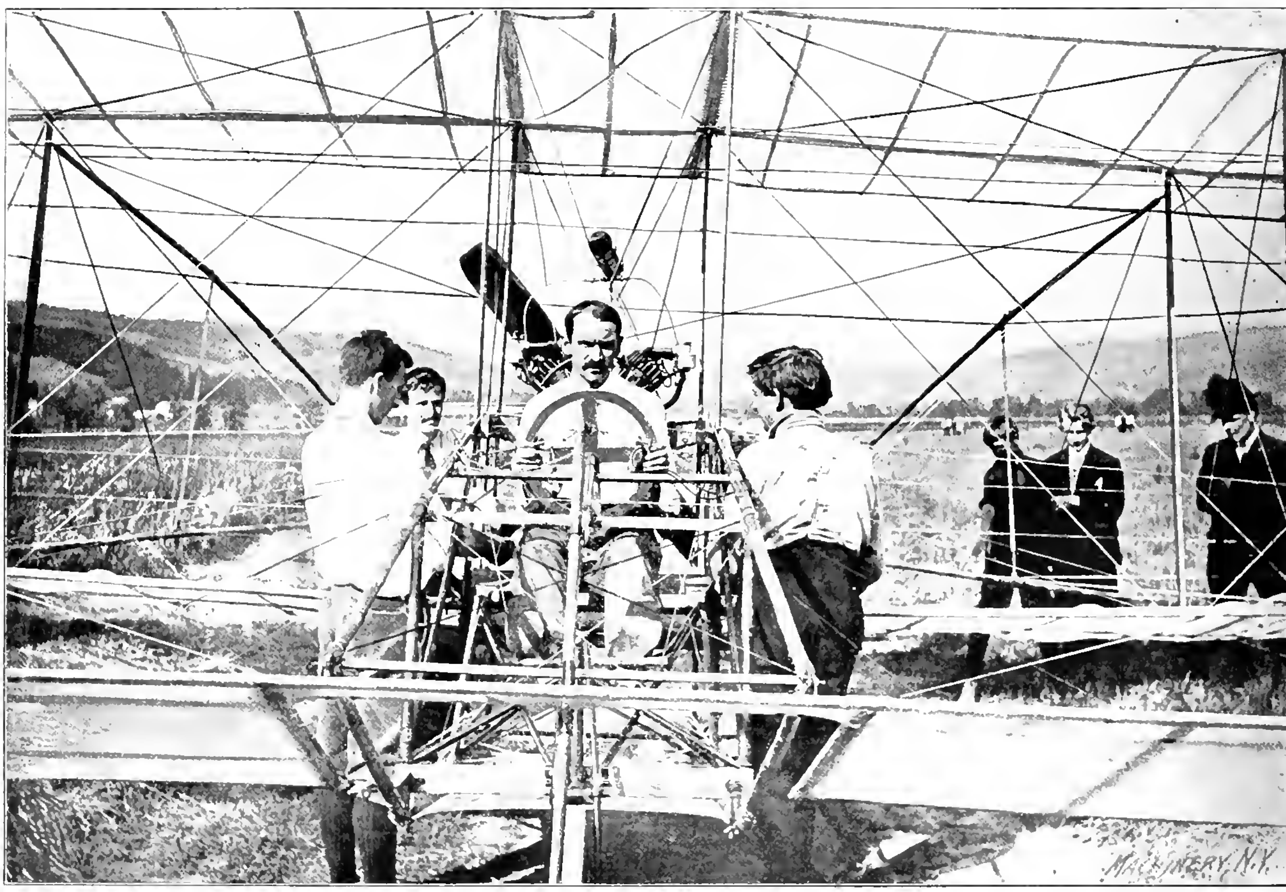

Fig. 1. Glenn H. Curtiss in the "June Bug," Ready for Flight

The third machine built by the association was the *June Bug* and on July 4, 1908, with it Mr. Curtiss contested for and won the *Scientific American* trophy, offered to the first machine heavier than air to fly one kilometer in a straight line. In this contest he made a record of 1¼ mile in 1 minute 42 2/5 seconds.

Three more machines were built, including the machine which one year later made a second record for the *Scientific American* trophy, July 17, 1909, flying 24.7 miles in 52 minutes

See article, "Aeroplane-Type Flying Machines," December, 1908

* Since this article was written S. Lefebvre was killed at Juvisy-sur-Orge, France, September 7.

30 seconds, and the machine in which, representing the Aero Club of America, Curtiss won the Gordon Bennett International Aviation Cup at Rheims, August 28, 1909, flying 20 kilometers (12.42 miles) in 15 minutes 50 3/5 seconds, a speed of 47 miles an hour, bringing this famous cup and contest to America where the race for it will be held next year. Mr. Curtiss also won, during the "Aviation Week at Rheims," the Prix de la Vitesse by flying over a course of 30 kilometers in length, in 23 minutes 29 seconds, surpassing the best records of the foremost aviators in the world.

A description of the machine with which Mr. Curtiss accomplished these wonderful results will be interesting:

The Herring-Curtiss No. 1, as it is now called, is a biplane with front control, rear control, side control or wing tips, starting and landing wheels, and motor. The main surfaces are 28 feet 9 inches by 4 feet 6 inches, one superimposed upon the other and separated by vertical struts, 4 feet 6 inches being the distance between the two planes. These planes are

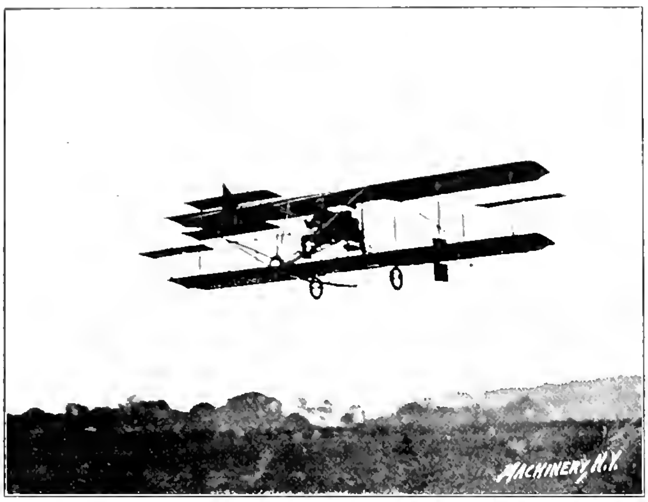

Fig. 2. The "Gold Bug" in Flight

covered with Baldwin rubber-silk material and the total area is about 258 square feet. There are twenty-two ribs used in the surfaces made of spruce and ash laminated and formed to a curve; they are spaced 15 inches apart and the covering material is laid over them and fastened by a strip of featherbone, laid on the upper side of the material and tacked to the ribs. The angle of these surfaces to the direction of motion is between 4 and 5 degrees when flying. The front control consists of two surfaces each 6 feet wide and 2 feet deep and 2 feet apart and placed about 12 feet in front of the main planes. This whole structure, like a box-kite, is pivoted ten inches back from its front edge upon the frame-work which extends in front of the machine; a rod is connected to the upper part of this control and extends to the steering wheel which can be moved forward or back, thus turning the

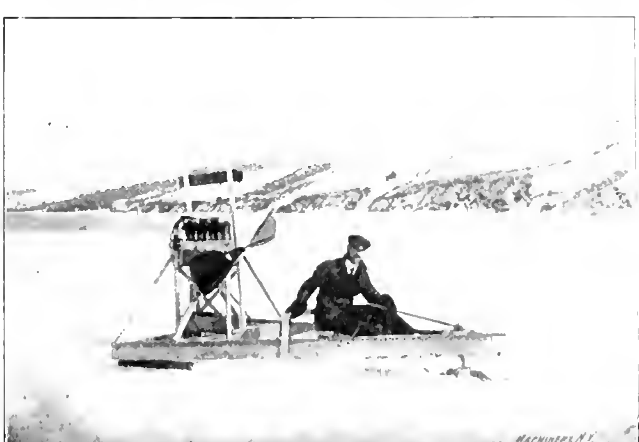

Fig. 3 Glenn H Curtiss on a Motor-driven Ice Boat, on Lake Keuka, near Hammondsport, N. Y

front control or rudder on its axis making the surfaces point up or down. This tends to raise or lower the front of the machine as, according to its positive or negative inclination, the wind blows against the upper or under side of this front rudder. The rear control consists of a horizontal surface or tail 2 feet 3 inches by 6 feet at the extremity of the framework, about 12 feet in the rear of the main planes, about the same distance to the rear that the front control is ahead of the

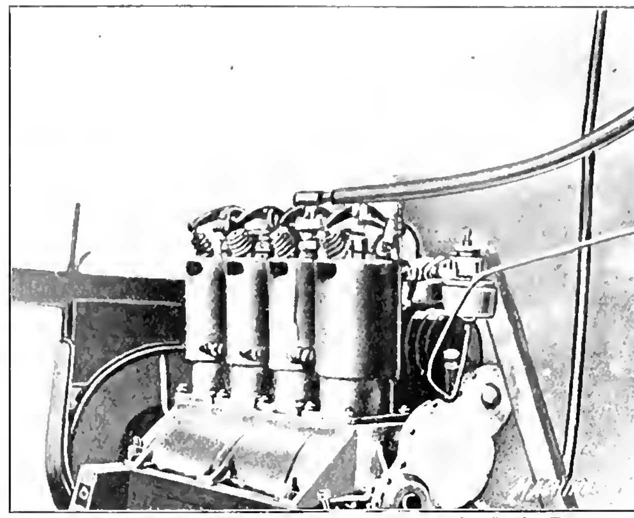

Fig. 4 A Four-cylinder Aeroplane Motor under Brake Test

machine. There is also a vertical rudder 2 feet by 3 feet 4 inches, pivoted 8 inches back from its front edge which is connected by wires to the steering wheel which turns and steers the aeroplane in the horizontal plane in the same manner that a rudder steers a boat in the water.

The side control or wing tips which govern the balancing are perhaps the simplest form of apparatus for accomplish-

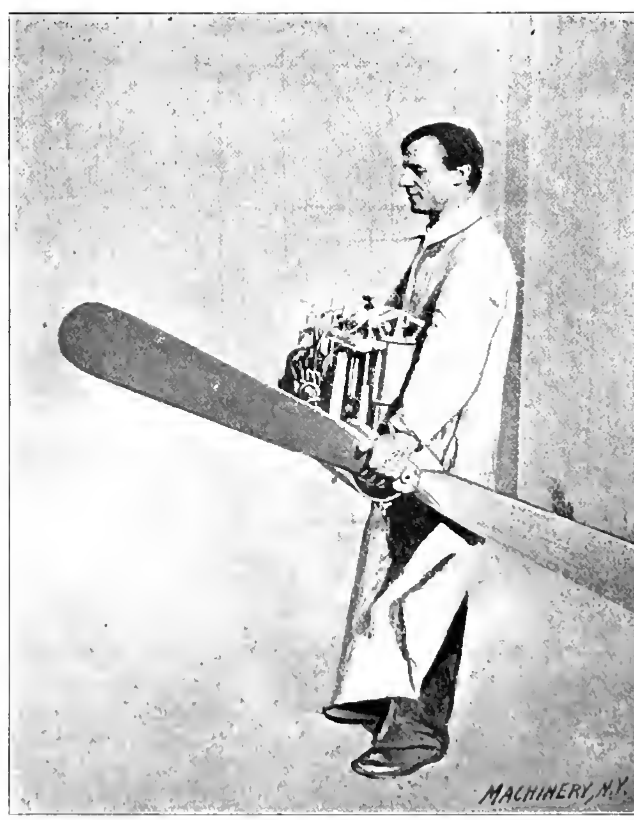

Fig. 5. G. von Rattweiler, Designer of the first Three Curtiss Motors, holding a Four-cylinder Motor and Propeller in his Hands

ing this most essential feature and one that has baffled inventors of flying machines more than any other one point. These small surfaces are placed between the main planes at their outer extremity and are 6 feet wide and 2 feet deep. They are hinged at their front edge and both are connected to a pivoted lever in the center of the machine which has a yoke or fork extending on each side of the operator's shoulders in such a manner that when he leans to one side or the other this movement will cause the side planes to act in unison, one, however, pointing down as the other points up. If the machine tips so that the right-hand side is lower than the other, the operator naturally leans to the left or highest side. This movement causes his shoulder to press against

the lever, thereby moving it to the left, and by means of the wires which extend to the planes the right-hand plane is turned to a lifting angle and the left-hand plane to the contrary or a depressing angle in such a manner that the wind will blow against the under side of the right-hand plane and against the upper side of the left-hand plane, thus forming a "couple" tending to right the machine.

The materials of which the machine is constructed consist of Oregon spruce, which is used in the main frame-work, and bamboo which is used in the frame-work supporting the forward and rear controls; steel wire is used for the main bracing and a fine strand wire cable for other bracing and to operate the rudders and controlling planes. The structure for mounting the three 20-inch pneumatic tire wire wheels upon which the machine runs when starting and alighting is made of steel tubing and wood. These wheels are provided with extra wide hubs in order to enable them to withstand any severe lateral strain in landing, and a long skid or reach bar of wood extends from the center of the axle of the two rear wheels, which are directly under the lower main supporting plane, to the single front wheel from which wooden braces extend directly to the engine bed and the upper plane to take up the shock of landing.

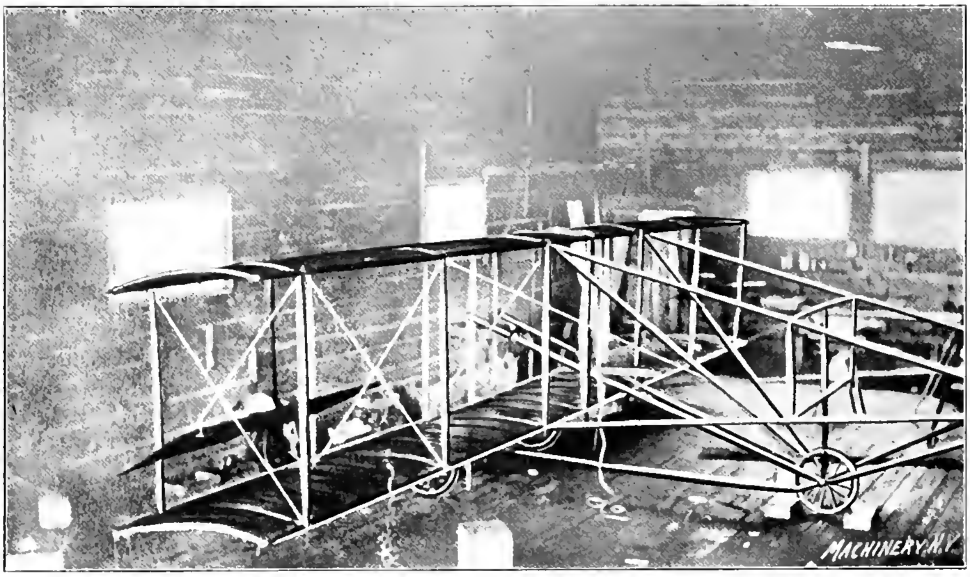

Fig. 6. The "Gold Bug" in Curtiss' Shop at Hammondsport, N. Y.

The operator's seat is just in front of the motor and in the center of the main planes, slightly toward the front of the central panel. The steering wheel is directly in front of him, which he pushes away from him to go down and pulls back to go up, and turns to the right or left to steer in the horizontal plane. At his right foot which rests on a cross-bar is a pedal operating a brake on the front wheel used to bring the machine more quickly to a standstill after landing, and at the same time operating a switch to cut off the motor. The left foot has a small pedal operating the throttle and governing the speed of the engine.

The Curtiss motor is perhaps as important, if not more important, than any other part of the aeroplane. Very few flying machine builders build their own motors, and many were delayed or kept from success by the lack of a good motor. The Wright brothers built a flying machine and then built their motor, while Mr. Curtiss had developed his motor to a state approaching perfection and then built his flying machine.

The motor ordinarily used is a four-cylinder, four-stroke cycle engine, water-cooled by geared pump, with gray iron cylinders 3 7/8 by 4 1/8 with steel water jackets, giving 28 horsepower at 1,450 revolutions per minute on a water-cooled brake test of six hours continuous running. The compression is high, being about 92 pounds. The lubrication is by high pressure oil system, the pump being built in the crank-case and operated from the cam-shaft, the oil being forced through the cam-shaft which is made of one piece with a 5/16 hole. The oil passes to the main bearings which are plain and to the hollow crank-shaft, 1 7/8 inch diameter, which is made of Krupp chrome nickel steel. The oil returns to a reservoir underneath the engine and is pumped over again through the system. The ignition is by Simms-Bosch high-tension magneto. "Mercedes" spark plugs are used, and a Curtiss carbureter. The valves, both in the head of the cylinder, are mechanically operated, very ingeniously, by a rocker arm and a single push rod and cam. The crank-case is of aluminum alloy, also the pistons and connecting-rods. The weight of the engine complete with propeller, carbureter and magneto is about 92 pounds. The propeller is made of wood 5 feet 4 inches in diameter with a five-foot pitch and gives a thrust of 225 pounds pulling against a scale.

The total weight of the machine with operator is about 550 pounds and the complete power plant, including radiator, water and oil, weighs about 195 pounds.

The machine used in Rheims were fitted with an eight-cylinder motor, with cylinders 4 by 4.5 inches placed together like the letter V. It is practically two of the four-cylinder motors put together, weighs, complete, about 200 ponuds, and develops about 60 H.P. A large thirteen-gallon and a small three-gallon fuel tank were fitted for the long races and the speed tests respectively. Fifteen inches of surface were taken off each main plane, and the side controls were arched and placed a little further out at the extremities. The propeller gave a thrust of 280 pounds, and the total weight of the whole machine loaded was about 700 pounds. Mr. Curtiss also made some changes in his propeller at Rheims to get the highest efficiency out of his machine, for the relation of speed of the machine, speed of the motor, and size and pitch of the propeller is very important. A. P.

* * *

Many hospitals in England, says the *Scientific American*, are provided with a special apparatus for extracting iron and steel chips from the eye by means of powerful electro magnets. The magnet employed has a core three feet long and six inches in diameter of the best Swedish soft iron. Two hundred pounds of insulated wire are wound in two coils about the core. The end of the magnet is threaded to receive terminals of different shapes to suit various conditions. The magnet is mounted on ball bearings, and can be moved in any direction. The strength of the magnetic field may be varied at will by means of a rheostat. When used at its maximum power, the magnet exerts a pull of 30 pounds per square inch at a distance of an inch. A special type of apparatus is provided for reclining patients; in this case the magnet is mounted on trunnions, and is tilted by means of suitable gearing operated by a hand crank.

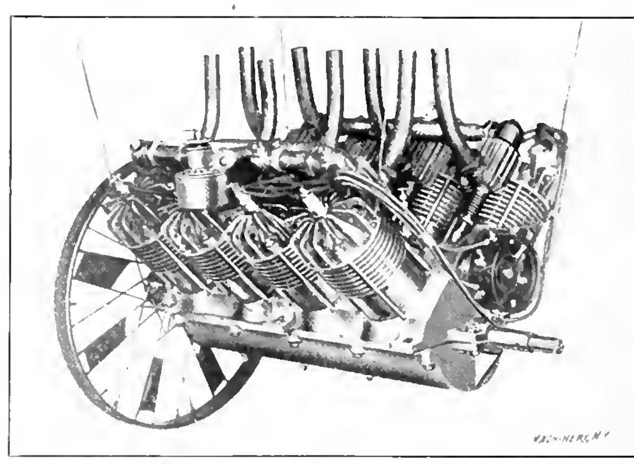

Fig 7. Forty Horse-power Eight-cylinder, Air-cooled, Curtiss Motor, weighing 145 pounds

BEGINNING OF STEAM NAVIGATION*

Robert Fulton

The one-hundredth anniversary of the successful application of steam to the propulsion of ships by Robert Fulton, and the three-hundredth anniversary of the exploration by Henry Hudson of the river that bears his name, is now being commemorated by a great celebration given by the state of New York. This dual celebration, which is under the auspices of the Hudson-Fulton Commission, began on September 25 and will continue until October 9. It will doubtless surpass, in magnitude and grandeur, anything which has been held on this side of the Atlantic, as every detail which would contribute to its success has been carefully planned and a vast sum of money, roughly estimated at one million dollars, has been expended. As far as possible, exact replicas of Hudson's vessel, the *Half Moon*, and Fulton's historic *Clermont* with which he demonstrated the practicability of the steamboat, have been built. These quaint craft will, in connection with a great naval parade, be convoyed on October 1st by a fleet of American and foreign men-of-war, up the Hudson.

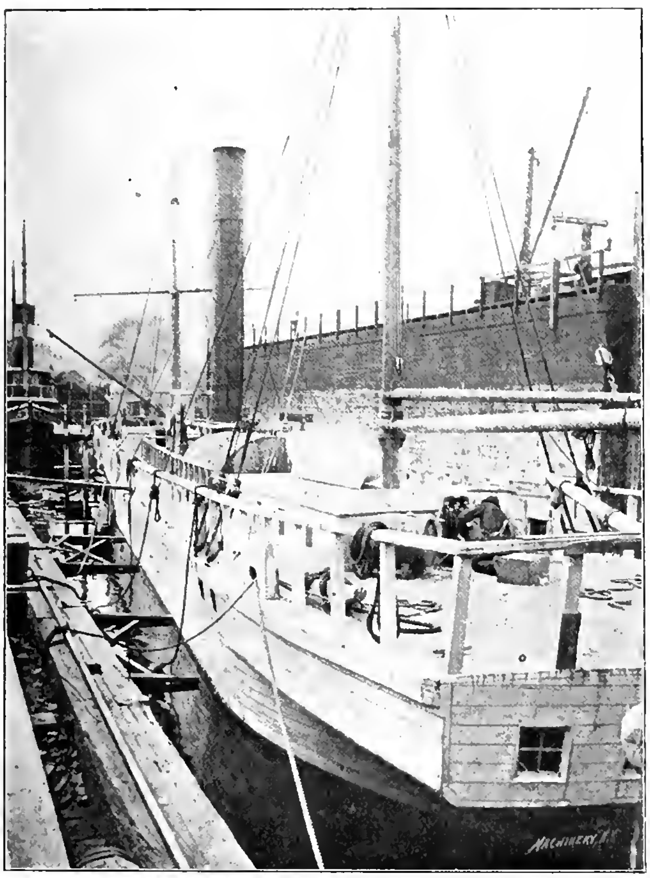

Fig. 1. The Replica of the Clermont

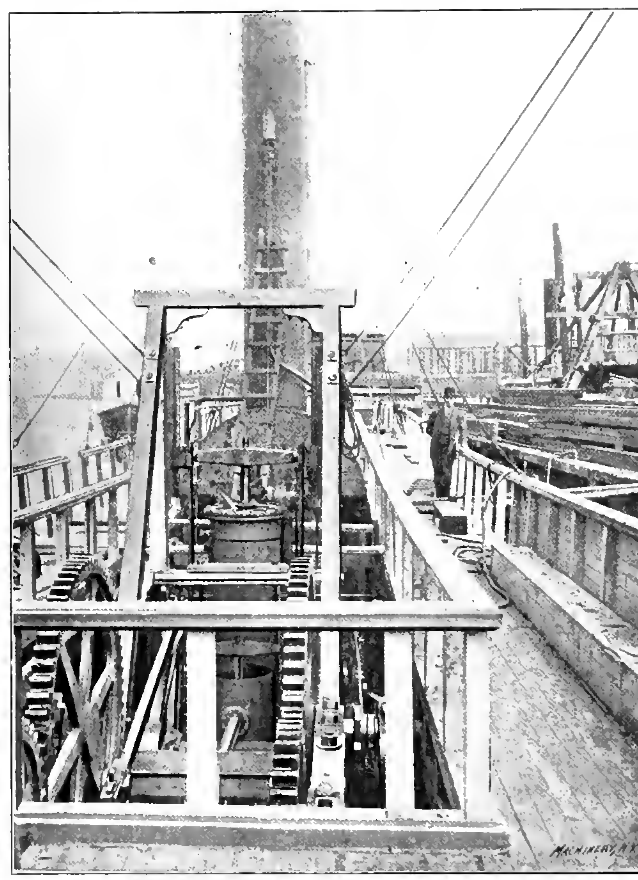

Fig. 2. View of the Engine after Installation

As is well known, Robert Fulton was not the first man to build a steamboat, a number of other boats using steam having preceded the *Clermont*; but if we may judge from descriptions and models of some of these, their priority detracts but little from Fulton's achievement, as he constructed the first boat that was a commercial success. Nevertheless, much that Fulton accomplished was undoubtedly due to the ideas he obtained from those whose experiments antedated the construction of the *Clermont*. James Rumsey began experimenting as early as 1785, and a year later John Fitch is said to have constructed the first steam-propelled craft which met with any degree of success in America. It was a most clumsy contrivance, however, being propelled by gangs of oars arranged in a frame-work at the sides. The second American steamboat was run by Fitch on the Delaware at Philadelphia in 1787. In the same year Rumsey is said to have built the third boat which operated on the Potomac. The propulsion of this novel craft was accomplished by sucking in water at the bow and expelling it at the stern—a method which has been tried in recent times, but without success. In the two following years Fitch built two other steamboats, after which Samuel Morey built a stern-wheeler, which made a trip from Hartford to New York. Fitch, who had been conducting his experiments on the Delaware at Philadelphia, came to New York where he operated the seventh American steamboat on the old Collect Pond, a small body of water which then existed where the City Prison and Criminal Courts Building now stand. This boat was propelled both by paddle wheels at the side and a screw propeller. The construction of the mechanism was exceedingly crude and primitive, the boiler being made from a ten-gallon iron kettle, which was closed by a heavy plank lid. The factor of safety was probably a most uncertain quantity.

John Stevens began his work in steam navigation in 1791. In 1798, a steam-propelled vessel was tried on the Passaic River. The New York Legislature was petitioned by Stevens for a monopoly of steam navigation, but the petition was not granted. In 1804 a 68-foot boat, 14 feet wide, fitted with a single-screw propeller, was built by Stevens and in 1805 a twin-screw boat was launched on the North River. The machinery of this boat was afterward placed in a larger boat, the *Phœnix*, which was 103 feet 3 inches long, 16 feet wide, and 6 feet 9 inches deep. While the launching of the *Phœnix* occurred after that of the *Clermont*, if one may judge from models, the lines of Steven's craft were much superior to those of the *Clermont*. The engine also shows greater simplicity. In the spring of 1809, the *Phœnix* made a number of trips between New York and New Brunswick, a distance of 37 miles, in $9\frac{1}{2}$ hours including stops, but perhaps owing to the fact that the nearly completed *Raritan* (Fulton's second boat) was intended for operation over this course, it was decided to sail the *Phœnix* to the Delaware River by way of the Atlantic. She left New York on June 8, 1809, arriving at Philadelphia on June 17. Thus was accomplished the first sea voyage of a steam-propelled vessel. The *Phœnix* ran as a passenger boat on the Delaware, stopping at Philadelphia,

* For additional information on this subject, see the article on "Early Steam Navigation," published in the May, 1902, number of MACHINERY.

Bordentown, and Trenton where connection was made with stages across New Jersey to New Brunswick, one of the terminals of the *Raritan*. After running for a number of years over this route the *Phoenix* was wrecked at Trenton in 1814.

The original *Clermont* was built at Charles Brown's shipyard near Corlear's Hook, New York. According to a letter written by Fulton to James Watt, she was 175 feet long, had a beam of 12 feet, and a depth of 8 feet. After making four trips the length was reduced to 150 feet and the width increased to 18 feet. The hull was flat bottom, and wedge shaped at both the bow and stern. The sides were nearly vertical, the width across the main deck being only a little more than at the bottom. As there was no keel, two steering-boards or leeboards were provided to prevent drifting sideways. The propulsion was by paddle wheels, 15 feet in diameter, which were placed well forward. These were driven by a single-cylinder condensing engine of the side-lever type, which was imported from England, as the facilities in this country at that time for engine building or similar work were very poor. This engine with its driving mechanism was located amidships, and was uncovered. An idea of its construction may be obtained by referring to Fig. 3 which shows an elevation and plan of the engine built for the new *Clermont*. Fig. 2 shows the appearance of the engine after installation. The cylinder, which was designed for a working pressure of 20 pounds, is mounted vertically on a cylindrical condenser, which is connected to the air pump by a channel-way of cast iron, which forms the bed-plate of the engine. The valves, which are of the single poppet type, are located in cylindrical steam chests arranged at each end of the cylinder. The valve gear of the first *Clermont* required four men to start the engine. It was afterwards changed to the Stevens type, the fundamental principles of which are seen in the engines of the modern river boats. The diameter of the cylinder is 24 inches, and the length of stroke 4 feet. The fly-wheels are located outside of the hull, and are driven from the paddle-shafts on either side by two-to-one gearing. This gearing is of cast iron, and machine molded. The fly-wheels are also cast iron and have a rim section of 4 x 4 inches. It is said that upon one occasion when one of the paddle-wheels was disabled, paddles were attached to the fly-wheel and the voyage continued. The side-levers, which are connected with the cross-head and paddle-shaft cranks, are counterweighted as shown, to balance the weight of the piston-rod, crank, air-pump gear, etc. The air pump is single-acting and is connected with the side-levers by links. From the cross-head of the air pump the feed and bilge pumps are driven.

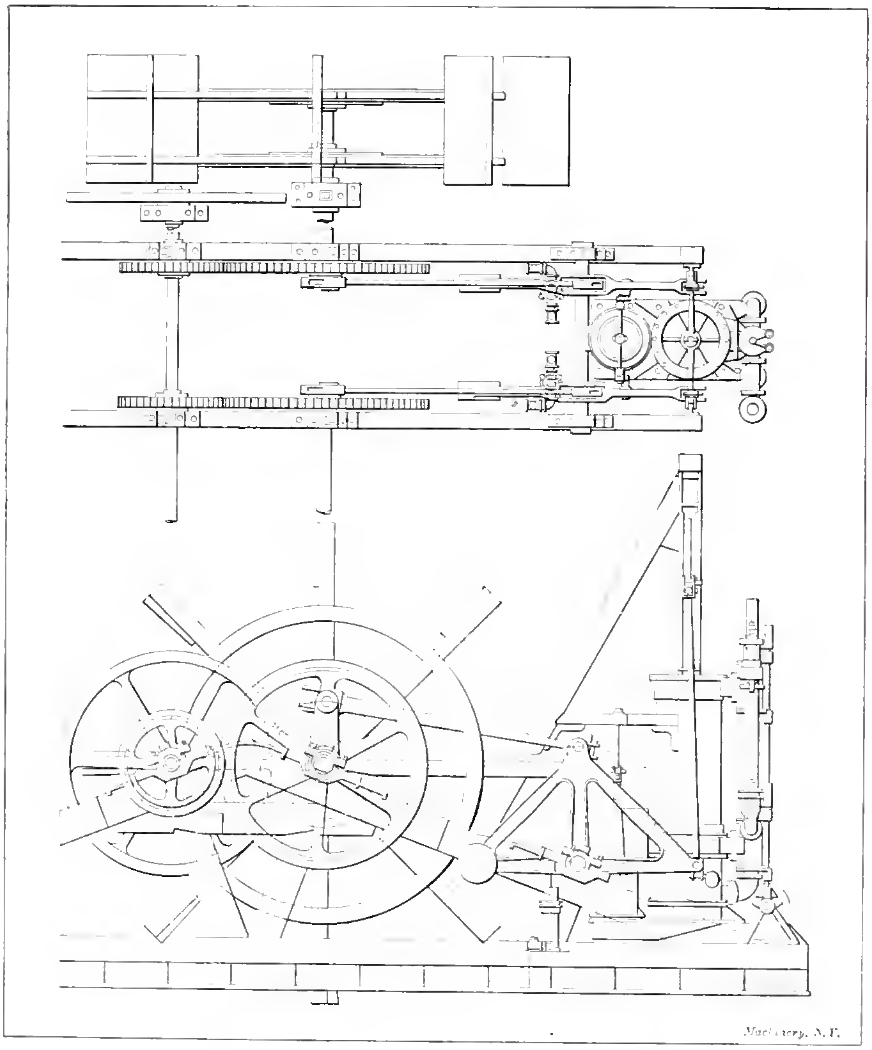

Fig. 3. Plan and Elevation of the Engine which was built for the new Clermont

The boiler of the original *Clermont* was of copper, but no attempt at an exact reproduction of this part has been made, as such a boiler would not pass the United States inspection laws. With this single exception, however, the new *Clermont* is said to be an accurate reproduction of the original. The problem of constructing such a boat was exceedingly difficult, for while drawings of the engine were in existence there was no contemporary picture of the hull. After a careful and painstaking investigation on the part of her architects, the firm of J. W. Millard & Bro. in conjunction with Mr. Frank E. Kirby, consulting engineer, sufficient data were obtained to accomplish the desired result.

The famous voyage of the original *Clermont* from New York to Albany began on August 17, 1807. The start was made from a point near the square, which is now bounded by Washington, West Tenth, West and Charles Streets. Leaving New York at one o'clock in the afternoon, the *Clermont* arrived at the estate of Chancellor Livingston, at 10 o'clock on Tuesday, having traveled 110 miles in 24 hours at an average speed of 4.6 miles per hour. On the remaining 40 miles of the journey to Albany, this speed was increased to 5 miles per hour, making 32 hours the total time for the trip. The next day the return journey began, and just 30 hours afterward the maiden voyage was ended.

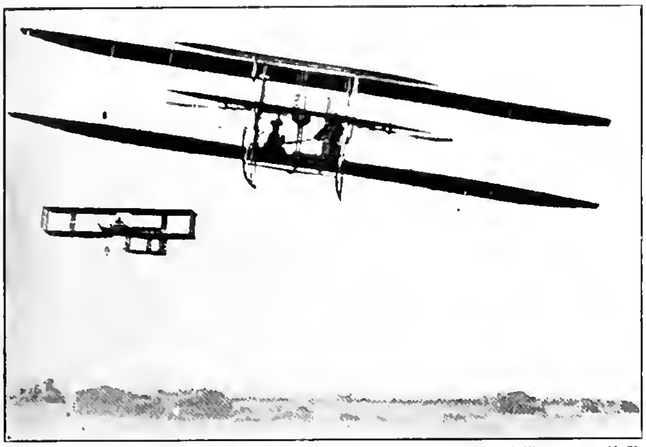
On returning from the first trip, the *Clermont* underwent some improvements to better fit her for regular passenger traffic. At the end of this time the following rates to various points from New York were advertised: Newburgh, $3, time 14 hours; Poughkeepsie, $4, time 17 hours; Esopus, $4.50, time 20 hours;; Hudson, $5, time 30 hours; Albany, $7, times 36 hours. Under favorable conditions trips were made to Albany in 28 hours, at a rate of 6 miles an hour. At times as many as 100 passengers were carried. These trips were continued until late in the fall of 1807, and the service was resumed in the spring of 1808. In writing to Livingston of the financial return from passenger traffic, Fulton says: "By carrying for the usual price there can be no doubt but the steamboat will have the preference because of the certainty and agreeable movement. I have seen the captain of a fine sloop on the Hudson. He says the average of his passages has been 48 hours. For the steamboat it would have been 30 hours certain. The persons who came down with me were so pleased that they said were she established to run periodically they would never go in anything else."

The construction of the *Clermont* did not mark the beginning nor the end of Fulton's achievements, for both prior and subsequent to the advent of this famous craft, his genius expressed itself in valuable pioneer work with submarine boats, torpedoes, inland canals, and in other directions in the realm of mechanics and marine construction; and, through the efforts of this early inventor, much was accomplished toward laying the foundation of our present nautical development.

AVIATION RECORDS AT RHEIMS

A. P.

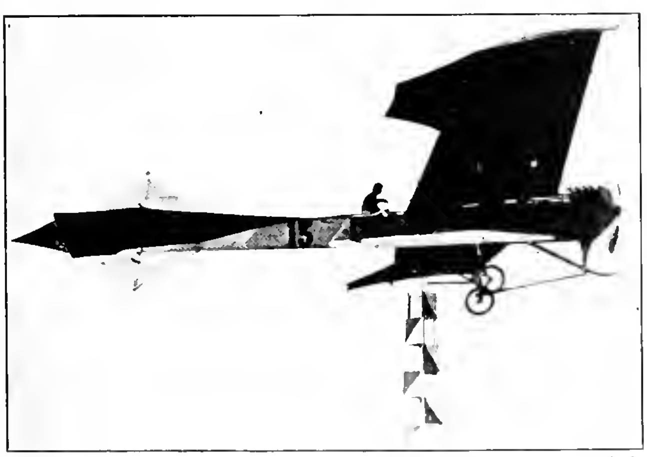
The international meet of flying machines or "Aviation Week," at Rheims, France, in the latter part of August, was the most notable event in the history of aviation. America was ably represented by Mr. Glenn H. Curtiss, who won the Gordon-Bennett International Aviation Cup, on August 28. He represented the Aero Club of America, with a machine of his own make, and defeated one representative of England using a French machine, and three representatives of the Aero Club of France. Mr. Curtiss flew 20 kilometers (12.42 miles) in 15 minutes 53 3/5 seconds, his speed being about 47 miles an hour. His nearest rival was M. Louis Bleriot who made the course in 15 minutes, 56 1/5 seconds, while Mr. Latham got third place, his time being 17 minutes, 32 seconds. M. Lefebvre made fourth place, his time being 20 minutes, 47 seconds. Each contestant was allowed only one trial. The prize was a trophy valued at 12,500 francs ($2,500), which goes to the club of which the contestant was a representative, and a cash prize of 25,000 francs ($5,000) to the winner.



Paul Thompson, N. Y.

Fig. 1. The Wright Machine at Rheims followed by Paulhan. Two Machines caught by the Photographer in the Same View

The Gordon-Bennett contest was the culmination of the most intensely interesting sporting event ever held in the history of the world, and was epoch-making in the annals of mechanical flight. The contest revealed a new field of sport and pleasure heretofore absolutely unknown except to scientists and inventors.



Paul Thompson, N. Y.

Fig. 2. Bleriot rounding Turn at Rheims. View taken from Paulhan's Machine

Curtiss also won the Prix de la Vitesse of 20,000 francs ($4,000), making 30 kilometers (18.63 miles) in 25 minutes, 29 3/5 seconds with the penalization of one-tenth. Bleriot won the prize for the fastest time for one round of the course, 10 kilometers (6.21 miles) in 7 minutes, 47 seconds. Henry Farman won the Grand Prix de Champagne, 50,000 francs ($10,000) by a world's record flight of 180 kilometers (111.98 miles) in 3 hours, 4 minutes, 56 seconds. He flew after the official hour for the timers to leave, 7:30 o'clock, until he had covered 190 kilometers, the time being 3 hours, 15 minutes. The excess distance, however, is not a part of the official record. Mr. Farman also won the passenger carrying contest, carrying two passengers 10 kilometers (6.21 miles) in 9 minutes, 52 seconds. Herbert Latham won the Prix de l'altitude, 10,000 francs ($2,000), reaching a height of 155 meters or over 500 feet.

There were six principal types of machines used, the Wright and the Curtiss biplanes (American), and the French biplanes of Farman and Voisin, and the monoplanes of Latham (Antoinette) and Bleriot. It is estimated there were altogether 1,300 flights made during the aviation week. The following is a tabulated record of the principal events, competitors, and time:

GRAND PRIX DE CHAMPAGNE

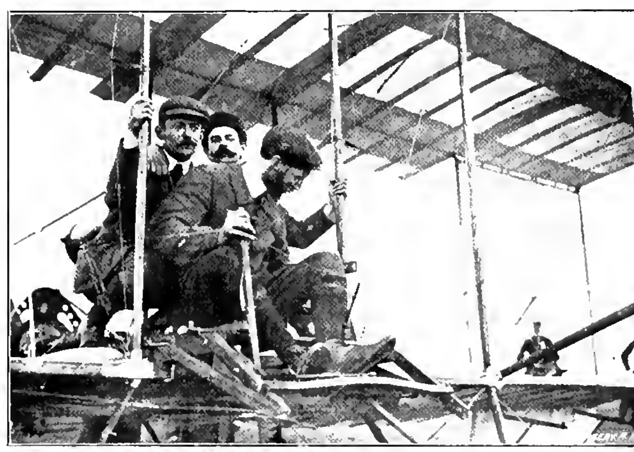
(Long Distance Test)

	Competitor	Machine	Kilometers	Time	Prize, Francs
1.	Farman	Farman	180	3h. 4 m. 56s.	50,000
2.	Latham	Antoinette	154½	2h. 1 m. 19s.	25,000
3.	Paulhan	Voisin	131	2h. 43m. 24s.	10,000
4.	De Lambert	Wright	116	1h. 52m.	5,000
5.	Latham	Antoinette	111	1h. 38m. 15s.	5,000
6.	Tissander	Wright	110	1h. 46m. 52s.	5,000

PRIX DE LA VITESSE, 30 KILOMETERS

(Three Lap Speed Test)

	Competitor	Machine	Time	Prize, Francs
1.	Curtiss	Curtiss	23m. 29s.	10,000
2.	Latham	Antoinette	25m. 18s.	5,000
3.	Tissander	Wright	28m. 59s.	3,000
4.	Lefebvre	Wright	29m.	2,000



Paul Thompson, N. Y.

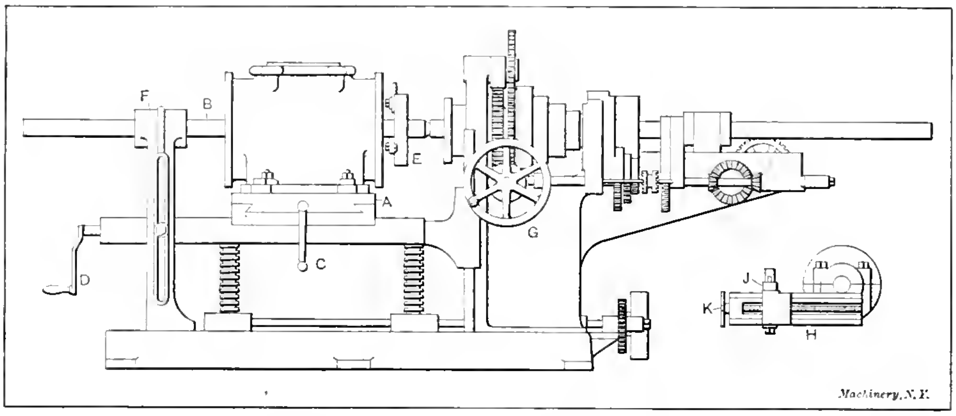
A centennial exposition and world's fair will be held in Winnipeg, Manitoba, in 1912, according to a report by Vice-Consul-General Carl R. Loop.

* The following notes and articles giving records obtained with aeroplanes and airships have previously been published in MACHINERY: Delagrange record, August, 1908; Zeppelin, August, 1908, engineering edition; various aeronautic records, October, 1908, engineering edition; miscellaneous records mentioned in an article entitled "Aeroplane-Type Flying Machine," December, 1908, engineering edition; Wilbur Wright's record, March, 1909; Bleriot's flight across the English Channel, August, 1909.

MACHINE SHOP PRACTICE*

BORING CYLINDERS

The type of machine tool used for boring cylinders, and also the method of procedure is determined largely by the size of the work and the quantity which is to be machined. The lathe of both the plain and turret types, as well as horizontal and vertical boring mills are used for this work, and in automobile factories or other shops where a great many cylinders are bored, special machines are often employed. When a common lathe is used, the casting, providing it is too large to be bolted to the face-plate or held in the chuck, is clamped to the lathe carriage, with sufficient blocking beneath it to bring the rough bore in alignment with the lathe spindle. A boring-bar equipped with one or more cutters centrally located, is mounted between the lathe centers and driven by a dog. As the cutters revolve, the work is fed against them by the regular carriage feed. As the boring-bar is the only special tool needed when the work is done in the lathe, cylinders are often bored in this way in shops which do not have a boring machine. If cylinders are to be bored in quantity by this method, a special fixture should be provided for holding them upon the carriage, which is so designed that clamping and adjusting may be quickly done.



Horizontal Boring and Drilling Machine

The Shop Operation Sheet accompanying this number gives an example of small cylinder boring in the turret lathe; the cylinder being of the type used for gasoline engines. By referring to the illustrations and descriptions, it will be seen that the turret, which is, practically speaking, a large tool holder, is equipped with boring tools for both roughing and finishing cuts; also a reamer for finishing the cylinders to size. As these tools may be brought into position as needed by simply revolving the turret, it is possible with such a machine to do work with considerable rapidity.

The accompanying engraving shows the general construction of a common type of horizontal boring and drilling machine, and also the way a cylinder is set up for boring. The table *A* to which the cylinder is clamped, has a horizontal adjustment, both lengthwise and crosswise of the bed, and also a vertical adjustment so that the cylinder to be bored can easily and quickly be set in alignment with the boring-bar *B*. The horizontal adjustments are effected by the handles *C* and *D*, while the table is raised and lowered by power. The boring-bar is supported and kept in alignment with the spindle by an outboard bearing *F*, through which it slides as the cutters in the boring head *E* are fed through the work. This longitudinal movement of the bar is controlled by a feed mechanism which permits the amount of feed per revolution to be varied. Provision is also made for the rapid adjustment of the bar in or out by the hand-wheel *G*. Facing arms *H* may be attached to the bar on either side of the cylinder for facing the flanges after the boring operation. The turning tool is fastened to the slide *J* which is fed outward a short distance each time the star-wheel *K* is caused to turn by a stationary pin against which it strikes.

When setting a cylinder which is to be bored it should, when the design will permit, be set true by the outside of the flange, or what is even better, by the outside of the cylinder itself, rather than by the rough bore, in order that the walls of the finished cylinder will have a uniform thickness. The last or finishing cut, should invariably be a continuous one, for if the machine is stopped, even for a short time, there will be a ridge in the bore at the point where the tool temporarily left off cutting. This ridge is caused by the cooling and the resulting contraction and shortening of the tool during the time that it is stationary. For this reason, independent drives for boring machines are desirable. The position of large cylinders while they are being bored is an important consideration, the disregard of which has often caused trouble. Such cylinders should be bored in the position which they will subsequently occupy when assembled. For example, the cylinder of a horizontal engine should be bored while in a horizontal position, as the bore is liable to spring to an oval shape when the cylinder is placed horizontal after being bored while standing in a vertical position. If, however, the cylinder is bored while in the position in which it will be placed in the assembled machine, this trouble is practically eliminated.

There is a difference of opinion among machinists as to the proper shape of the cutting point of a boring tool for finishing cuts, some contending that a wide cutting edge is to be preferred, while others advocate the use of a comparatively narrow edge with a reduced feed. It is claimed that the narrow tool produces a more perfect bore, as it is not so easily affected by hard spots in the iron, and it is also pointed out that the minute ridges left by the narrow tool are an advantage rather than a disadvantage, as they form pockets for oil and aid in the matter of lubrication. It is the modern practice, however, to use a broad tool and a coarse feed for the finishing cut which is, of course, always right. When boring with machines which are equipped with bars not sufficiently rigid, the tool face will have to be made narrower than would otherwise be necessary, to avoid chattering.

FULTON EXHIBIT, ENGINEERING SOCIETIES BUILDING

The Hudson-Fulton celebration is essentially a recognition of the explorer and the engineer. To show the relation of the latter to the celebration, models of the *Clermont* and other early steamboats, through the courtesy of the Smithsonian Institution, are now on exhibition at the rooms of The American Society of Mechanical Engineers in the Engineering Societies Building, 29 West 39th St. The exhibit includes the *Clermont*; the *Phoenix*, built by John Stevens; and one of John Fitch's early types. Original drawings by Fulton, an oil portrait of Fulton painted by himself, Fulton's dining table, oil portraits and a bronze bust of John Ericsson, models of the *Monitor*, all owned by the society, and Ericsson's personal exhibit at the Centennial Exposition, are also exhibited. Through the courtesy of the Hamburg-American line, a beautiful model of the *Deutschland* shows the highest type of the development of steam navigation.

The model of the *Clermont* represents the boat as she was on her first trip before undergoing alterations to fit her for regular passenger service. The model of the *Phoenix* shows that boat at the time of making the first sea voyage ever made by a steam vessel. The trip was made in 1809, leaving New York on June 8 and arriving in Philadelphia on June 17. Fitch's boat was built in Philadelphia in 1786 and successfully tried on the Delaware River. In 1790 a similar boat carried passengers and freight on the Delaware River for several months.

The exhibition will be open to the public every week day from 9 a. m. to 5 p. m.

Further experiments in wireless telephony recently carried out in France proved it possible to exchange messages for several hours over a distance of 155 miles. It is proposed to extend the distance, due to the success already attained.

THE SPINNER VARIABLE SPEED INDUCTION MOTOR

On the occasion of the joint summer meeting of the Institution of Engineers and Shipbuilders and the Northeast Coast Engineers and Shipbuilders, in Scotland, the works of Messrs. Mavor & Coulson, Ltd., Glasgow, were opened and among the interesting novelties a three-speed 5 H.P. spinner motor was shown in operation illustrating the method of speed control for electric ship propulsion. The spinner motor, which is illustrated assembled and disassembled in Figs. 1 and 2, is an interesting example of the most recent development in the direction of variable speed induction motors. Although the spinner motor has been upon the market for some time, it is not so well known as more commonly used types, and a description of the machine exhibited, will undoubtedly be of general interest to our readers.

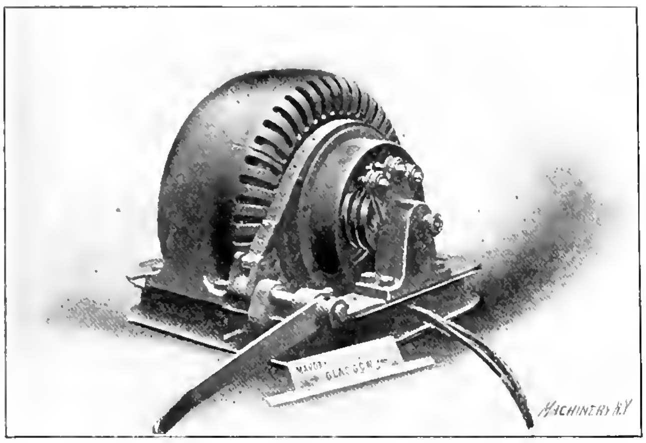

Fig. 1. Mavor & Coulson, Ltd., Variable Speed Induction Motor

There are two elements in the motor which may revolve, these being the ordinary rotor which is mounted on the main shaft, and the spinner. The spinner is cylindrical in form and fits between the annular space between the rotor and the stator. The spinner is carried on end brackets adapted to revolve freely upon extensions of the bearings of the main shaft. A brake wheel is provided on one of these end brackets over which is fitted a metal brake band whereby the spinner can be prevented from rotating when desired. On the outside periphery of the spinner there is a closed circuit or squirrel cage winding, and on the inner surface, next to the main driving motor, there is a winding like that on the stator. In order that the current may be supplied to this winding it obviously is necessary to connect the terminals through slip or collector rings. Both windings on the spinner are placed in slots in the usual manner.

It will be seen from the foregoing description that the machine consists of two motors concentrically arranged around the common axis. Starting from the outside and taking each part separately we first have the ordinary stator winding and then there is the closed circuit or squirrel cage winding on the spinner which together with the stator constitutes one motor. Next on the same spinner there is a winding which only differs from the stator winding in that it can revolve and that its ends are connected to slip rings. Lastly there is a squirrel cage motor mounted on the main shaft and revolving inside the spinner. The current is delivered from an outside source to the primary winding of the fixed stator and spinner respectively, passing in each case through a simple reversing switch.

To illustrate the action of the spinner motor it may be assumed that the primary winding on the spinner is wound so as to give four pairs of poles and that the stator proper of the other or outside motor is provided with eight pairs of poles. If, now, a brake is applied to the spinner and current at a periodicity of 25 cycles be supplied to the primary winding through the collector rings, the speed of the rotor and consequently the driving shaft (if we neglect the slip) will be 375 revolutions per minute. If the stator winding of the other motor with its eight poles be connected in circuit and the spinner simultaneously released, the latter can be made to revolve in the same direction as the main motor, or in a reverse direction. The direction is determined by the reverse switches. Now, since the outside stator has eight pairs of poles the synchronous speed of the spinner can be only 187.5 revolutions per minute, and it is evident that according to the direction of the rotation of the spinner this speed can be added to or subtracted from the 375 revolutions per minute of the rotor obtained when the spinner is held stationary. If, then, the switches are closed so that the spinner revolves in the same direction as the main motor the shaft speed becomes $375 + 187.5 = 562.5$ revolutions per minute. If the reversing switches are closed so as to cause the spinner to revolve in the opposite direction to the motor, then the lowest shaft speed is obtained, or $375 - 187.5 = 187.5$ revolutions per minute.

From the foregoing it is seen that this induction motor has three speeds which are obtained without the use of resistance

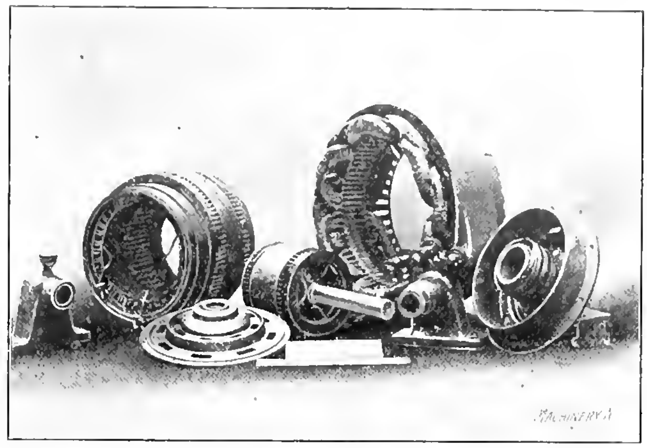

Fig. 2. Mavor & Coulson Variable Speed Induction Motor Disassembled

in the rotor circuit and without varying the periodicity of the main circuit, and without pole-changing in the ordinary sense.

Fig. 3 shows an interesting application of the spinner motor, wherein it is employed for starting purposes and not for speed regulation. By the use of the spinner, the motor may be started without the employment of resistances or an auto-transformer, and the load may be taken up gradually and without jerks, which is of great importance with colliery haulage gears, etc.

A simple switch is all that is required to manipulate. The rotor which is of the squirrel cage type is coupled to the

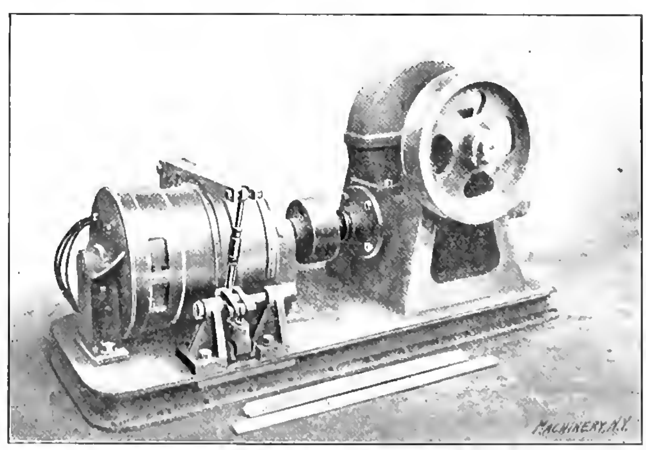

Fig 3. Application of One-speed Spinner Motor to Haulage Gear

driving shaft of the haulage gear. The spinner which encircles the rotor, and which is free to revolve when the brake is released carries a three-phase winding. The current is supplied to the collector rings of the spinner and at the moment when the gear is switched on, the hand brake is off so that the spinner is free to revolve. Now, if the spinner is free to revolve, it is evident that so long as the brake is off there is no tendency for the rotor to revolve, for in order to turn, it must exert a torque to overcome the load to which it is mechanically connected. If, however, the brake is applied so as to gradually stop the spinner, the rotor works up to speed and drives the haulage gear. This device may also be employed for reducing the speed of haulage when required.

DRAWING DIES FOR HOLLOW RIVETS

CHARLES WESLOW*

One day I stood in the doorway of a large factory "rubbering," when the boss came along and inquired of me if I wished to see anyone in particular. "No," I replied, "I am a toolmaker, and have just come from a neighboring shop looking for a job, and in passing I stopped to see what was going on in the building where I happened to learn my trade." "You learned your trade here?" he asked. I assured him that I did, but that I had been apprenticed to a concern which previously occupied the building, but which had since gone bankrupt. "Well!" he said, "if you are a toolmaker, I'd like you to come into the office." I went in with him, but under the impression that he probably knew of a place where I could get a job. Instead, he handed me a sample string of hollow rivets, such as those shown at *A* Fig. 1, which had just come from the die, and asked me if I thought they could be drawn out longer. An idea as to how this could be done instantly struck me, and as it would not be expensive, I was quite prompt in assuring him that the rivets could be lengthened without difficulty. He asked me if I would take the job fixing up the dies, or making new ones, and guarantee that the rivets would come a sixteenth of an inch longer. I told him that I would if it was worth while. He then asked me, with an air of incredulity, if I would do it on contract, and as I assented, he gladly agreed to pay me fifty dollars for the job, remarking that he had already spent about two hundred dollars on those dies, but to no avail. Before leaving to go home for my "kit" he remarked that all their "store" dies and presses gave pretty good satisfaction, except this gang die for rivets, the punch of which would break through before the work even reached the third operation.

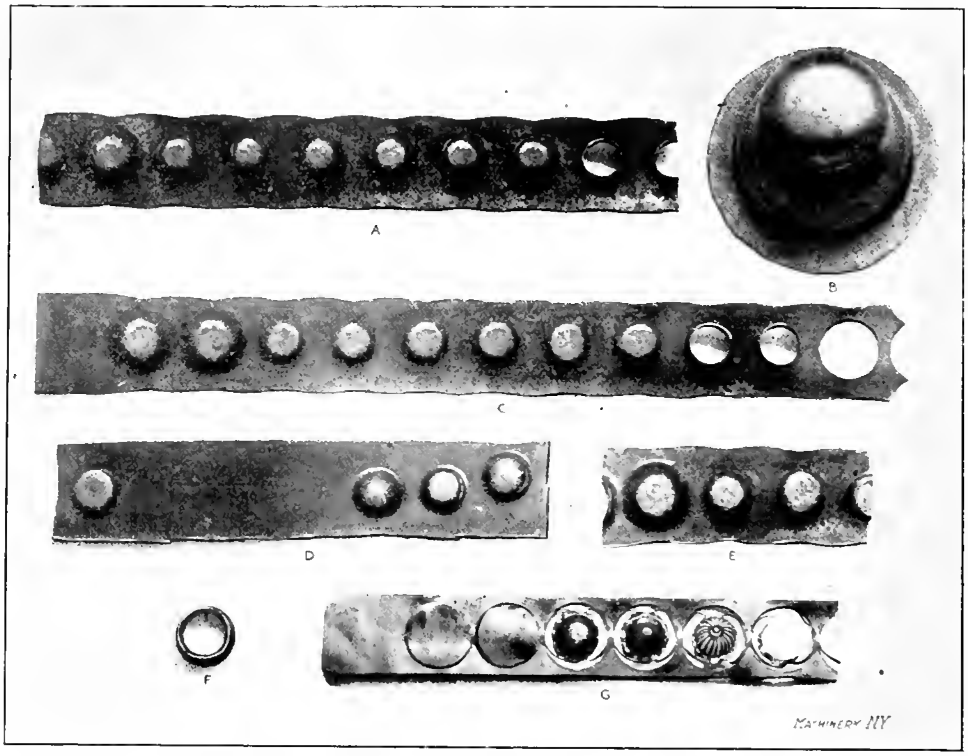

Fig. 1. Samples showing the Results obtained by both the Smooth and the Stepped or Roughed Punches

I reported the following morning and after examining the work of the dies in question, and watching their movements for awhile, I took down the set, and decided to change the shape and size of the second and third dies and punches. Fig. 2 shows the construction of the punches and dies as they were, each alternate die being shown in section. *K* indicates the "knock-outs." The stripper is not shown. Fig. 3 shows the changes made in both the punches and dies.

These dies were laid out to make two rivets at one throw. In Fig. 2 the order of the various operations, as originally performed, are indicated by the numbers there given. In the first operation a boss is created, the size of which is found by experiment (in some shops this is called "finding" the blank). The punches and dies number 2 then work this boss into a conical shell. The third operation was evidently intended to reduce the diameter of the cone, which was then converted by the next set of dies into a straight shell. The bottom was then cut out by set number 5, while the next and last dies blanked out the finished rivet. This die failed because the punches would break through the bottom of the shell before the latter was completed.

While I knew from experience just what was wanted, I really couldn't go right ahead and fix the dies in a couple of hours, and then have the nerve to ask for the "fifty." So, after much trying to conceal my zest and knowledge, I decided to "kill time" by doing "government work," as some of my own equipment needed repairs. After tinkering around four days, the boss came around and asked me, again in an incredulous manner, if I was confident of success. "Yes," I said, "as far as the dies are concerned," but I added that I didn't know how I'd manage to collect the "fifty." (I really wondered if he would pay it.) "Well," he said, "if you make those dies work in a week, you'll get besides your fifty dollars the price of a pleasant evening with your best girl. So, spurred on by this prospect, I decided that I would make one week the limit and then collect.

By referring to Fig. 3 the changes made in operations numbers 2 and 3 may be seen. It will also be noted that the original operation number 4 is omitted. Instead of making any alterations concerning the location of the fifth and sixth operations, I merely removed the number 4 dies and punches from the press, leaving it to the boss to decide about renewing the whole set, by his own die-maker, since my work ended as soon as I could demonstrate the style of die to use. Therefore the fourth operations on the string *A*, Fig. 1, are merely dummies in string *C*, which is a product of the dies after I had changed them. The stock used was number 18 of the cheapest cold roll that could be bought, but it made no difference how cheap the metal was when it was drawn by the improved method. The original dies, however, only worked successfully on good stock.

In another factory I have also seen the same trouble on brass shells, such as shown at *B*, Fig. 1. In this case the punch should simply have been made rough. I also happened to be poking in the junk pile, and picked up the piece shown at *D*. While I made no inquiry as to its origin, I did keep it as a keepsake, inasmuch as it showed someone's experiments on the same problem as the hollow rivets. This die-maker also got "stuck," since the punch broke the bottoms as shown in the engraving.

Referring to the particular style of punch I substituted for the third operation (see Fig. 3), it can be readily understood that as the punch is irregular in size it has a tendency to imbed its shoulders into the side of the shell, thus pulling the stock into the die as well as pushing it in, and distributing the strain throughout all parts of the shell. Of course this reduces the thickness of the stock on the sides, but when I showed the boss my sample he said that it was good enough for the purpose and just what he wanted. It might be well to explain that the steps on these punches are shown exaggerated in the illustration.

Fig. 4, at *A*, shows an end view of the string *E*, Fig. 1, with the finished shell sawed in half. This sectional view shows the shape of the shell after it is drawn by the stepped punches. Nothing could be done, however, until the die and punch for the second operation were properly formed, as shown in Fig. 3, where they are shown nearly straight. An-

* Address: 332 Jersey St., Harrison, N. J.

other mistake my predecessor made was in continuing the conical shaped die until the fourth operation was reached, and then changing to a straight die. The new die, as will be seen, begins in the second operation to form a nearly straight shell out of the conical boss, and then in the third the stepped punches are applied as previously described. If it were necessary to produce a still longer rivet, the first operation would need to be changed so that there would be a larger boss, and the whole gang would need to be separated more. Figs. 1 and 4 at *F* and *B*, respectively, show a rivet made by the improved dies, slightly curled over to prove its pliability after the stretch.

At *G*, Fig. 1, is shown a sample of a string of brass ornaments as they were manufactured in a fancy goods factory

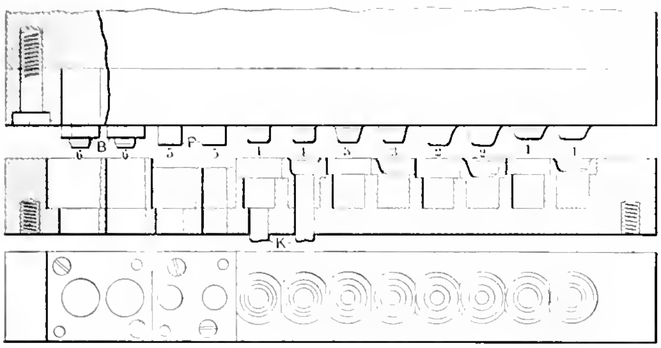

Fig. 2

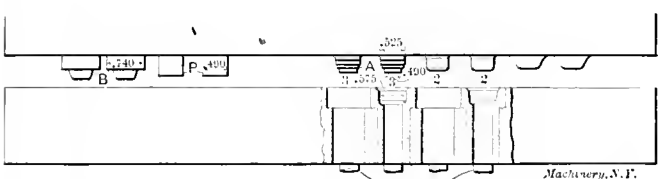

Fig. 3

Fig. 2. Punch and Die in which the Piece shown at A, Fig. 1, was formed. Fig. 3. Improved Punch and Die with Stepped Punches

I had been with. In this case the job is similar to the rivets, because they are also knocked out on a progressive die, but they are pointed cup-shape and easier to form. The first operation is to nearly cut the blank, leaving enough stock to keep it connected with the ribbon, in order to facilitate handling it. Six dies are used: the first and second to nearly blank out; the third to form a cup; the fourth to "coax" the cup to a point; the fifth to corrugate it and further its point, and the sixth to cut it through and trim it.

It may interest some readers to know that taper shells made of brass, silver or aluminum are made just the reverse

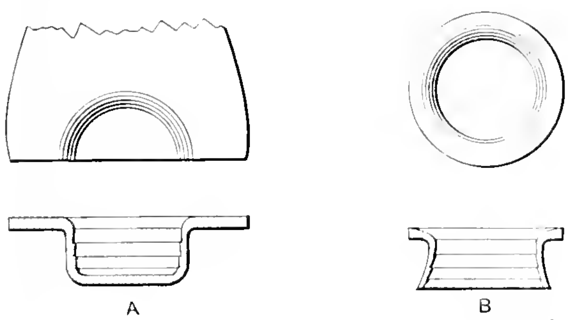

Fig. 4. Sectional View of Drawn Rivet Shell, showing marks left by Stepped Punch

of the way the improved dies described in the foregoing make hollow rivets. The shells are first drawn to the shape of a cone pulley, the number of steps depending on the length and taper of the shell. The corners of the steps are left rounded. This irregular sized shell is then placed beneath a drop-press containing a punch and die having the required taper, and it is "ironed out." The punch is prevented from sticking in the die by an adjustable collar that strikes the die harder than the taper punch. This collar is made in the form of two lock nuts.

SELDEN PATENT UPHELD

Decision was filed in the United States Circuit Court for the Southern District of New York, by Judge Hough, September 15, sustaining the famous Selden patent on gasoline automobiles. The decision holds that the claims of the Selden patent, on which suit was brought, are valid and infringed. The suit is that of George B. Selden and the Electric Vehicle Co., against the Ford Motor Co., C. A. Duerr & Co., O. J. Gude Co., John Wanamaker and others, Société Anonyme des Anciens Etablissements, Panhard, Levassor, Andre Massenat, and Henry and A. C. Neubauer. The decision is voluminous, reviewing the entire case and concluding that the invention of George B. Selden is a pioneer invention of great merit. It holds that Mr. Selden is first in this art and broadly construes claim 1 so that it covers all gasoline automobiles. Claim 1 reads as follows:

"The combination with a road locomotive, provided with suitable running gear, including a propelling wheel and steering mechanism, of a liquid hydrocarbon gas engine of the compression type, comprising one or more power cylinders, a suitable liquid fuel receptacle, a power shaft connected with and arranged to run faster than the propelling wheel, an intermediate clutch or disconnecting device and a suitable carriage body adapted to the conveyance of persons or goods, substantially as described."

The Selden patent No. 549,160 was granted November 5, 1895, and, therefore, expires in 1912. The remarkable feature about this patent aside from its broad claim is that the application was filed in the Patent Office May 8, 1879, and the application was kept alive during that period by the technicality of the patent laws, which allow applications to be renewed year by year provided an amendment is filed within two years of the date of rejection.

George B. Selden was a lawyer in Rochester, N. Y., during the seventies and spent his spare time experimenting with horseless carriages. After six years of hard work and the construction of five or six different engines he produced a carriage that would run, and finally applied for a patent on the same, submitting a model which is still in the Patent Office. (See MACHINERY, May, 1903.)

The American automobile manufacturers who will not be adversely affected by the decision are the licensees comprising the Association of Licensed Automobile Manufacturers, as follows:

American Locomotive Co., Apperson Bros. Auto Co., Autocar Co., Buick Motor Co., Cadillac Motor Car Co., Chalmers-Detroit Motor Co., The Columbia Motor Car Co., Corbin Motor Vehicle Corp., Elmore Mfg. Co., Everitt-Metzger-Flanders Co., H. H. Franklin Mfg. Co., Haynes Auto Co., Hewitt Motor Co., Hudson Motor Car Co., Knox Auto Co., Locomobile Co. of America, Lozier Motor Co., Matheson Motor Car Co., Packard Motor Car Co., Peerless Motor Car Co., The Pierce Arrow Motor Car Co., The Pope Mfg. Co., Royal Tourist Car Co., Alden Sampson, 2nd, Selden Motor Vehicle Co., F. B. Stearns Co., Stevens-Duryea Co., Studebaker Auto Co., E. R. Thomas Motor Co., Toledo Motor Co., Walter Automobile Co., Waltham Mfg. Co., Winton Motor Carriage Co.

Representative of defendant automobile makers assert that the decision will not affect their business, and that the case will be carried to the Circuit Court of Appeals, and if necessary to the Supreme Court.

* * *

According to *Frankfurter Zeitung*, the German railways occupy the leading position among the railways of the world in regard to safe traveling. The following figures apply to the year 1907 and give the number of passengers killed and injured per million passengers:

	Killed	Injured
Germany	0.08	0.39
Austria-Hungary	0.12	0.96

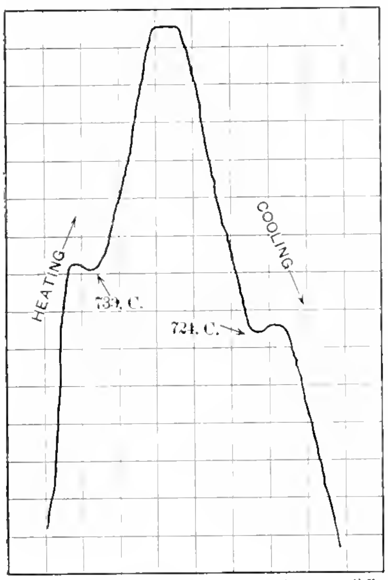
In Germany ninety-two per cent of the railways are owned and operated by the government.

RECALESCENCE AND ITS RELATION TO HARDENING

J. E. STOREY[*]

Everyone interested in the hardening of steel will have noticed the increasing frequency with which reference is made to the recalescence point of steel, in articles appearing in the technical press from time to time. It is only during the past few years that this peculiarity in steel has come to the front, and there are still very many who do not possess even a rudimentary knowledge of the subject. The somewhat obscure references one usually sees in articles on hardening will not help the man in the hardening shop very much to a better understanding of the matter, and therefore an elementary explanation of the phenomenon will be welcome to many. It may be quoted that, as a matter of history, hardening has been done with more or less success, from the days of the famous Damascus swords up to only a comparatively short time ago, without anyone having discovered that steel possessed such a peculiarity as recalescence, but nevertheless its relation to hardening has always existed, and its discovery paved the way for much scientific investigation into a subject that had been previously controlled by rule of thumb.



Curve made by a Recording Pyrometer, showing the Recalescence Points

The "recalescence" or "critical points" (also sometimes designated Ac. 1 and Ar. 1) that bear relation to the hardening of steel, are simply evolutions that occur in the chemical composition of steel at certain temperatures during both heating and cooling. Steel at normal temperatures carries its carbon, which is its chief hardening component, in a certain form—pearlite carbon to be more explicit—and if heated to a certain temperature a change occurs and the pearlite carbon becomes cementite or hardening carbon. Likewise, if allowed to cool slowly, the hardening carbon changes back again to pearlite. The points at which these evolutions occur are the recalescence or critical points, and the effect of these molecular changes is to cause an increased absorption of heat on a rising temperature and an evolution of heat on a falling temperature. That is to say, during the heating of a piece of steel a halt occurs, and it continues to absorb heat without appreciably rising in temperature, at the recalescence point, although its immediate surroundings may be hotter than the steel. Likewise, steel cooling slowly will, at a certain temperature, actually increase in temperature although its surroundings may be colder.

The accompanying illustration shows a curve, taken on a recording pyrometer, in which the recalescence points are well developed. From this it will be seen that the absorption of heat occurred at a point marked 733° C on the rising temperature, and the evolution of heat at 724 C on the falling temperature. The relation of these critical points to hardening is in the fact that unless a temperature sufficient to produce the first action is reached, so that pearlite carbon will be changed to hardening carbon, and unless it is cooled with sufficient rapidity to practically eliminate the second action, no hardening can take place. The rate of cooling is material and accounts for the fact that large articles require to be quenched at higher temperatures than small ones.

A very important feature is the fact that steel containing hardening carbon *i. e.*, above the temperature of recalescence, is non-magnetic. Anyone may demonstrate this for himself by heating a piece of steel to a bright red and testing it with an ordinary magnet. While bright red it will be found to have no attraction for the magnet, but at about a cherry-red it regains its magnetic properties. This feature has been taken advantage of as a means of determining the correct hardening temperature, and appliances for its application are on the market. Its use is certainly to be recommended where no installation of pyrometers exists; the only point requiring judgment is the length of time an article should remain in the furnace after it has become non-magnetic. This varies with the weight and cooling surface, but may be tabulated according to weight, leaving very little to personal judgment.

It is difficult to quote reliable temperatures at which recalescence occurs, as the observation of different investigators do not show concordant results, probably owing to the lack of uniformity in the means of measuring the temperatures. It varies with the amount of the carbon element contained in the steel, and is much higher for high-speed than for ordinary crucible steel. Special electric furnaces are generally used for obtaining recalescence curves, but with care it can be done in an ordinary gas furnace, with a suitable pyrometer. All that is necessary is to bore a blind hole in a piece of the steel to be treated, to form a pocket to receive the end of the pyrometer. This must be of sufficient length to cover the resistance coil in the end of the pyrometer. The specimen should then be put in the furnace, with the pyrometer in, of course, the gas applied, and, if the furnace is allowed to heat up very slowly toward a temperature of say 750° C., the recalescence curve will be developed, if the pyrometer is a recording one. In the same way, if the furnace is allowed to cool slowly it will be seen that at the second recalescence point, the specimen gives off heat and even increases in temperature for a time. Experiments of this kind are scarcely practicable for the average hardening shop, but when it is desired to find the lowest hardening temperature for a piece of steel, the magnet can be used to advantage.

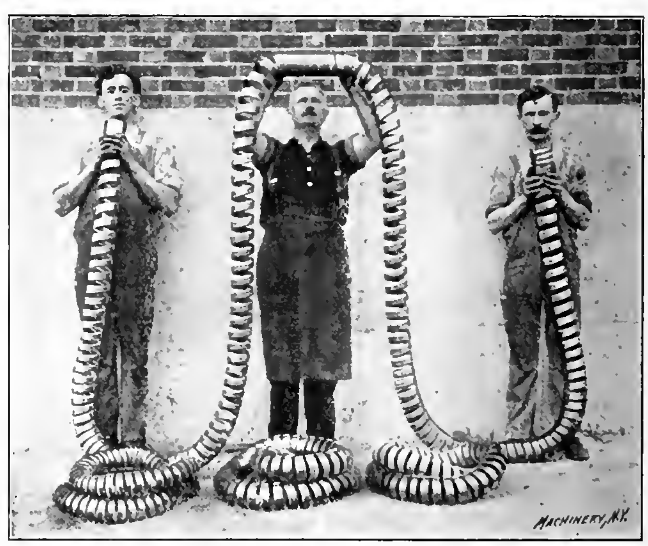
BRASS SPIRALS MADE ON SCREW-CUTTING MACHINE

The illustration shows four brass spirals supplied to the United States government by the Screw Cutting Company of America, 17th St. and Sedgley Ave., Philadelphia, Pa. The spirals were made by cutting a 1½-inch pitch thread, ¼ inch wide, on hard drawn seamless brass tubing 3¾ inch diameter,



Brass Spirals made from Tubing by the Screw Cutting Co. of America for the United States Government

No. 18 British wire gage (0.049 inch). The spirals are used for reinforcing hose, and the longest was cut from a brass tube ten feet long. The company was able to do this work rapidly and efficiently on its special screw cutting machines (see MACHINERY, April, 1909, for illustrations of products), and is prepared to produce similar work in brass, steel or other metal, and on any length of tubes that can be made and shipped. It is of the opinion that the proposition by any other process than its own would have been very difficult and costly.

ACCURATELY LOCATING WORK ON THE FACE-PLATE

The object of this article is to show how easy it is to accurately locate work on the face-plate by the use of plugs and size blocks. The way in which the casting shown in Fig. 1, which is part of the milling fixture, Fig. 5, is located on a lathe face-plate so that it may be bored central with the end bearings, will be explained. By this method all chances of error which might occur in trying to center such a casting in the old way are eliminated. The function of the casting, when in the assembled fixture, is to hold the part shown in Fig. 4 while a groove *G*, 1/16 inch wide and 1/32 inch deep, is being milled on the inner surface, which is spherical. As this groove must have the same depth at each end, the reader will readily see the importance of accurately locating the

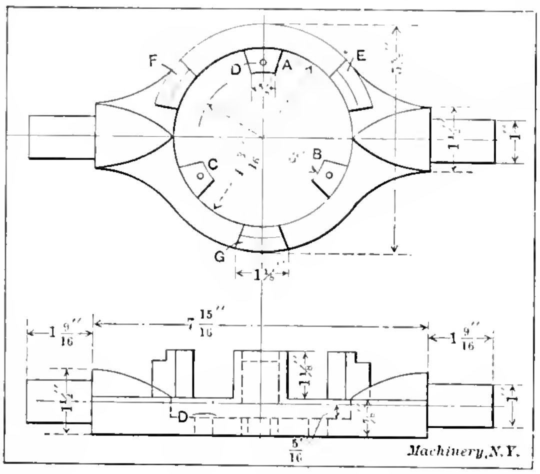

Fig. 1. Work to be Located with Reference to the End Bearings

fixture casting for the boring operation. A plug *A*, exactly one inch in diameter, was first inserted in the lathe spindle as shown in Fig. 2. The two V-blocks, also shown in this engraving, are used on regular tool work, and when made were planed accurately to 1⅝ inch wide, 1⅝ inch long, and 1⅝ inch from the bottom to the center of a one inch plug placed in the V. The distance, therefore, from the sides to the center of the blocks is 13/16 inch, and as there is a 1-inch plug in the spindle, the block to be used between the plug and the parallel upon which the V-blocks are to rest when

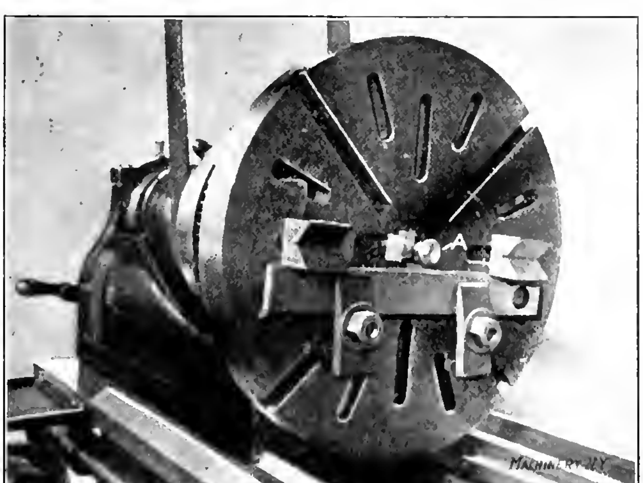

Fig. 2. Setting Parallel and V-blocks from a Central Plug

setting the parallel, would be 13/16 inch minus 1/2 inch, or 5/16 inch. By referring to Fig. 1, we find that the distance between the shoulders of the end bearings is 7 15/16 inches. One-half of this amount is 3 31/32 inches, which minus half the plug diameter leaves 3 15/32 inches, which is the required size of the blocks to be used between the plug and the V-block, only one of which was set in this way. When the casting was placed in the blocks, it was carefully set against the block which had been previously located. The other block was then brought up against the shoulder of the bearing on the opposite end. These V-blocks happened to be tapped in the bottom for a ⅜-inch screw, which, with clamps to hold them against the parallel, made it easy to locate them. The casting was set parallel with the face-plate by the use of a surface gage. Fig. 3 shows the work after the three projections

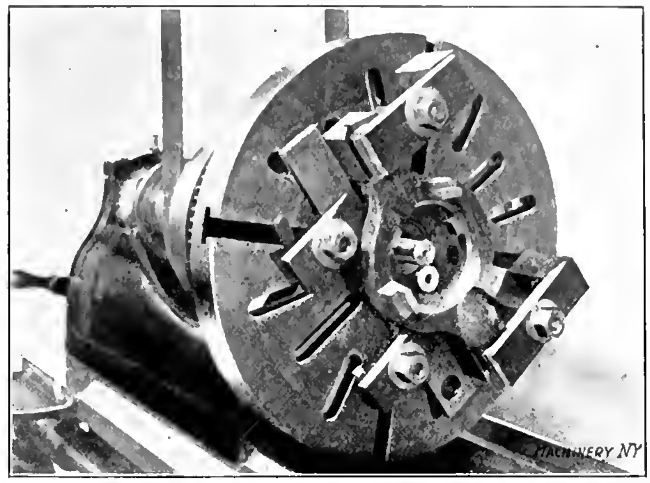

Fig. 3. Use of Central Plug and Ring Gage for Sizing Projections located 120 Degrees apart

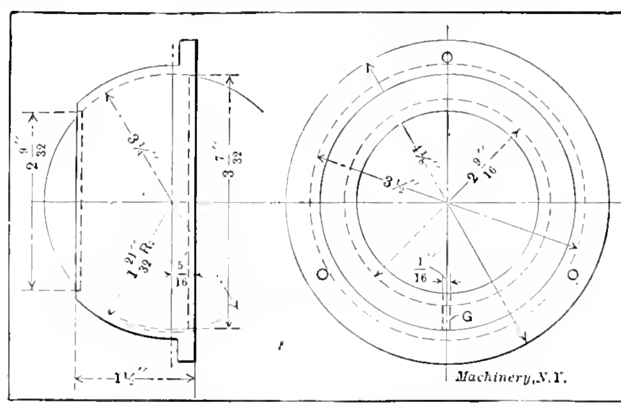

Fig. 4. Casting which is held in the Fixture, Fig. 5, while a Groove is being milled in its Spherical Surface

A, *B*, *C* and the surface *D*, Fig. 1, had been bored and faced. The inner projections were bored to a 3-inch circle by using a standard one-inch ring as a gage (as shown in Fig. 3) which, when placed against the plug, gave a radius of 1½ inch. By referring to the elevation in Fig. 1, it will be seen that the surface *D* must be 5/16 inch below the center line. As the distance from the base of each V-block to the center of a 1-inch plug resting in the V is 1 5/8 inch, 5/16 subtracted from this amount leaves 1 5/16, which is the thickness of the block to set between the point of the tool and the face-plate when setting the tool for the finishing cut. The projections *E*, *F*, and *G* were turned to fit a ring 5 inches inside diameter. A plug was made having one end 3 inches in diam-

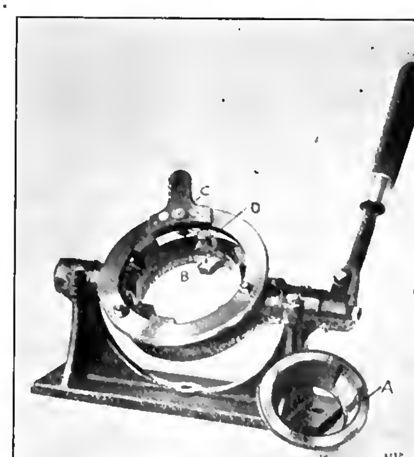

Fig. 5. Fixture of which the Casting shown in Fig. 1 forms a Part

eter to fit the inside of the lugs A, B, and C, Fig. 1, and the other end turned to fit the 3 7-32-inch bore of the spherical casting, Fig. 4. This plug was for locating the piece to be milled so that the pins in the projections A, B, and C would be in such a position that when the work was subsequently located by them, the center of its spherical surface would coincide with the axis of the rotating part of the fixture. Two of these locating pins were also set in a line parallel with the center line of the fixture. All this work was done before removing the casting from the face-plate. It will be understood that if the work should become shifted in any way it can be readily and accurately reset again by this method.

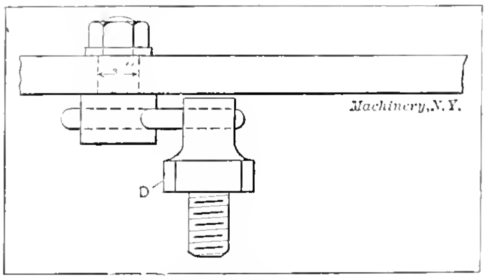

Fig. 6. Detail of Clamping Device for Fixture shown in Fig. 5

The completed fixture is shown in Fig. 5, with a sample of the work held by it at A. This illustration, as well as the detail Fig. 6, shows the locking device by which the work is clamped in place. After the casting is located by pins B which fit into holes bored in the casting flange, it is secured by a movement of the ring C to the right, which causes three locking screws D to turn simultaneously, and clamp against the flange. ALBERT C. SAWYER.

Dorchester, Mass.

TWO GAS ENGINE JIGS

In selecting the two jigs shown in the illustrations from among those in use in the manufacture of a well-known gas engine, I have digressed from the usual custom of choosing only the best for description, believing that there is as much to be learned from the mistakes as from the successes. These jigs while embodying some very good features, are offered as examples of jigs possessing points to be avoided.

Fig. 1 shows a piston boring jig. It is a well-designed jig in every respect except one, and that is in the method of clamping the work. This method is the one usually followed for securing cylindrical work, either in a jig or to the drill press table, and it is very effective—so effective, in fact, that more or less work is spoiled by being either cracked or sprung. Gas-engine pistons are necessarily rather light, and to hold them tight enough and still not injure them requires more care than the average operator can be depended upon to exercise. It is almost impossible to avoid springing the pistons, and often they take a permanent set. As an improvement in this and similar jigs I would suggest that the work be clamped longitudinally. This would probably not be as convenient as the method shown, but it should be as effective and certainly would not injure the work.

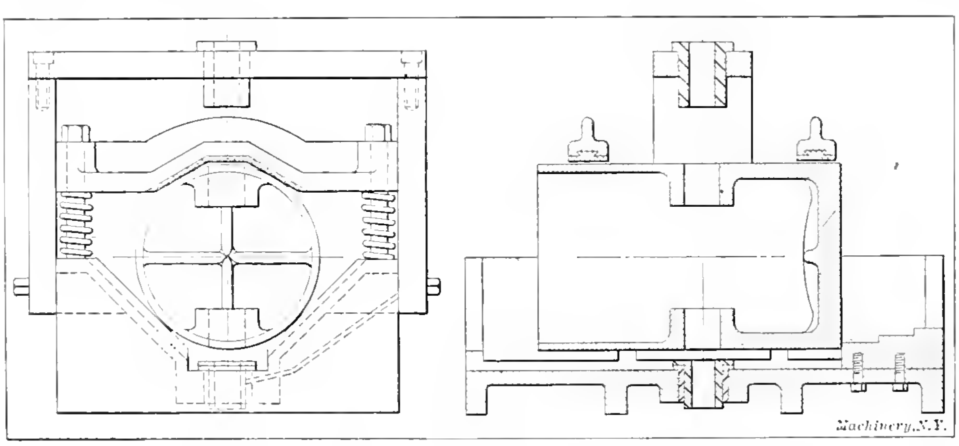

Fig. 1. Elevation and Section of Jig for Piston Boring with Work in Place

A good point of the jig is the springs to hold the clamps up while changing the work. In places where springs can be employed, they will save much time in avoiding the removal of the clamps each time the work is changed. Another good point of this jig is the babbitt metal facing of the clamps, which prevents scarring the pistons.

The fixture shown in Fig. 2 is a chuck for connecting-rods, for use on the milling machine. The method of clamping is quite ingenious, as the turned heads are used both to align and hold the rods. This looks all right on the face of it, but in actual practice it was found necessary to make the addition of adjusting screws under the heads of the rods to prevent them turning on their respective axes under uneven cuts. This added so much to the time of chucking that practically all the advantage gained by the manner of clamping was overcome. J. F. MIRRIELEES.

Cincinnati, O.

CLEANING MICROMETERS

In my travels I have seen many mechanics trying to get emery and grit out of micrometer screws and nuts, either by washing them in benzine, alcohol, kerosene, or other oils, or alkalis, or by digging out the dirt with pine sticks, or pith. At one time mine became clogged with emery, and I sent them to the manufacturer. It cost me 50 cents besides prepaying all charges. When they were returned to me they were worse than ever, so I decided to experiment. I placed the screws in benzine to remove the oil which had been collecting the emery. Then the parts were heated just enough to be held comfortably in the hand, and a coating of beeswax was applied to the screw and nut. The screw was then placed in the nut, after it was cold, which forced all the small particles of dirt out with the surplus wax, and closed up the slots, avoiding the possibility of dirt and emery becoming clogged in them. A small thin coating of wax was therefore left between the screw and nut. The screw was then removed from the nut, and all surplus wax removed, and a drop of thin oil applied. Anybody having trouble with their micrometers will find this remedy O. K. Mine have been in daily use for nearly three years, with the same coating of wax, and are to-day in good condition. FRANK G. STERLING.

Franklin, Mass.

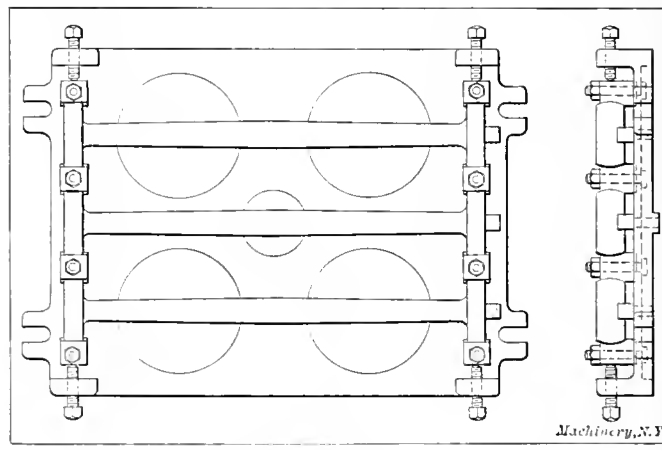

Fig. 2. Design of Fixture for Connecting-rods, which proved Objectionable

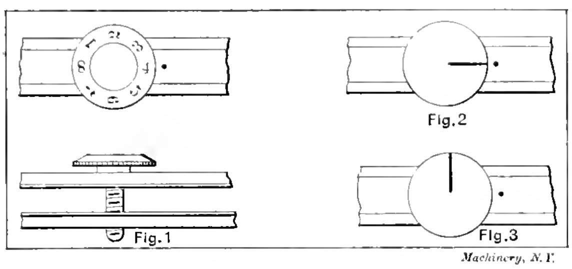
GRADUATED SCREW HEADS ON DRAWING PENS

Having had some difficulty in getting all the lines on a drawing of the same width, it occurred to me that it would be a good scheme to graduate the screw heads of the drawing pens, so they could always be set for some pre-determined width of line before beginning to draw. With this object in view, a bevel was turned on the upper faces of the screw heads which were stamped with numbers from 1 to 8, as shown in the plan view in Fig. 1, and a center punch mark was made on the blade of the pen, against which to

read the numbers. After the different pens in the set of instruments are marked, they can be adjusted by trial on a waste piece of paper until they all draw the same width of line, and a record made of the reading of each screw, as shown in the accompanying table, there being two records for each pen, one of which is for light lines, and the other for shade lines. There is not much use for a shade line adjustment on the compass pens, as nearly all draftsmen

	Small Compass	Large Compass	Straight Line
Light line..............	4	1	7
Shade line..............	6	3	1

shade their circles by springing the needle leg, but it is of occasional use in drawing short arcs. The record shown in the table can be hung up on the wall, placed in the cover of the instrument case, or anywhere that is convenient for reference. As the pens are sharpened, or the screws wear in the thread or under the shoulder, the record for the pen settings will have to be altered at quite long intervals, depending on how much use each pen gets. Some makers supply straight line pens with a graduated screw head somewhat larger than usual, but mine were of the kind that is ordinarily supplied with drawing instruments, and were rather



Ruling-pen Screw-heads Graduated to obtain Lines of Uniform Width

small in diameter, so the numbers were not very large; however, I find it a great help. Anyone not having facilities for stamping numbers can place two ink marks on the screw heads—one red mark for light lines and one black mark for shade lines; or only one ink mark can be used on the screw head, having it point as in Fig. 2 for light lines, and as in Fig. 3 for shade lines. This ink mark scheme is not original with me, as I am indebted to R. A. Gleason for it. The marks will last quite a while, as the ink is on the flat side of the screw head that is not supposed to be handled.

Brooklyn, N. Y. WALTER GRIBBEN.

CHUCKING TRANSMISSION SLEEVES FOR INTERNAL GRINDING

A special steady-rest and chuck for use in the grinder when grinding a certain make of automobile transmission sleeve, is shown in the accompanying illustrations. Fig. 1 shows a

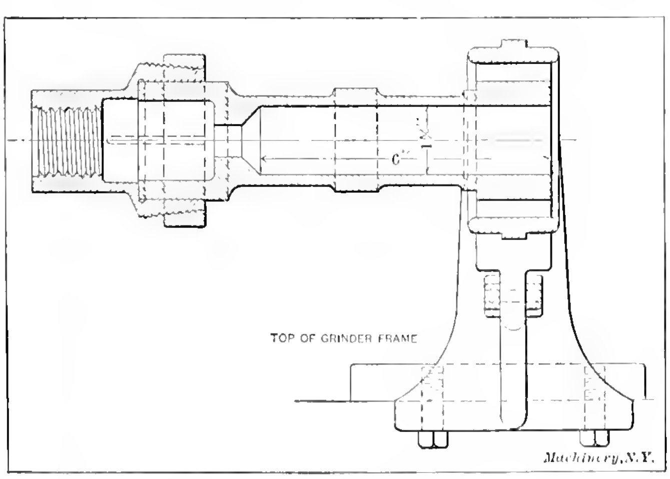


Fig. 1. Plan in Section of Grinder-Rest and Chuck with Work in Place

plan view in section of the chuck and rest with the work in place, and Fig. 2 an end elevation. The sleeve, which is a steel drop forging, is finished all over, after which the hole 1 5/8 by 6 inches long is ground to fit a plug gage. This method of holding the work enables it to be quickly set so that the hole will be finished perfectly concentric with the outside surfaces. The chuck which holds one end of the sleeve is of the ordinary spring collet type. It has six milled slots, and the chucking end has a taper of 7 degrees

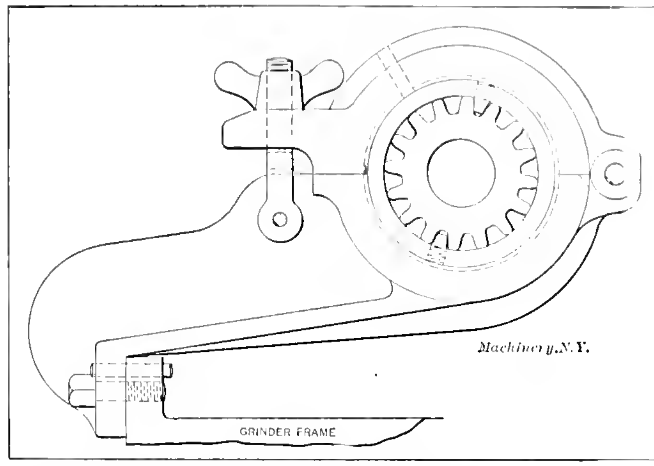

Fig. 2. End Elevation of Rest, showing Method of Holding End of Work

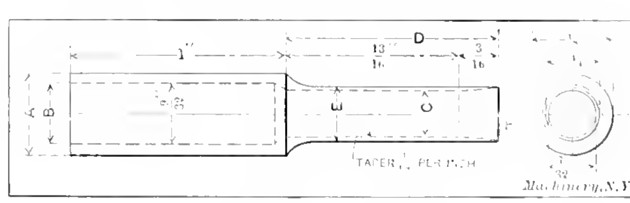
which is threaded. A machine steel ring-nut with holes for a spanner wrench is threaded to fit the taper part of the nut. Both the chuck and the ring are hardened and ground to size. During the grinding operation the outer or gear end of the sleeve is held in a one-piece bronze ring. This ring is provided with a tongue which is a neat working fit in a groove in the steady-rest. As shown in the end elevation, this rest has a hinged cap which is held in place by a hinged clamping bolt provided with a suitable wing-nut. Bolts and dowel pins secure the rest to a rib on the grinder frame. In the bronze ring there are two steel studs which are flush with the outside diameter and which protrude inward as shown in the end view. These studs are shaped to fit the teeth of the gear, thus causing the bronze ring to turn with the sleeve during the process of grinding. With this form of rest, the chucking, grinding the inside of the sleeve, and removing it, is all done in about eight minutes, which is seven minutes less than formerly required. There is also little danger of error because of an unskilled or careless operator, as he cannot make a mistake in chucking the work.

M. HEARTILLIIEN.

A DRILL FOR PAPER

The accompanying engraving illustrates a tool which is remarkable for its simplicity and efficiency. This tool was developed in a jobbing shop where tools were being made for loose leaf ledger work. There was considerable trouble with the tools for punching the ledger leaf holes, it being difficult to get the punches to cut "clean," through any considerable thickness of paper, so an attempt was made to drill the holes instead of punching them. It was soon discovered that the paper could not be drilled with any kind of lip drill, because, no matter how the lips were shaped, they would catch and tear the paper. After considerable experimenting, the tool



A Tool for Cutting Holes through Paper

shown in the engraving was developed, and it was found to be far superior to the ordinary method of punching. This tool requires but little explanation. To make it, take a piece of tool steel and catch it in the lathe chuck, allowing it to extend from the chuck far enough to permit of its being turned the full length, and then cut off. Next turn the diameter *A* allowing 1/64 inch for a finishing cut. Turn down the end to the diameter *E*, and to the length *D*, again leaving 1/64 inch for a finishing cut. Now drill through the full length of the

tool, a hole slightly smaller than C, so that it may be trued up with the boring tool. Before finishing this hole, bore out the clearance hole B which should be 1/16 inch larger than C to allow the scrap or paper cuttings to pass through freely. Next finish the hole C, making it 1/64 inch per inch taper, the largest part of the hole being at the back. This hole should be 1/32 inch smaller than the outside diameter E, which is the exact size of the holes to be drilled in the paper. The diameters A and E are next finished, E being made 0.001 inch smaller at the back than at the cutting end. Taper the mouth of the tool as shown at F, bringing it to a fine edge at the outside diameter. The tool may now be cut off and hardened. It should be hardened in oil, and drawn to a dark brown at the cutting edge, this color running off gradually to a blue at the back end of the tool. If care is exercised in hardening, there will be no necessity for grinding or lapping. The tool may be used in the drill press, and it should run about 1,500 revolutions per minute. The press or speed lathe in which the tool is used should have a hollow spindle to allow the paper cuttings to pass through. If, however, a hollow spindle machine is not available, a chuck with sufficient space to permit the cuttings to pass out between the jaws, may be used, or a special holder may be made, of simple design, to serve the purpose. One who sees this tool work for the first time will be surprised to observe how clean and freely it will cut.

C. W. D. and W. B.

ADJUSTABLE ELECTRIC LAMP BRACKET FOR THE SHOP

In many shops it is found to be quite a problem to construct an electric lamp bracket for the bench, which can easily and quickly be adjusted to any height and position. The Cincinnati Shaper Co. uses a bracket which fills the bill and the cost of which is trifling. The illustrations, Figs. 1 and 2, show this bracket assembled and in detail. The same reference letters are used in each illustration for corresponding parts, so that the construction of the bracket may be more easily understood. The small cast iron angle-plate A is screwed to the wall. The top of this plate, as shown in the plan view, Fig. 1, is serrated so that the arm to which the lamp is attached, will remain in the desired position. These serrations are cast in, and the only machining done to this

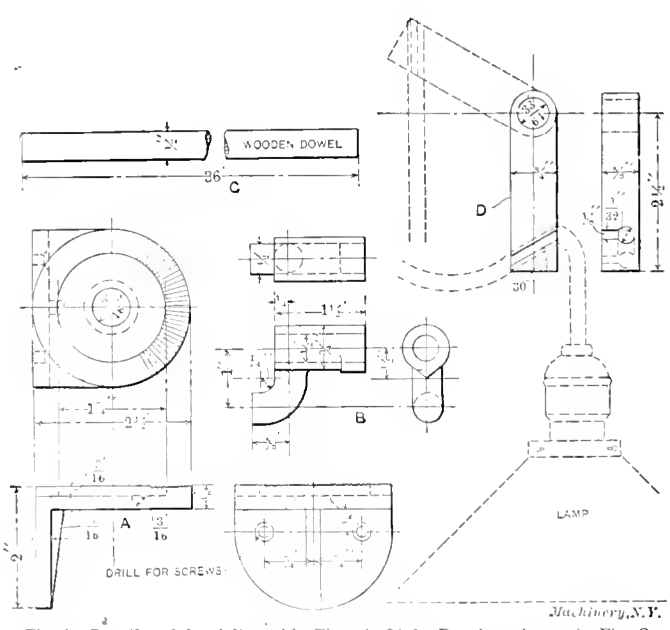


Fig. 1. Details of the Adjustable Electric Light Bracket shown in Fig. 2

piece is the drilling of the screw holes for fastening it to the wall or window sill. The small casting B, which is attached to one end of the wooden arm C, has a curved end which fits into a hole in A. A ½-inch hole is cored into casting B, and into this hole the wooden dowel C, which is about 36 inches long, is driven. As will be seen by referring to the end view, the casting B has a sharp V-shaped projection on the bottom of the front end; this rests in the serrated part of the angle-plate. The piece D, located at the end of the arm C, is of fiber. This is drilled 1/64 inch larger than C to permit it to slide back and forth easily. The hole through which the lamp wire passes is drilled at an angle of 30 degrees, as shown in Fig. 1, to prevent the wire from slipping. A slot is milled into this hole on one side so that

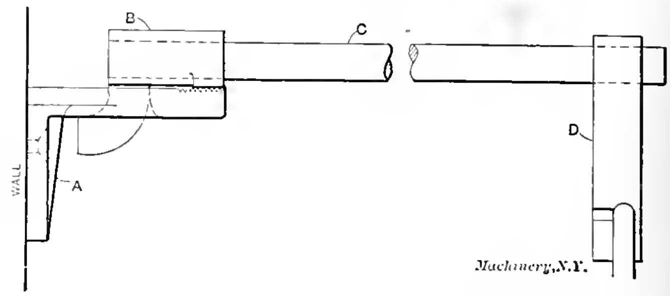

Fig. 2. Simple Design of Adjustable Electric Light Bracket

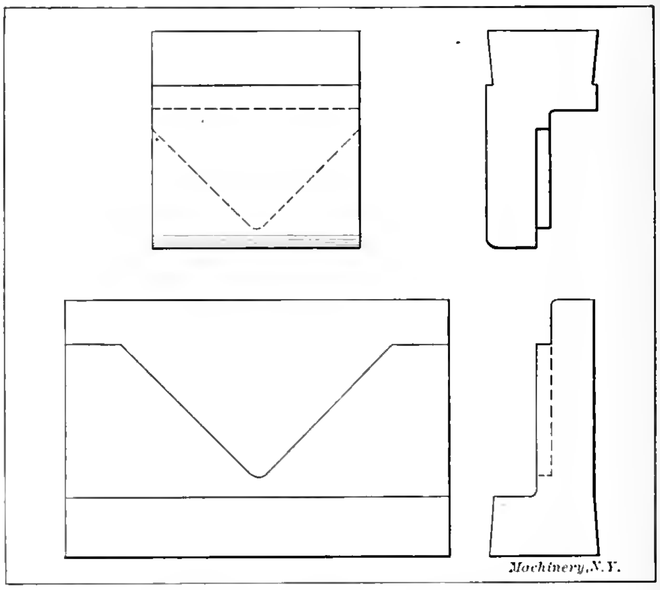
the wire may be placed into position. By raising the block, as shown by the dotted lines, the lamp can easily be adjusted to any height.

H. DONNERBERG.

Cincinnati, O.

A BENDING DIE

A type of punch and die that is adapted for bending at right angles, edgewise, soft steel strips, in size from ⅛ × 1-inch to ⅜ × 1-inch, is shown in the accompanying engraving. This tool commends itself from the fact that it is of simple design, easy to make, and that, in bending the stock,



Die for Bending Soft Steel Strips Edgewise

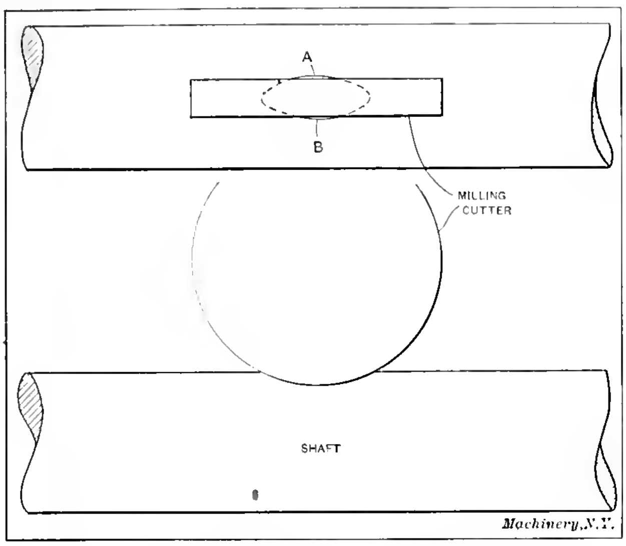
the inner angle does not increase in thickness to any appreciable extent. When accurate work is required and no increase whatever in thickness at the bend is allowed, the punch and die may be locked together by extending a part of the punch over the rear of the die. This will eliminate any tendency of the two members springing away from each other in action. As the stock bent in this die was in long strips and extended beyond the die, a stop (not shown) was attached to the side of the bolster. This tool is run in a press with a stroke of 4 inches. Both the punch and the die are planed at an angle of ten degrees to fit the holder, and they are both hardened.

ENGINEER.

CENTERING SHAFT WITH MILLING CUTTER WHEN KEYSEATING

The micrometer gage for centering work with milling cutters, described by Mr. Chapman in the July number of MACHINERY, would do this work with considerable precision were it not for the fact that in the present rush and hurry in manufacturing probably 80 per cent of the milling cutters do not run perfectly true on the arbor; and, in that event, there would be great chance that the accuracy of the micrometer would be useless. Assuming that the cutter runs perfectly true, then undoubtedly the tool referred to is all right

from a standpoint of accuracy; but I fear that in a majority of shops, it would be too fine a tool to suit the foreman, who is naturally supposed to be anxious to do things in a hurry. I recall one such foreman, from whom I received many a good lesson on economy and rapid production, and one of these was on how to locate a shaft with the cutter when milling a spline or key-seat. This method works equally as well on a planer as on a milling machine. After the shaft and the tool or cutter is in place, start the machine and either plane or mill a flat spot across the top of the shaft as wide or a trifle wider than the key-seat; then set the tool by this finished surface. For example, when a shaft is to be set central with a milling cutter, the latter is first sunk into the work as shown in the accompanying engraving. The shaft is then fed crosswise under the cutter and a spot milled as indicated by the dotted lines in the plan view. After this spot is milled a trifle wider than the width of the cutter, the work may be set by sighting down over the top of the cutter and adjusting the work until the same amount of



Method of Setting a Milling Cutter Central with a Shaft

milled space shows at A and B. The cutter should be revolving while this adjustment is being made so in case it runs out laterally, the high sides will appear at the bottom in such quick succession that it may be set the same as a true running cutter. After the first shaft is located, the operator should not move the cross-feed screw until all of the shafts are finished. Of course, on the planer the locating spot will have to be machined for each shaft. This should not be done by feeding down a broad nose tool, for while any kind of a tool may be used, it must be fed crosswise in order to finish a surface which is parallel with the planer platen. I have used this method for years and find it satisfactory both in regard to time and accuracy. Therefore I pass it along hoping that it may be of help to someone.

Bridgeport, Conn. H. E. Wood.

ACCURATE BORING ON THE HORIZONTAL BORING MILL

Among the standard tools of to-day in most machine shops is found the horizontal boring mill, and although not as old as the lathe, planer, and some others, it is equally as necessary on some classes of work as these older and more standard tools; but in operating this tool the workman generally finds great difficulty in obtaining an accurate hole of a very great length, especially if the equipment, including bars and guide bushings, are not absolutely new, in addition to being accurate. A simple equipment that is generally used is shown in Fig. 1. The bar A is made of annealed tool steel, and the cutter B is held in a central position by the wedge C and a fitting on either side of the bar. The bushing D is bored to fit the bar and turned to suit the hole in the yoke of the machine. This bushing is held in the yoke by two set-screws which are spotted into it to prevent any slipping or turning without subjecting the bushing to any great strain. Here lies the chief difficulty to which the writer desires to draw particular attention, and acquaint the reader with a very desirable and successful remedy.

As the bushing is always in the same position, a large portion of the wear comes on the bottom. This wear, in turn, allows the cutter to run closer to the table as it proceeds away from the machine until it reaches the yoke; then the work receives the full benefit of the worn or inaccurate bushing and a hole is produced which is not parallel with the table and of an elliptical shape, the vertical axis being the longest because of the play the bar has in the bushing. Even when the bushing is made a suitable running fit, a hole will show

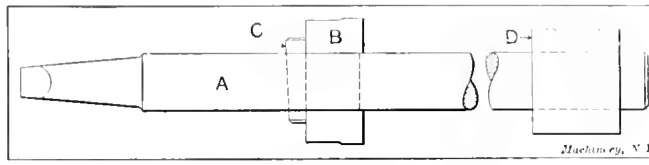


Fig. 1. Boring-bar with Solid Bushing

from one to four one-thousandths difference between the horizontal and vertical axis. From the foregoing it is readily seen that the object required is to maintain the bar in a perfectly central position with the spindle at all times, just enough freedom being provided to allow the bar to turn.

Fig. 2 shows a form of split adjusting bushing which is very old in principle, but which produces excellent results in this case. The outside bushing A is turned to suit the hole in the yoke of the boring mill, and it is bored parallel to receive bushing B which, in turn, is bored taper to receive bushing C, the inside of which is bored parallel to the exact size of the bar. This inner bushing is split in three parts. Two washers or end plates D are required, whose bore is 1/16 inch longer than largest bar; these are each secured to bushing A by four tap bolts, as shown, and they are also drilled and tapped for two set-screws E, which bear against bushing B. Two of these set-screws are required on one end for tightening and two on the other for loosening bushing B.

The pressure sometimes applied on these set-screws is enough to nearly burnish the bar with heat, when a particularly fine finish is required, so that the allowance for a running fit is reduced to an absolute minimum, and the resulting cut will be just as true as the machine, less the wear of the

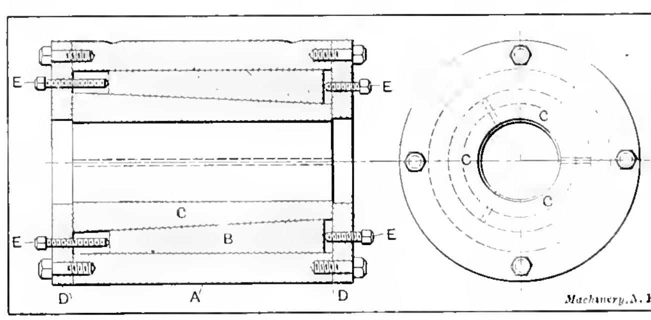

Fig. 2. Split Adjustable Bushing for the Boring-bar

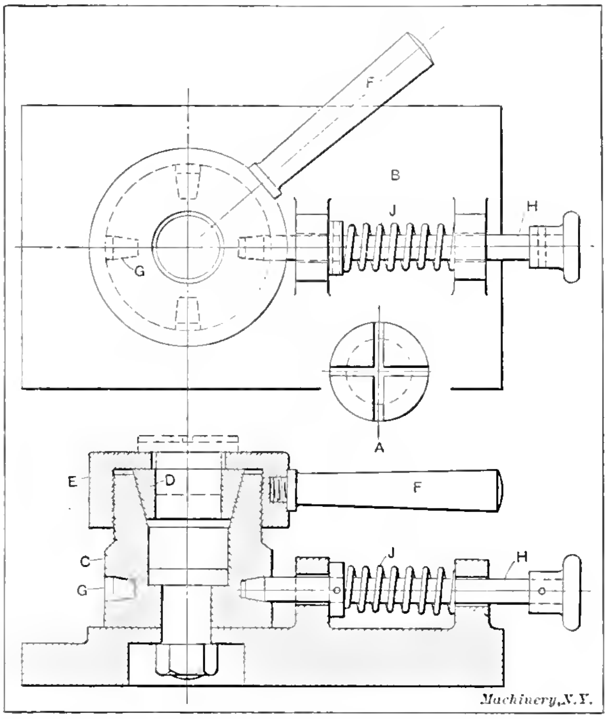
tool, which will vary slightly according to the quality of the steel in the tool compared with the material being cut; when these both agree, accurate work will result. The construction of the device is not confined to any set dimension or taper, but it is preferable that the taper be quite abrupt to obtain quick adjustment, to allow for a large take-up for wear, and to obviate too much of a wedging effect. The different diameters of bars are taken care of by having a number of split bushings C, the inside diameters of which correspond with each bar.

R. S. F.

MILLING FIXTURE FOR SMALL CYLINDRICAL WORK

A chuck for holding a small plug, a plan view of which is shown at A, while grooves are being milled at right angles across its upper face, is shown in the accompanying engraving. This chuck consists of a base B which is fastened to the milling table. On this base is pivoted a cylinder C which is threaded on the upper end, and turned tapering on the inside to receive a conical bushing D which fits the taper of the

cylinder. This bushing is split so as to allow it to be sprung together when forced down by the cover *E* which is threaded to fit the cylinder *C*. This cover is turned by means of the handle *F*. The taper of the bushing and the recess in *C* should be of such an angle that the two pieces will not grip and hold fast. An angle of from thirteen to fifteen degrees is about right. In the lower part of the cylinder *C* there are



Milling Fixture for Holding the Plug shown in the Plan View at A, while the Grooves are being milled

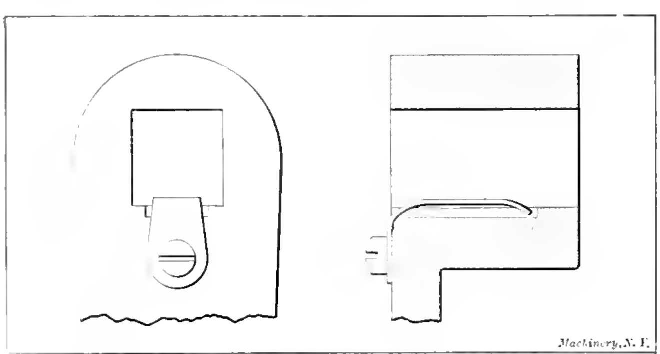
four holes *G* which serve for spacing the cuts. On the base *B* there is mounted a pin *H* which is held in one of the holes *G* by means of the spring *J*.

The operation of the fixture is as follows: By turning the handle to the left, the cover raises and the bushing *D* slips up and expands. The plug is then dropped in place, as shown by the dotted lines, and the handle turned to the right, which forces down the cover *C* and bushing *D*, causing the latter to spring together and grip the plug. A cut is then taken across the top. Then by pulling back the pin *H* and turning the handle *F* to the right until the next hole *G* comes in line with the pin *H* the work is indexed for the next cut. Then the handle is turned to the left again, and the plug released and another inserted.

This chuck could be used for many different kinds of work by having the proper bushings. E. B.

SECURING CRANK HANDLES

The crank handles supplied by many builders with their machine tools, soon find themselves as much at home on the floor as on the squared end of a feed-screw. In the course of



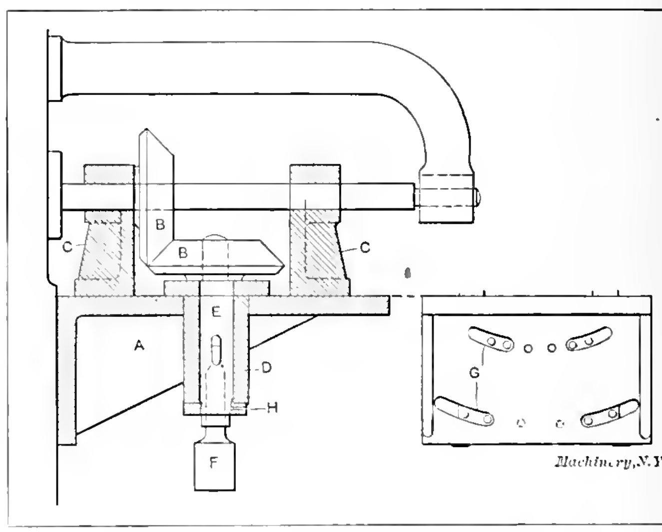
Crank Handle with Pressure Spring which prevents it from coming off

a year, a great deal of time is spent in picking up these fallen handles, to which must be added the cost of new ones to replace those of cast iron which still are sometimes foisted upon us. Half an hour's work will fix any handle so that it will not fall off. As seen by the illustration, a small groove is chipped part way through the hole for the squared end of the screw, and a bent flat spring is fastened to the handle. Unless the handle is very loose on the feed-screw, the spring need bear on the latter with but little pressure to keep it in its place. Then it can be slipped on and off almost as readily as without the spring, when it is necessary to do so to place it in a convenient position.

Middletown, N. Y. Donald A. Hampson.

MAKING A VERTICAL MILLING ATTACHMENT

Much has been done of late years in the way of developing the vertical attachment for milling machines, as this little attachment permits one to do a great variety of work. There are, however, thousands of milling machines in the field today which do not possess one of the model up-to-date vertical attachments, and therefore I shall give a brief description of how one of them was made in a rush one day when the occasion demanded it. As the draftsman and patternmaker both happened to be on a vacation, it fell to me to rig up the attachment with the things I had at hand, which I proceeded to do by retiring to the casting house, where the two brackets *C* and the flanged casting *D* were found. After some more rooting around the shop I dug up an old pair of miter gears that had been discarded from an experimental job. Then, taking one of the regular angle irons *A* away from a planer, I proceeded to lay out and cut the radial slots *G* shown in the end view. These were to allow the vertical



Vertical Milling Attachment made from Miscellaneous Scrap

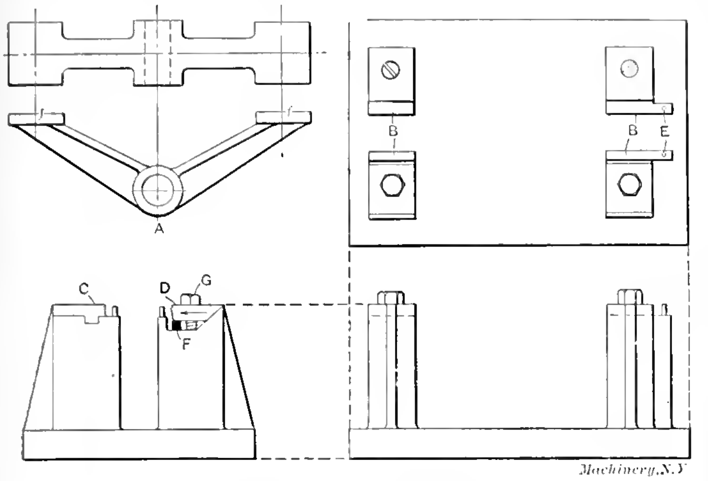
spindle to be tilted. During the time this was going on, another man was boring out and turning the casting *D*, but to no particular size, just enough metal being removed to clean it up. The feet of brackets *C* were also planed. The angle iron *A* was put on a drill press and drilled and bored to a driving fit for bushing *D*. The spindle *E* was next made, from a piece of scrap shaft, to match casting *D* and gear *B*, and then collar *H* was made to suit the spindle. When this was done, we were ready to assemble. To do this it was necessary to drill several holes in this milling machine column, and right here is where many of the machine owners and old-school mechanics would have objected and said: "Don't drill any holes in that machine; every hole you drill knocks $10 from its value if you ever want to sell it." Now let me say to them that a machine is in a shop for the purpose of earning all it can for the owner, and it is not an ornament to be kept nice so that it will sell for $19 more some day. Therefore it is up to the foreman to get all he can out of every machine, but of course he has no right to needlessly destroy it. Then again, in this particular case, the vertical attachment would add ten times more to the value of the machine than the holes could possibly take off. When assembling the attachment a makeshift boring-bar to bore out the castings *C* was used. We had to bore the holes larger and bush them down to match our regular arbor; the gear *B* had also to be bushed down. This article is offered in hopes that it may possibly suggest to someone else a method of getting around some of their milling machine troubles. Of course we know

that vertical attachments usually come now with new machines, but nevertheless there are thousands of milling machines without them, the owners of which do not care to expend the amount of money that one of them costs.

Bridgeport, Conn. H. E. Wood.

A SHAPER FIXTURE

The engraving shows a shaper fixture used for holding the bracket *A* while the feet are being planed, as indicated by the finish marks *f*. This bracket rests upon the surfaces *B*, and it is held in place by jaws *C* and *D*, and the pins *E*, which prevent the thrust of the cut from shifting it endwise. The steel stationary jaws *C* are held in place by a tongue which is re-



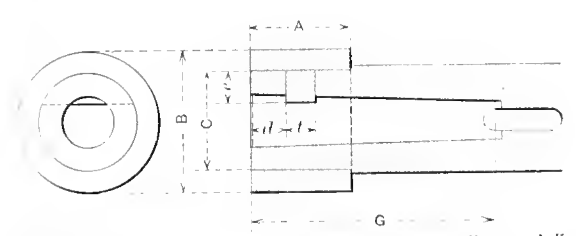
Shaper Fixture for Holding a Bracket

cessed into the jig body, and by the fillister head screws as shown. The steel jaws *D*, which are finished on one end to an angle of 45 degrees, are forced against the work by tightening the cap-screws *G*. The inside ends of the jaws *D* rest upon stationary blocks *F* of solid rubber. Both sets of jaws are hardened, and the working faces are serrated. This forms a very simple but effective way of holding the bracket, as the jaws *D* will have a downward and an inward movement when they are tightened, which, with the serrated faces, will cause the bracket to be gripped firmly. Jig and Tool Designer.

DRIVE FOR DRILLS AND REAMERS

Recently there have come upon the market several devices that are designed to eliminate the tang troubles commonly experienced in connection with the use of Morse standard

DIMENSIONS OF SOCKET AND KEY FOR MORSE TAPER SHANKS WITH FLAT SIDE



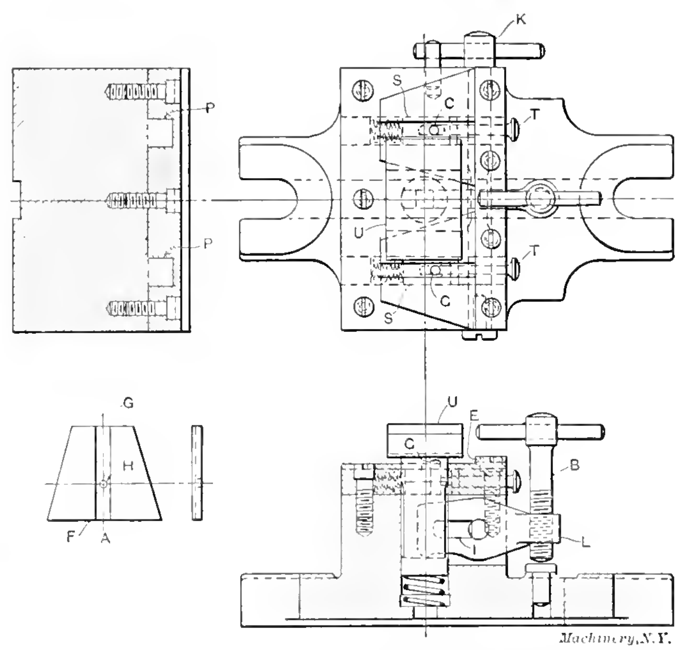
Taper No	A	B	C	G	d	t	e
1	7/8"	1 1/4"	7/8"	2 1/8"	5/16"	1/4"	9/32
2	1 [illegible]	1 3/4	1 [illegible]	2 9/16	1/2	5/16	7/16
3	1 [illegible]	1 3/4	1 [illegible]	3 3/16	1/2	[illegible]	5/16
4	1 [illegible]	2 1/4	1 1/4	4 1/16	1/2	[illegible]	13/32

taper shanks on drills and reamers for severe service. The apparent demand for some method to increase the strength of taper shanks suggests that a device which has been in use for a number of years in the factory where the writer is located, may be of interest. The accompanying engraving and table, taken from the writer's notebook, gives the dimensions of standard Morse sockets fitted with a key, which engages with a flat side on the drill or reamer shank. This key is inserted by milling a slot across the socket near the end, so that the slot will cut through into the tapered bore. A piece of flat steel, or a Woodruff key, is driven tightly into this slot, and then the outside of the socket, including the projecting part of the key, is turned off for a short distance from the end, and a steel collar driven over it. This collar retains the key in place and reinforces the socket. The shanks of the drills and reamers are milled flat on one side so as to fit against this key when driven into the socket. For milling the shanks so they will be interchangeable, master shanks are used, which are put on centers in the milling machine and used to set the milling cutter by. The master shank is then removed and the tool to be milled put on centers and milled with the tool setting obtained from the master shank. The flat on the side of the shank is milled parallel to the axis of the shank. For use in connection with the sockets described, the shanks are made without any tang upon the end, but in all other respects they are made according to the standard Morse tapers. As stated, this device has been in use for a number of years and the results are satisfactory. Bruce C. McAlpine.

Jackson, Mich.

EFFICIENT TYPE OF MILLING FIXTURE

The fixture shown in the engraving was designed to mill the groove *G* in the work which is shown at *A*. This groove is 0.187 inch wide and 0.042 inch deep, and it is necessary that it be central with the hole *H* and at right angles with the face *F*. The fixture was designed to hold two of these pieces at one time. It is composed of a cast-iron base on



Milling Fixture with Efficient Locating and Clamping Devices

the top of which is a steel plate held by fillister-head screws and located by the tongues *P*. These tongues or projections are cut away in the center, and into these spaces are fitted the slides *S* which carry a centering pin *C*, which fits the hole in the work. The slides, by means of the compression springs behind them, force the face *F* of the work against the shoulder *E* thus locating this face at right angles with the feed of the table. When the pieces are being placed over the pins *C*, the slides *S* are operated by the thumb-plungers *T*. The T-clamp *U* holds the two pieces of work, one on each side. It is operated by screw *B* through the lever *L*, and a spring underneath keeps it up when no work is in the fixture. The shaft *K* upon which *L* fulcrums extends through the fixture and it is milled flat on opposite sides at a point where it passes through the lever, to a little less than the width of slot *I*. When this shaft is turned 90 degrees from the position shown, these flat sides are in alignment with this slot and the lever can then be pulled out clear of the clamp so that the latter may be lifted out of the fixture. The advantages of a clamp of this style are that it can be quickly removed, thus making it easy to brush away chips. The milling arbor can also be brought close to the work, thereby allowing the use of small cutters when necessary.

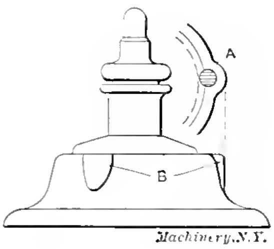
Athol, Mass. W. A. Sawyer.

SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary

HOLDER FOR THE INK BOTTLE



The ink-bottle holder illustrated in the April number of MACHINERY is very similar to one brought out and patented in Scotland some three years ago, the difference being that instead of using a retaining spring to hold the bottle, round india-rubber inserts are used instead. These rubber retainers are inserted as shown at *A*, the bosses *B* on the side of the base being drilled to receive them.

BOTTLE HOLDER.

SCRIBER FOR SMALL HOLES

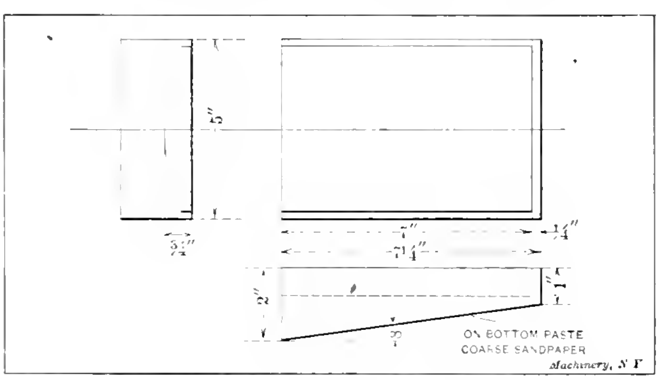
It is sometimes necessary to scribe holes in places where an ordinary scriber cannot be used, as through holes 1/16 inch diameter in a thick piece of metal. I overcame this difficulty by using a jewelers' pin-vise, with a darning needle held in it for a scriber. The darning needles used are about four

inches long and 0.040 inch in diameter. These needles cost five or six cents a dozen and they can easily be replaced when one is broken or dulled. I have shown this scriber to fellow tool-makers, and it is readily adopted wherever shown.

Passaic, N. J. L. ROSENTHAL.

DRAFTING TABLE PENCIL-HOLDER

The pencil holder shown in the illustration may be made of either wood, or aluminum. A very pretty effect is secured by making it of ½-inch strips of maple and cherry alternating. As an eight degree tilt is a convenient one for a table, this holder is made with the same angle so as to keep the



pencils from slipping out. By having sandpaper on the bottom, it can be used on a table that is considerably tilted by turning it around and having the cleat down. Most all draftsmen are subject to annoyances arising from having their pencils and pens scattered all over the table; this holder, as can readily be seen, will remedy that.

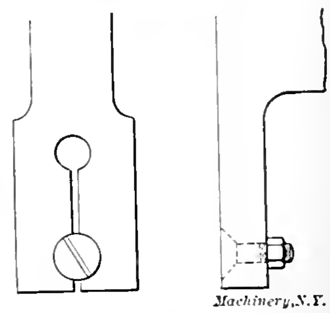
Three Rivers, Mich. E. G. PETERSON.

RESTORING OVER-EXPOSED BLUE-PRINTS

The average drafting office cannot keep a boy constantly making prints, and, consequently, when the boy is started tracing and intends to keep an eye on the printing frame, the print is often sadly neglected. Finding that in time this waste of paper was quite an expense item, we bought a quarter pound of potassium bi-chromate (a reddish crystal), dissolved it in a gallon of water, and placed the solution in a tray beside the wash tank. If a print is overexposed or "burned," it is first placed in this solution and then washed in clear water; in this way we seldom lose a print because of overexposure. It is, of course, possible to so burn a print that it cannot be bleached, but the ordinary burn of from two to ten times the required exposure, responds to the above treatment. The solution keeps indefinitely, if a few crystals and also water are occasionally added when required.

Rochester, N. Y. RALPH W. DAVIS.

ADJUSTABLE SLOT-FINISHING TOOL

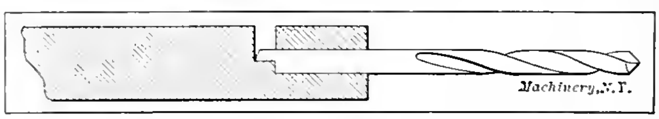


The accompanying engraving, which is self-explanatory, shows an adjustable slot-finishing tool for the planer. When much of this work is done, the dulling of the side edges will, in a few days, cause the tool to cut small, which, when the slots have to be exact, can be only remedied by forging. An adjustable finishing tool like this one will stay out of the blacksmith shop a dozen times as long as a solid tool.

Middletown, N. Y. DONALD A. HAMPSON.

AN EXTENSION DRILL

The accompanying illustration shows a way of making small extension drills, that may be new to some. In the extension rod a hole is first drilled which is a snug fit for the shank of the drill to be used. Then, after measuring the depth of this hole and marking it on the outside of the rod, a slot is filed at the farther side of the mark half way through the extension rod, so that it just meets the bottom of the hole. This slot should be approximately as wide as the diam-



eter of the drill. Next, the shank end of the drill is filed to the center for a distance equal to the width of the slot. After the drill is pressed into the extension rod as shown, it is ready for use. In this way an extension drill can be made much more quickly than by the old soldering method, and after using, it may be easily pulled apart without injury to the drill. CHESTER L. LUCAS.

East Saugus, Mass.

TO REMOVE BROKEN WOOD SCREWS AND NAILS

Perhaps nothing is more exasperating to the amateur wood worker than to have a wood screw break in hard wood just before it is screwed home, or to break off a nail where another nail must be driven. Such accidents are particularly provoking to a machinist. His experience on metal work is not of much assistance to him in overcoming such dilemmas, and to such the following kink is worth description. Secure a brass or steel tube slightly larger than the shank of the broken screw. File teeth in the end and give them the proper set, bending alternate teeth out and in. You thus are equipped with a hollow drill, which can be slightly squared at the other end to fit a carpenter's brace. With this tool the wood surrounding the broken screw can be trepanned out; the hole should then be filled with a plug of the same wood set in glue. After the glue has set a hole can be bored and a new screw can be put in, and no one will be the wiser.

M. E. CANEK.

* * *

The principal buildings, bridges, and other municipal structures of New York will be ablaze with lights during the Hudson-Fulton celebration. All bridges and principal buildings are outlined with rows of eight-candle power electric lights, and 1,500,000 lamps have been strung. The incandescent lights alone amount to 12,000,000 candle power, and will require about 42,000,000 watts or 56,000 horse-power. Beside the incandescent lamps there will be flaming arcs and other lamps of great power. The illumination will continue every night from September 25 to October 9 from 6:30 to 12:30.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

BATH DUPLEX INTERNAL GRINDING MACHINE

An improvement on the duplex internal grinding machine brought out by the Bath Grinder Co., of Fitchburg, Mass., which was mentioned in a note in the April, 1909, issue of MACHINERY, has recently been placed on the market. This improvement embodies a number of new and interesting features which are illustrated in the accompanying half-tones, Figs. 1 to 4 and in the line engraving Fig. 5. This machine is distinctly a new departure in internal grinding machines, and places internal grinding on as practical a basis as that which external grinding has achieved during the last decade.

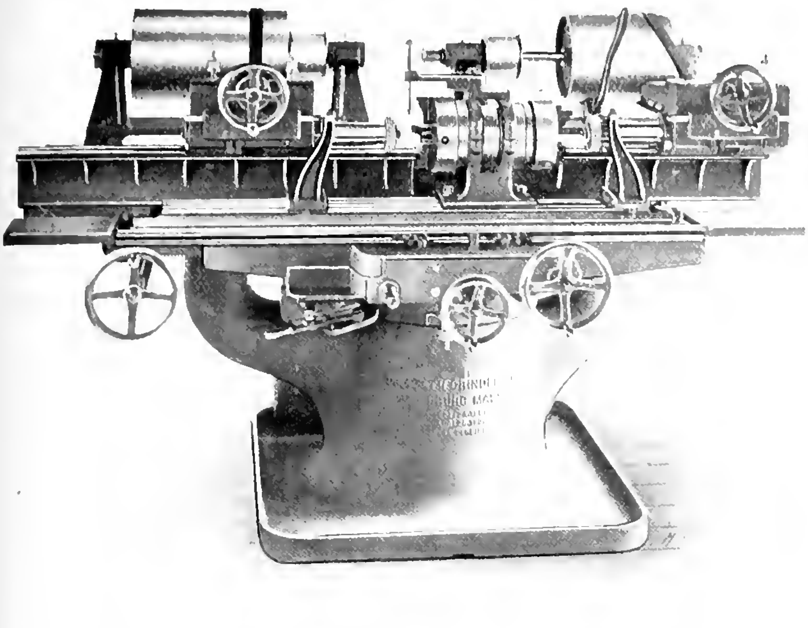


Fig. 1. Bath Duplex Internal Grinding Machine, having Two Wheel-spindle Heads

General Features

The principal advantage of the Bath duplex grinder is that the arrangement of the grinding spindles and the work-holding head or heads makes it possible to gain considerable time in the grinding and gaging of internal work; two pieces can be ground on the machines simultaneously, and it is not necessary to shift the reciprocating slide in order to gage, insert or remove the work. It is possible to use two grinding wheels at once, one operating from each end of the work. It is also possible to use a number of grinding wheels mounted on a supported spindle between the two grinding heads, and to quickly grind the inside of a sleeve or bushing by having one wheel after the other enter the work, the previous wheel, of course, leaving the work before the next one enters. This saves considerable time over the necessity of reversing the reciprocating table for each cut, as is necessary with grinding machines of the common type.

The novel feature which distinguishes this machine, in particular, from other designs, is that the grinding wheels and spindles pass in through the back end of the head-stock spindle as shown in Figs. 2 and 5, instead or running into the head-stock spindle from the front as in other grinders. Internal grinding has commonly been considered as a slow process when a large amount of stock has to be removed, but this objection is effectively overcome by the innovations in this design, and a considerable increase in production has thus been made possible.

Fig. 1 shows the machine set up for grinding bushings held in four-jaw chucks, one chuck being mounted on each end of the head-stock, and the grinding heads, wheels, and wheel spindles being shown one on each side of the head-stock. In Fig. 2 the machine is shown especially fitted up for automobile work, and is set up for grinding the bores of spur gears. In front of the machine on the floor, a variety of work that has been ground on this machine is illustrated.

The spur gear standing on its face in front of the machine is one of the pieces being ground at the moment in the machine. In this case, two head-stocks are mounted on the table, the spindles of these head-stocks being 8 inches in diameter. The object of the large head-stock spindle is to make it possible to grind large work, up to 6 inches in diameter, by holding it inside of the chuck spindle, thereby absorbing and eliminating the vibration and the twisting stresses when the wheel is brought against the work.

In front of the machine to the left of the handwheels is shown the reverse lever. This lever, by being turned one-quarter of a revolution, automatically stops the machine at the end of its stroke, and also reverses the reciprocating slide. The operator does not need to wait to operate the lever until the slide reaches the end of the stroke, but can turn the knob at any time during the stroke at the end of which it is wanted to stop the machine automatically. When the machine is stopped, the end of the work in one of the head-stocks is exposed to view, and is in position to be gaged instantly. To gage the work held in the opposite head-stock, the reverse lever is pushed over, which brings the other head in position to gage. The general relation of work and spindles is plainly shown in Fig. 5. The distance between the two head-stocks is sufficient so that when one of the spindles is in the position shown with the wheel to the right just projecting through the work and head-stock, the work in the other head-stock can be easily removed and a new piece of work mounted in position for operation. It will be also noticed that considerable time is saved by this construction when gaging the work, as it is not necessary to move the reciprocating slide away from the head-stock in order to measure the size, as is

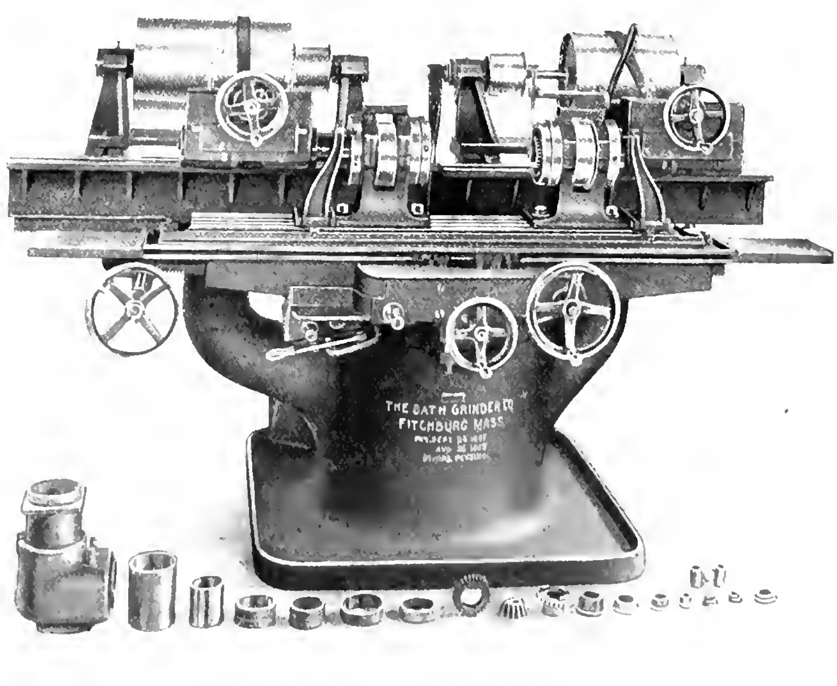

Fig. 2. Bath Internal Grinder Specially Equipped for Automobile Work

required in internal grinding machines of general design; the time consumed in measuring two pieces of work is practically no more than that required for measuring one in a single-spindle machine.

Head-stock and Spindle Heads

The head-stock spindles are driven directly from a drum counter-shaft, the same as in ordinary grinding machines, the only difference being that one belt is, of course, required for each head-stock. The grinding-wheel spindles are driven by a belt from drums provided directly on the machine as shown, the shafts on which these drums are mounted being provided with small pulleys driven directly from the counter-shaft. Thus the complete machine is driven by a two-piece counter-shaft, one for furnishing the power for the wheel-spindles and one for the head-stocks, in a manner similar to that of the ordinary type of grinders.

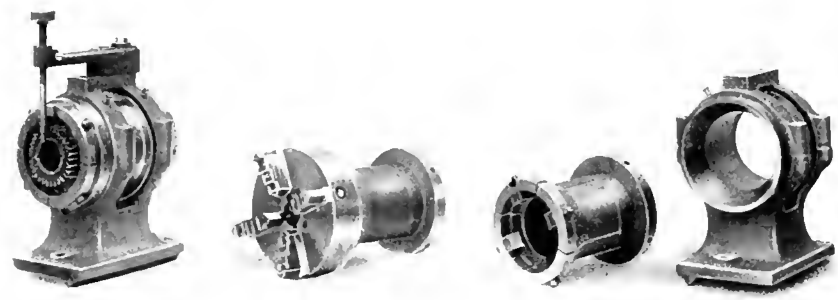

Fig 3. Assembled and Dismounted Head-stock and Parts

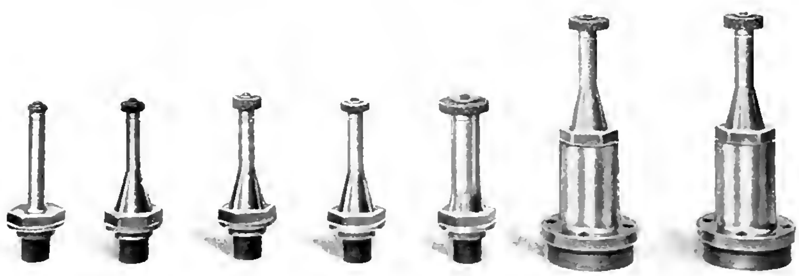

Fig. 4. A Set of Grinding Spindle Extensions for the Duplex Grinder

Each of the grinding-spindle heads is provided with an automatic sizing feed so that the wheels can be fed up to the work independently of one another. The automatic feeds are operated by hinged arms which come in contact with the ends of square rods on the head-stock, thus causing the automatic feed to be operated the same as the power automatic feed on grinders in general. Each spindle-head has a sizing device so that each slide can be set to remove a predetermined amount of stock, and when the required size has been reached the automatic throw-out arrangement disengages the feed. An adjustment is also provided for the variation in the diameter of the wheels.

The spindle-heads are carried on two long narrow slides instead of as formerly on one wide slide. On account of this construction the wheel-head is much more rigidly mounted and the deflection commonly met, due to the pressure of the grinding wheel, is largely eliminated. The narrow slides on which the spindle-heads are carried are mounted on a beam so that the spindle-heads can be placed in position longitudinally instead of moving the head-stock or vice versa.

In Fig. 3 are shown the two head-stocks shown in Fig. 2 with one of the head-stocks disassembled to show the method of holding the spring chucks. The four-jawed chuck is mounted in the same manner. At the outer end of the spring chuck there are four hardened steel jaws, which are detachable and which can be changed according to the diameter or size of work; special chuck jaws may also be furnished for holding either bevel or spur gears on the pitch line. The jaws are ground on the machine so that they are absolutely true with the spindle. The head-stocks shown in the illustrations are for straight work only, but swivel head-stocks of the type shown in Fig. 5 are furnished if required, so that straight or taper work can be ground, the tapers being set at any angle required. As the heads are entirely independent of one another, a straight hole can be ground in one head while a taper hole is being ground in the other. A traveling diamond is mounted on the top of the head-stock for truing the wheel whenever necessary.

The reciprocating slide is run at a speed of from 2 to 12 feet per minute. It has five changes of speed and is operated by a gear box underneath the cross-slide on the left-hand side, as shown in Figs. 1 and 2, and is controlled by a single lever.

Grinding Spindles

In Fig. 4 is shown a set of seven grinding spindles. The set of two spindles at the right, shown mounted on the extension arbor, are the two spindles shown in use in Fig. 2. The other spindles complete a special set furnished for automobile work, having lengths and diameters to suit the work to be ground. The extension arbor is attached to the wheel-head by fillister-head screws. Into this extension is threaded the secondary extension provided with a hexagon head on its end. This extension contains the bearings for the spindle proper, which revolves inside and which is driven from the main spindle by means of a projecting key or tongue on the end, engaging

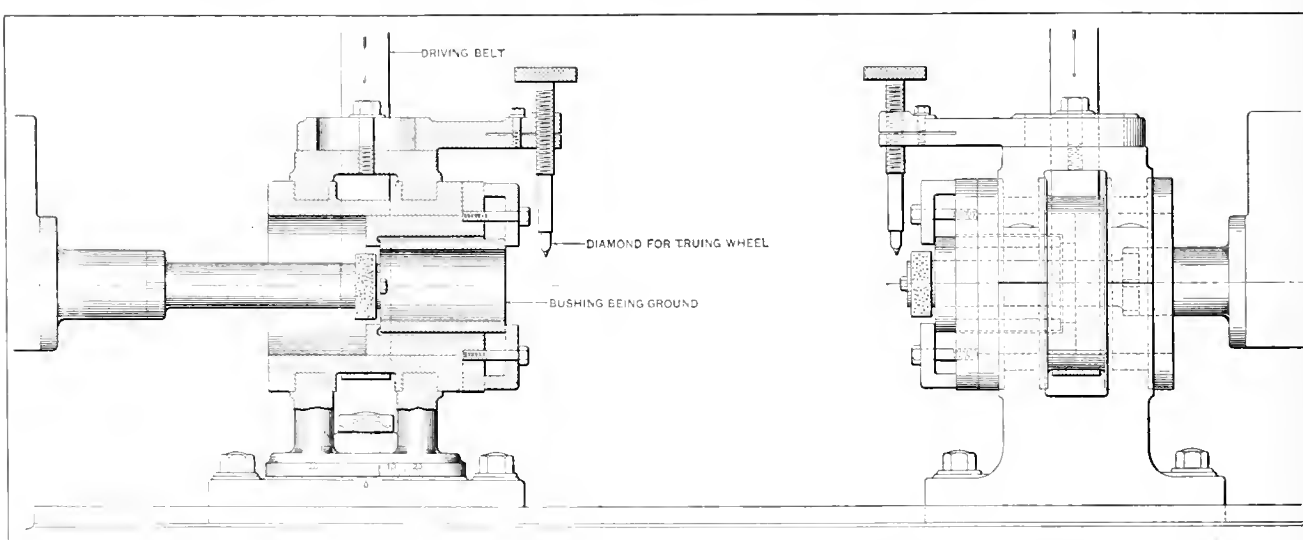

Fig. 5. Section and Elevation of Head-stocks and Work and Relation of Head-stocks to the Grinding Wheels

into a square slot in the end of the main spindle. The hexagon head on the secondary extension is a feature which was provided for special reasons. In changing these spindles, the operator of the machine many times loses the spanner wrenches, and to avoid inconvenience, a monkey-wrench can be used which at the same time assures that the spindle will be tightened up firmly.

The machine is also furnished with a supported spindle that can be mounted at each end in the spindle-heads and on which can be mounted from one to six grinding wheels. For example, in grinding a bushing 2 inches long, the wheels would be spaced apart the length of the bushing, and all six could pass through the bushing before being reversed. Another method that can be advantageously used is to hold the work to be ground in the spring collet and use the two single-ended grinding wheels brought up together and grinding at the same time, removing the stock within 0.001 or 0.002 inch of size. After this is done, one of the wheels can be stopped and the hole finish ground with a single wheel. Still another method advantageously used on this grinder is to employ a coarse wheel on the one head for roughing and a fine wheel on the other head for finishing the same piece of work. Parts like those for pneumatic hammers which have four bearings to be ground concentric with each other can be ground without reversing the work when once mounted, and the work can be gaged from either end of the chuck.

The amount of power consumed by the grinder is 2.7 H. P. By means of a brake provided, it is possible to stop the machine in four seconds with the belts at full speed. The machine in general has been rigidly designed so that it is possible to use larger and wider wheels and remove a larger amount of stock than with former designs.

Some examples of the capacity of the machine may be interesting. Some manganese car wheels having a bore of 3⅛-inch, 6 inches long, were ground in 55 minutes each, removing 5/32 inch of stock with a single spindle from a rough-cored hole. A 15/16-inch hole, 1¾ inch long, can be ground in two minutes with a single spindle removing from 0.006 to 0.008 inch of stock.

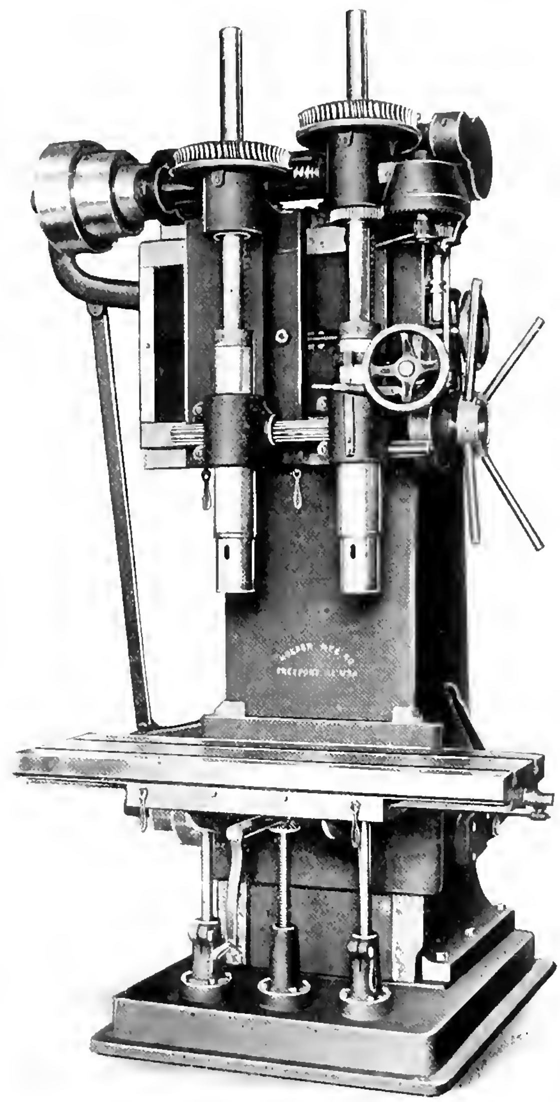
HOEFER VERTICAL TWO-SPINDLE CYLINDER BORING MACHINE

Considerable attention has been given by the Hoefer Manufacturing Co., Freeport, Ill., to the requirements of automobile manufacturers for a satisfactory cylinder boring machine. Such a machine must be able to finish the work both rapidly and accurately, and in order to accomplish these two objects the company has designed a very heavy two-spindle vertical automobile engine cylinder boring machine, an illustration of which is shown in the accompanying engraving.

The two heavy spindle heads are gibbed to a short stiff cross-rail. The right-hand spindle is solidly bolted to the rail and doweled with taper pins, while the left-hand spindle is adjustable by means of a screw operated by a hand-wheel, this adjustment providing for the variations in center distances in different sizes of engines. Tapered holes are provided in the adjustable head so that when jigs have been made for various sizes of engines, these holes can be drilled through into the cross-rail and pins inserted, thus providing positive stops for each size of engine cylinders, and a saving of time in locating the heads for each side.

The bearing of the spindle sleeve is slotted so as to provide for wear. The spindles themselves are made of high-grade crucible spindle steel, chosen with particular regard to its toughness, and are accurately ground so as to minimize the wear and insure the maintenance of accuracy, and are provided with No. 5 Morse taper sockets. The spindle sleeves are bushed with interchangeable phosphor bronze bearings, which can easily be replaced. The thrust bearings are also made of phosphor bronze. The spindles are driven through a pair of large double-threaded worms meshing with phosphor bronze worm-gears, the studs of which are ground and run in copper-hardened babbitt bearings. A substantial key in the driving worm-gear engages in a keyway in the spindle and insures that the drive is ample for any work within the range of the machine. The worms are encased in an oil pan provided with a felt oiler, thus securing sufficient lubrication. An oil pan is also placed under each worm-gear to return any oil to the worm oiling cases. The final drive is obtained through spur gearing and by means of a three-step cone pulley having wide steps for a belt of sufficient size.

A positive gear feed similar to that furnished with the company's regular line of drills is provided. This feed is driven directly from the main spindle, four changes are provided, and the entire gearing mechanism is encased in a feed gear box. The vertical worm is thrown into engagement with the phosphor bronze gear encased in the worm-wheel shell, by means of a small lever directly in front of the operator, and an adjustable automatic stop is provided for the disengagement of the power feed at any predetermined point. A long cross-spindle with teeth cut the entire length drives both spindles uniformly.



Two-spindle Vertical Automobile Engine Cylinder Boring Machine, built by the Hoefer Mfg Co., Freeport, Ill.

The table is made exceptionally deep vertically, to give it the necessary stiffness, and prevent springing when jigs are clamped to it. The bearings in the saddle are large, and proper provision is made for lubrication, the oil holes being in the front of the machine for convenience in oiling. The traverse of the table is obtained by means of a coarse lead-screw or by a rack and pinion, according to the requirements of customers. The table is gibbed to a rigid knee, which besides having ample vertical depth, is also provided with two supports in addition to the elevating screws. The bearings are wide both in the saddle and on the column, and stout ribs resist the twisting strains brought to bear upon the knee when the table is heavily loaded and at the end of the travel.

The method of operating the machine is very rapid and simple. Four units of two cylinders each can be placed in a properly designed jig, and cylinders Nos. 1 and 3, for instance,

are bored simultaneously. Then the table is moved over and cylinders Nos. 2 and 4 are bored. While the process of boring these cylinders takes place, cylinders 5, 6, 7 and 8 are placed in position in the jig. As soon as the work is completed on the first set of two units, the table is set over so that cylinders Nos. 5 and 7 can be bored, and then Nos. 6 and 8. Meanwhile new cylinders are placed in the jig on the opposite end of the table. Thus a practically continuous process of boring is made possible. The method, as described, insures great accuracy in the alignment of the bores.

The total height of the machine from the floor to the top of the column is 110 inches, and the maximum distance from spindle to table 39 inches. The maximum distance from center to center of the spindles is 19 inches, and the minimum 9½ inches, the distance from the column to the center of the spindle being 12½ inches. The vertical feed of the spindle is 19 inches, and the feeds per revolution of spindle are 0.062, 0.125, 0.187 and 0.250 inch. The size of the table is 18 x 56 inches, and the floor space 52 x 58 inches. The net weight of the machine is 8,000 pounds.

THE COIT TWENTIETH-CENTURY BALL-BEARING DRILL CHUCK

The drill chuck shown herewith is made by the Standard Machinery Co., Mystic, Conn. As may be surmised from a study of the parts, shown disassembled in Fig. 2, it is of the type in which the jaws are tightened on the drill by the resistance required to drive it. There is thus no possibility of its slipping, as the drive is proportioned to the work required of it.

The chuck consists, as may be seen, of a taper shank or mandrel (forming an integral part of the tool), a knurled shell or jaw holder free to revolve on the mandrel against a

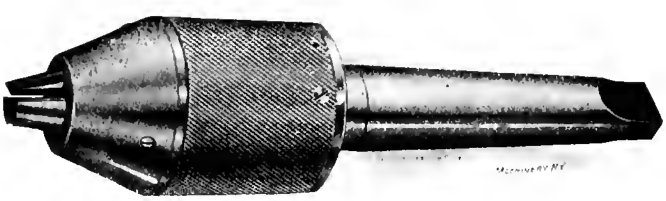


Fig. 1. Coit's Ball-bearing Drill Chuck, made by the Standard Machinery Co., Mystic, Conn.

ball thrust bearing, a collar provided with slots for the heads of the jaws, and the jaws themselves. The parts, it will be seen, are few, simple and of strong design. In operation, the turning of the knurled sleeve of the assembled chuck with its jaws, rotates also, on the threaded mandrel, the collar in which the heads of the jaws are contained. As the collar is thus screwed in or out on the mandrel, the jaws are screwed in or out of the chuck, and thus released or tightened on the work.

The use of a right-hand thread on the shank makes the chuck self-tightening for a right-hand drill. If the drill is barely caught in the jaws, the moment it strikes the work, resistance to turning is offered, and the rotation of the whole chuck sleeve and jaw is arrested. This screws the collar out on the mandrel, pushes the jaws forward, and thus tightens the grip. Any increase of resistance, accompanied by a corresponding slippage of the sleeve, is met by an immediate strengthening of the hold.

In spite of this positive drive, the operator can release the drill with a gentle twist on the knurled sleeve. This easy release is made possible by two things: first, the use of the ball thrust bearing; and second, the small diameter of the thread by which the adjustment is effected. This small diameter reduces the friction, and thus prevents jamming the chuck, no matter how strong the drive. It is, in fact, the practice of the workmen, in using this chuck, to insert and remove drills while the spindle is running, at all except the highest speeds.

Attention should be called to a number of points in the general design of the chuck. The end of the mandrel has a bearing in the sleeve, making a stiff unyielding journal for the turning of the one on the other. The jaws seal the only possible entrance for grit and chips into the interior, which is thus protected from injury and wear. One application of oil will last almost indefinitely. The mandrel is a part of the chuck, and is sold as such, so the expense of making it is saved. It will be furnished with any suitable taper, or with a straight shank. The separate jaws can be removed or inserted without taking the chuck apart.

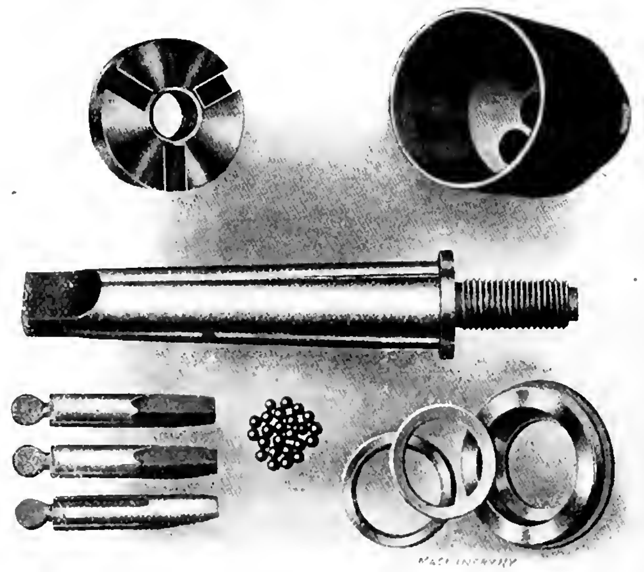

Fig. 2. Chuck Disassembled, showing Parts and Simplicity of Construction

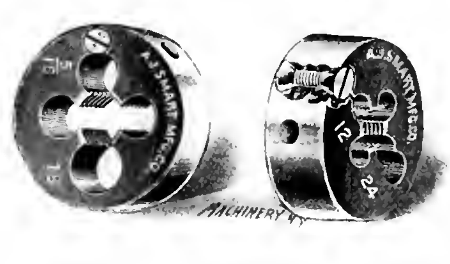
Perhaps the most valuable feature of a tool of this kind is the saving of the drills. Since there is no slip, the shanks are protected from marring and stripping, and their useful life is greatly lengthened. It is possible to drill to a reasonable depth also with an old, short drill, as a very short drive in the chuck jaws does as well as a longer one.

These tools are made with great care, to judge from what can be seen on a visit to the factory. Special pains are taken to make them accurate and interchangeable. Five sizes comprise the complete line, ranging as follows: No. 1, 0 to 13/64 inch; No. 2, 0 to 21/64 inch; No. 3, 0 to 17/32 inch; No. 4, 1/16 to 3/4 inch; and No. 5, 5/16 to 1 inch.

SMART ROUND ADJUSTABLE DIE

The accompanying engraving shows the design of a line of improved round adjustable dies made by the A. J. Smart Mfg. Co., Greenfield, Mass. The dies are sawed through on one side as usual, while the opposite side is drilled out and spring tempered, leaving but a small portion of the metal. As seen from the illustration, the adjustment of this die consists of a taper-headed screw, provided with the required de-



Round Adjustable Die of Improved Design, made by the A. J. Smart Mfg. Co., Greenfield, Mass.

gree of taper to insure a quick and positive adjustment. This screw enters into a cone-shaped nut of the same taper as the head of the screw. When the screw is turned to the left, the head will rise relatively to the nut and the spring temper causes the die to close, thus making it cut a smaller size. By turning the adjusting screw to the right, the screw enters further into the nut, and on account of its taper head, it spreads the die open so that it will cut a larger size. One of the principal advantages of this die is that it can be adjusted from the face without being removed from the holder in which it is used. These dies are made with 13/16, 1, 1 15/32, 1 1/2 and 2-inch outside diameters.

NEWTON TWO-SPINDLE LOCOMOTIVE FRAME DRILLING MACHINE

The accompanying half-tones, Figs. 1 and 2, illustrate a new design of two-spindle drilling machine recently brought out by the Newton Machine Tool Works, Inc., Philadelphia, Pa. This machine has been designed with the object in view of giving it sufficient range and flexibility of operation for work on parts for all sizes and types of locomotives, and is, in addition, particularly adapted for drilling the holes in locomotive frames.

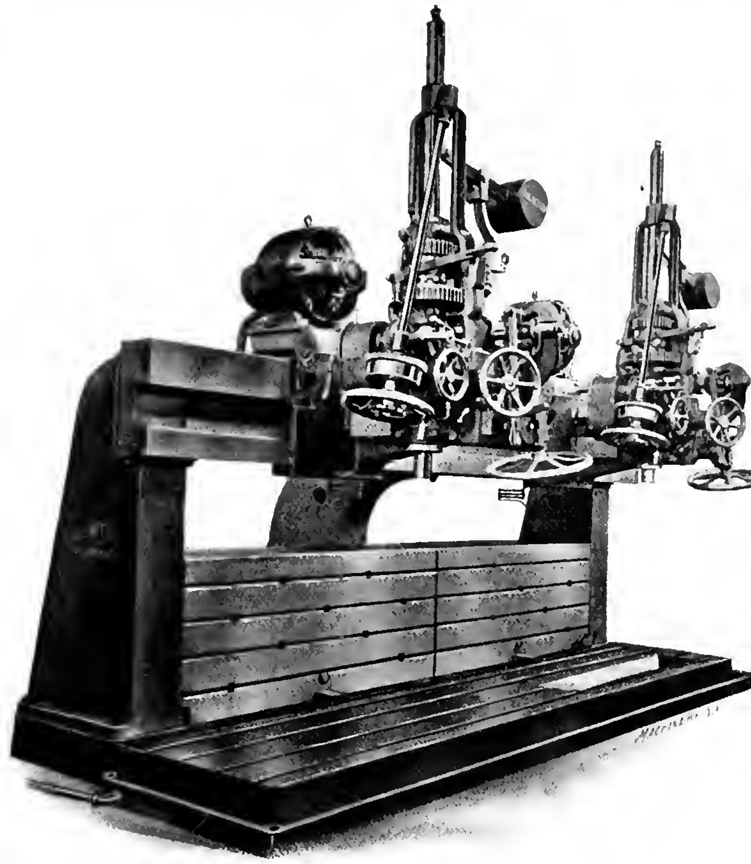


Fig. 1. Front View of Newton Two-spindle Locomotive Frame Drilling Machine

The spindles of the two drilling heads are 4 inches in diameter, and have an automatic geared feed of 18 inches, and a vertical adjustment of the same amount through direct connected gearing for the fast hand traverse, and through a worm and worm-wheel operated through a friction clutch for the slow hand adjustment. The range of the spindle speeds is from 28 to 456 revolutions per minute, and four changes of feed are obtainable, being, respectively, 0.0078, 0.0126, 0.0156, and 0.0225 inch per revolution of spindle. The spindle sleeves have a length over-all of 48 inches. The lower part of the sleeve bearing is in the head or saddle proper for a length of approximately 28 inches; this eliminates all unnecessary overhang. The spindle sleeve revolves in brass bushed bearings of ample dimensions, and the top of the sleeve is supported in brass bushed bearings in the rack sleeve yoke.

A departure from the common design of the driving mechanism lies in the fact that the spindle sleeve carries the clutch gears by which it is driven, and also the clutch for their engagement. The spindle is counter-weighted and is provided with a roller thrust bearing at the bottom of the rack sleeve. It is provided with a taper hole to take No. 5 Morse taper shank. Fast reversing traverse is provided for the saddle on the cross-rail by means of a double train of bevel gears and a clutch. A horizontal adjustment of the saddle is obtained by hand by means of the hand-wheels shown at the bottom of the arms in Fig. 1. The minimum distance between the centers of the two spindles is 4 feet, and the maximum distance 15 feet.

The spindles are driven by individual 10 horse-power electric variable speed motors, the speed variation being from 300 to 1,200 revolutions per minute. The motion is transmitted from the motor shaft to the horizontal driving shaft by spur gears. On the driving shaft is mounted a double train of bevel gears, and from here the power is transmitted to the vertical shaft on which the spur back-gears are mounted, giving two changes of speed in addition to the range of speed changes of the motor. The bracket on which the motor is mounted is cast solid with the arm, this giving a very rigid construction, which is, in particular, required when subjecting the machine to the heavy strains occurring when using high-speed steel drills.

As will be seen in Fig. 1, the gears controlling the feed mechanism are mounted in a gear box, the different combinations being engaged by a key controlled by a small hand lever, as shown. Lateral hand adjustment is provided for the spindle saddle on the arm, the range being from a minimum distance of 6 inches to a maximum distance of 24 inches from the face of the cross-rail to the center of the spindle. The arm has two bearings on the top of the cross-rail, these being removable for renewals and provided with brass taper shoes to compensate for wear. The cross-rail is of the box type construction and is of very heavy ribbed section.

The machine is furnished with two adjustable tables for holding the work, each being 30 inches wide by 36 inches high by 7 feet 6 inches long. These tables are of box type construction, having vertical and horizontal working surfaces provided with large T-slots for clamping the work. The machine is also provided with a floor plate, the front part of which is provided with T-slots and which provides for a work table 39 inches wide by 17½ feet long. This work table is entirely surrounded by an oil pan for receiving the lubricant. The bed plate also supports the three heavy uprights which hold the cross-rail. The upright in the center is of special construction in order to permit the two adjustable work tables to be adjusted or moved entirely out of the way, when the lower table is used, as shown in Fig. 1. In Fig. 2 are

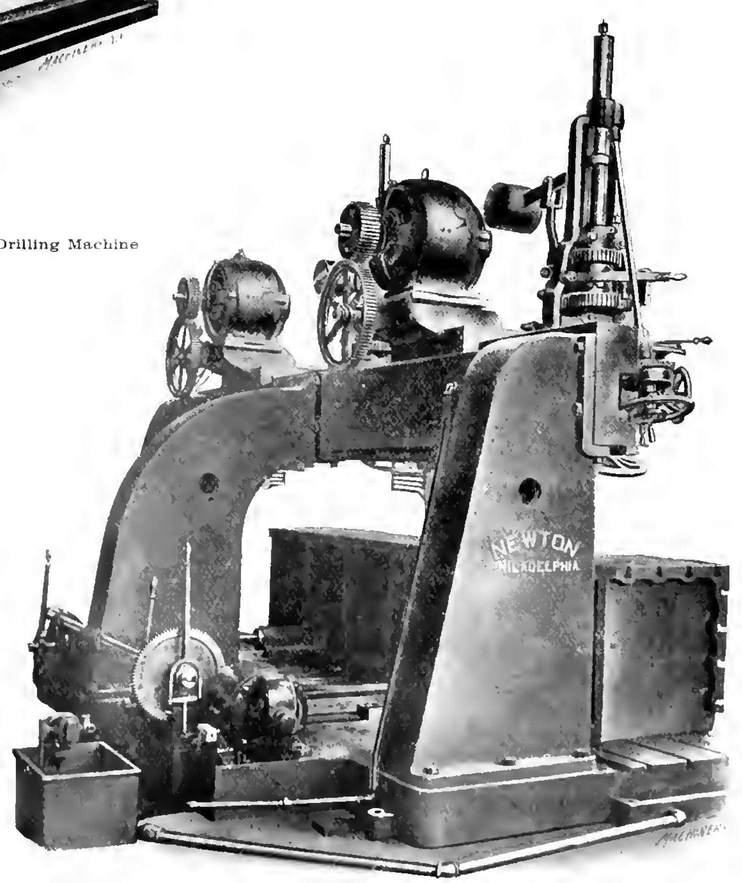

Fig. 2. Rear View of Newton Two-spindle Drilling Machine, showing Motor which operates the Adjustable Work Tables

shown the coarse-pitch screws provided for adjusting the work tables. The motion for this is transmitted through individual worms and worm-wheels from a five horse-power General Electric motor. This design permits of either simultaneous or independent power adjustment of the work tables. A pump, piping, and oil tank are also provided with the machine, as shown in Fig. 2. All bearings on the machine are bronzed bushed, and all gears are made either of steel or bronze.

The drilling mechanism is of the same general design as that provided for the radial drilling machines made by the Newton Machine Tool Works, with which it is possible to drill three-inch diameter holes at the rate of three inches per minute when using a flat twisted drill. Smaller diameter drills can be driven at a much higher rate of speed, in proportion. The maximum distance from the floor plate to the end of the spindle is 81 inches and the minimum distance 64 inches. The machine occupies a floor space of about 19 by 20 feet.

NOS. 3 AND 3A CINCINNATI AUTOMATIC GEAR-CUTTING MACHINES

In the May, 1908, issue of MACHINERY, we described an automatic gear-cutting machine built by the Cincinnati Shaper Co., Cincinnati, O. The making of this machine has since been transferred to the Cincinnati Gear-Cutting Machine Co., of the same city, which has brought out the smaller-sized

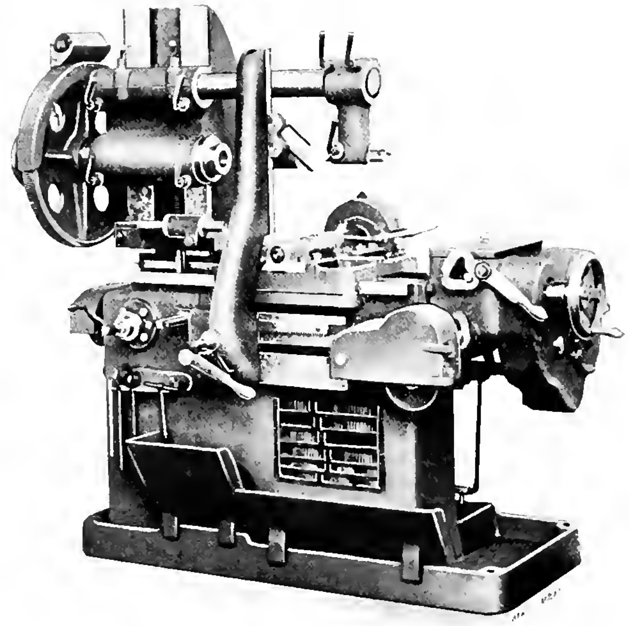

Fig. 1. A New Cincinnati Gear-cutting Machine, of a size well adapted to Automobile Work

tool illustrated herewith. This is made in two heights of column, giving maximum diameters of 26 inches and 36 inches respectively, for gears having any width of face up to 10 inches. It will be seen to be particularly adapted in its dimensions to automobile work, as well as to the general run of small and medium machine work.

The main features of the original design are retained. The machines are noticeable for their strength and simplicity. In the matter of rigidity attention is called to the carrying of the ways for the cutter slide beyond the column, and to the locating of the spindle bearing in the middle of the cutter slide. Fig. 3 shows the cutter slide turned bottom up, and gives a good idea of the construction of the full length taper gibs used. The principle of broad bearing surfaces with grinding surfaces located near together, is employed. The same principle applied to the work saddle prevents it from dropping out of parallelism when the clamps are loosened, to adjust the work to the required depth of cut. This adjustment is effected from the front of the machine, and is provided with a graduated index reading to one-thousandth of an inch.

The dogs for controlling the movement of the feed-slide are adjusted from the front of the machine, being mounted on threaded rods at the rear, connected by bevel gearing with crank-shafts at the front. A retractable tappet for these dogs is provided, so that the slides can be run to the extreme back position, for removing blanks without disturbing the setting of the dogs. There are twelve changes of feed. The cutter slide is fed forward and retracted by a screw, controlled by

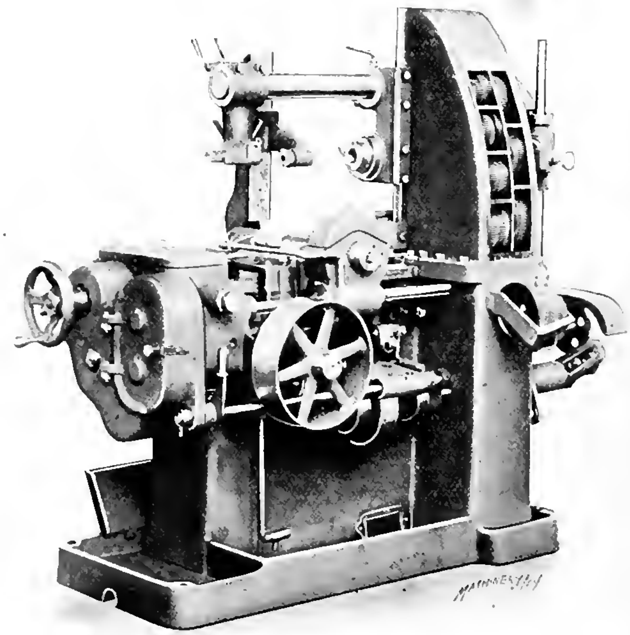

Fig. 2. Rear View of No. 3 Machine, showing Driving Connections

a reversing mechanism which gives a constant return speed, regardless of the feed. Twelve changes of feed are provided.

The cutter spindle shown mounted in its bearing in Fig. 5 is of large diameter, accurately ground and easily accessible for taking up wear. It is mounted in both taper and straight bronze bearings, and is adjustable endwise for centering the

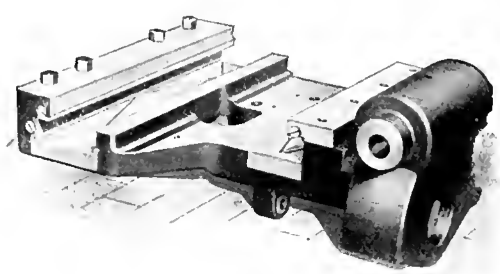

Fig. 3. Cutter Slide Reversed, to show Gibs and Bearing Surfaces

cutter. The drive, as shown, is through a worm and wheel, with means provided for taking up the end thrust of the worm. A removable outboard bearing for the cutter arbor is provided, the latter being drawn into place in the spindle or forced out by a threaded bolt. Six cutter speeds are provided.

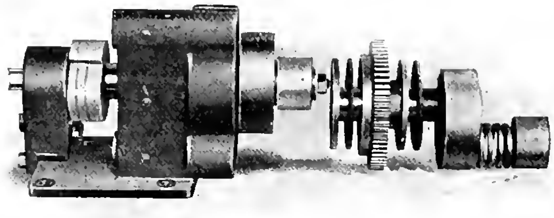

Fig. 4. Friction Stop Mechanism for Indexing; shown Assembled and Dismantled

The indexing mechanism is of unusually simple construction, there being fewer gears in the index train than on any other machine of this type. The motion is transmitted and controlled through a friction operated stop disk, simple and easily accessible. This mechanism is shown in Fig. 4. A spanner wrench is the only tool necessary for adjustment. The index worm can be disengaged from the wheel quickly,

and brought back into the exact meshing depth; or it can be disengaged from the index gears and rotated any desired amount for resetting work, after which it may be again secured. Besides provision for automatic indexing, it may be made to space once or revolve continuously, by a hand movement under the control of the operator. The mechanism is so interlocked with the cutter slide feed that the various movements must of necessity take place in proper sequence, thus making it impossible to spoil work from failure of the mechanism. The change gears furnished cut all teeth from 12 to 100, and all numbers from 100 to 450, with the exception of prime numbers and their multiples.

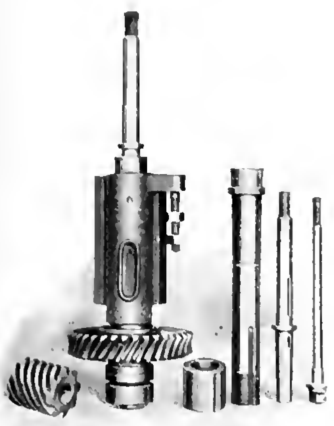

Fig. 5. The Cutter Spindle, its Worm-gear Drive and Axial Adjustment

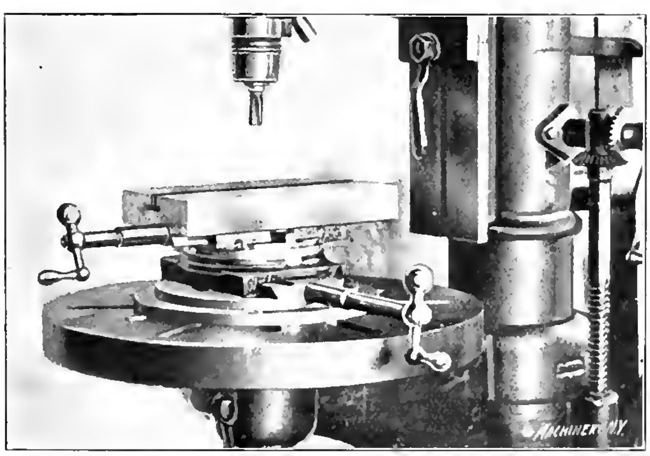
As may be seen, the work arbor is provided with an over-arm work support, in addition to the regular outboard support. The machine is regularly equipped with a counter-shaft, though if desired it will be furnished with tight and loose pulleys mounted on the initial driving shaft. It can also be arranged for motor drive if desired. This is a very simple matter as all the changes of feed and speed are effected by convenient transposing gears.

DAVIS MILLING ATTACHMENT AND COMPOUND TABLE FOR THE DRILL PRESS

The accompanying illustration shows a useful attachment manufactured by the Hinckley Machine Works, Hinckley, Ill., and known as the Davis milling attachment and compound table for the drill press. This device has been designed with a view to furnishing an attachment for the drill press table which enables milling work, particularly end milling, to be done in the drill press advantageously, when the regular mill-



Milling Attachment and Compound Table for the Drill Press, made by the Hinckley Machine Works, Hinckley, Ill.

ing machines in the shop are tied up with other work, or for use in cases where a regular milling machine is not available. The device is simple in its construction and consists of a circular base which is clamped down onto the drill press table. This base is provided with a dove-tail cross-slide for the saddle, which, in turn, carries a swivel slide, the top of which is provided with a dove-tail into which fits the slide of the table proper. Both the saddle and the table are provided with hand feed adjusting screws having ball-crank handles. The swivel slide is graduated in degrees and can be set to any angle. The table is provided with a ½-inch T-slot longitudinally, as shown in the engraving.

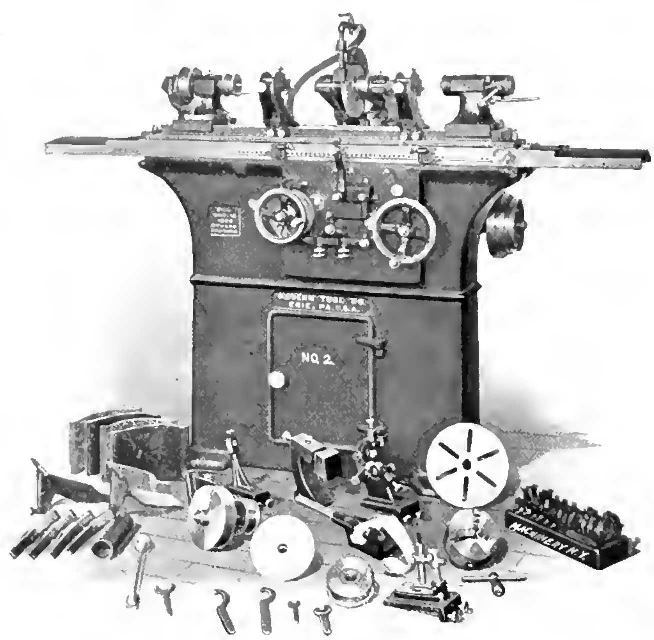
This device should prove a handy attachment for both large and small shops, and in repair shops where a regular milling machine is not available, in automobile garages, etc., it will prove of especial advantage on account of the simple and inexpensive substitute it provides for a regular milling machine.

MODERN UNIVERSAL GRINDER

The accompanying half-tone shows a universal grinding machine built by the Modern Tool Co., Erie, Pa., and designed with a view of placing on the market a heavy and rigid grinder with ample metal for absorbing the vibrations and preventing the ways from springing out of line.

The head- and foot-stock of this grinder are gibbed to the sides of the swivel table, this construction permitting of very large wearing surfaces, and making it possible to compensate for any wear which might occur on the head- or foot-stock. The head-stock is designed to swivel and is provided with a graduated base. The head-stock spindle is hardened, ground and lapped, and runs in phosphor-bronze bearing with means for taking up the wear. The end of the spindle is threaded and has a standard taper hole. Universal rests of new design, of great advantage when grinding long slender work, are furnished with the machine.

The driving and reversing mechanism is completely contained in and supported by a bracket bolted to the outside of



No. 2 Universal Grinder, built by the Modern Tool Co., Erie, Pa.

the machine thus being easily accessible for oiling. If it becomes necessary to take off the bracket, it can be removed by unscrewing four bolts, and the entire mechanism can then be taken to a bench for cleaning or repairs. The wheel spindle is made of tool steel, is hardened, ground and lapped, and runs in phosphor-bronze bearings provided with means for taking up the wear the same as the head-stock spindle.

The table travels automatically, as usual, and is reversed in the common manner, by dogs. The power to the table is transmitted by worm gearing imparting a steady movement, free from jars. The reverse lever is so arranged that the table can be run past the point of reverse without disturbing the adjustment of the table dogs. An automatic cross feed is provided which gives a range of feed from 0.00025 to 0.001 of an inch. The feed can be thrown out automatically when the work has been ground to size. A simple attachment is also provided for fine hand feeds. There is no removable front plate, and the machine is so designed that the mechanism inside the grinder can be removed and replaced if required, without disturbing the alignment of the ways. A diamond tool holder is furnished for truing the wheel.

The machine is made in two sizes, Nos. 2 and 3, respectively. The No. 2 machine swings 9 inches in diameter and takes 26 inches between centers. The table is graduated up to 3½ degrees and 1½ inch taper per foot. This machine takes emery wheels up to 9 inches in diameter and ⅝ inch face. The

weight of the machine is 2,300 pounds, and the floor space required 36 x 94 inches. The No. 3 machine swings 13 inches in diameter and takes 32 inches between centers. The table is graduated up to 5 degrees and 2-inch taper per foot. This machine will take emery wheels 12 inches in diameter, 3/4-inch face, and 9 inches in diameter, 1/2-inch face. The weight of the machine is 4,000 pounds and the floor space required 50 × 125 inches.

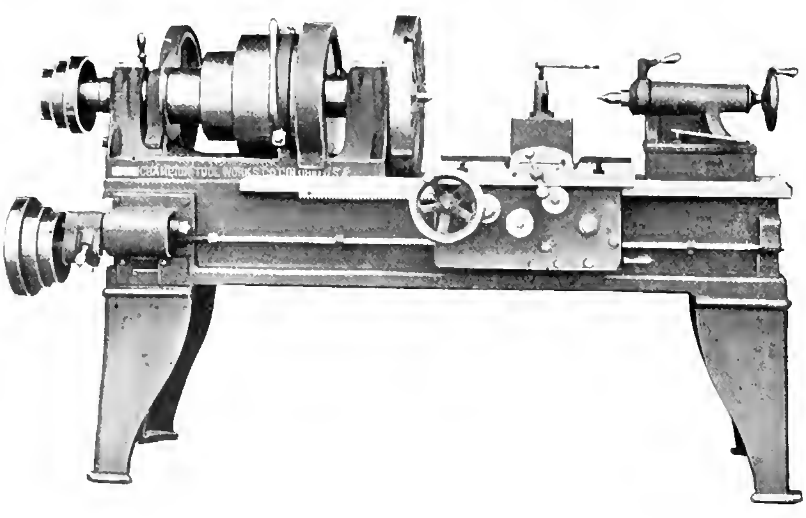
CHAMPION 18-INCH FRICTION BACK-GEARED MANUFACTURING LATHE

The heavy 18-inch lathe shown herewith was built by the Champion Tool Works Co., 2422 Spring Grove Ave., Cincinnati, O., to meet the requirements of the large automobile manufacturers. As may be seen, both drive and feed are belt operated, and the mechanism has been reduced to few but strong parts. No lead-screw for threading is needed or provided. The design has been found particularly successful in heavy manufacturing, requiring rapid reductions.

The spindle is driven by a three-step cone, whose large diameter is 14 inches for a 4-inch belt. The back gears are friction operated, the clutches being of the expansion ring type, operated by a toggle mechanism controlled by the lever shown at the front of the head-stock. This provision allows heavy roughing cuts to be taken at a slow speed, while a reversal of the lever gives the change to high speed for the finishing cut, without stopping the machine. The back gear ratio is 12 to 1. A 1 5/8-inch hole is provided through the spindle.

The feed cones carry a 1 1/2-inch belt. The lower cone is journalled in a swinging frame for tightening the belt, being clamped in position by a screw shown on the under side. An automatic throw-out clutch is provided on the feed rod inside the gear box. It is operative when feeding in either direction, and is controlled by the collars shown on the feed rod, which may be set at any desired point in its length. The feed can be reversed by the handle shown in the lower right-hand corner of the apron.

The lathe is equipped with a heavy plain tool block having power cross-feed. The tool used has a section of 5/8 inch by 1 1/4 inch. The machine swings 19 1/4 inches over the bed, and 13 1/4 inches over the carriage. With a 6-foot bed, it takes 24 inches between centers. The countershaft is driven by 5-inch belts running over 12-inch pulleys, provided with full 12-inch diameter rim frictions. The net weight of the machine with the 6-foot bed is 2,500 pounds.



A Heavy, Simplified 18-inch Lathe, adapted to Rapid Reduction Work

KERN 15-INCH DRILLING AND TAPPING MACHINE

The attractive looking tool shown herewith is a new product of the Kern Machine Tool Co., 4657-4659 Spring Grove Ave., Cincinnati, O. It is especially designed to handle light drilling and tapping in an expeditious manner, being so proportioned and contrived as to combine strength, ease of manipulation and accuracy.

As a drill press, it combines the features expected in a machine of the sensitive type. By a very ingenious provision six spindle speeds are obtained with very little complication.

An Ingenious and Effective Combination of Sensitive Drill and Tapping Machine

The provision for doing this makes use of the tapping attachment, as will be understood from a study of the engravings. The counter-shaft mounted on the rear of the machine carries a three-step cone pulley belted to a mating pulley on the jack-shaft at the top of the machine. A double quarter-turn belt connects this with a large and small pulley, either of which may be engaged with the drill spindle by the operation of a friction clutch controlled by the vertical lever shown hanging down at the front of the machine. Owing to the difference of diameter of these two pulleys, it is evident that the three speeds obtained by the cones can be doubled, giving six, by connecting either the slow forward or fast reverse pulley with the spindle. The fast reverse speeds, however, would run the drills backward. To obviate this difficulty, a positive clutch is provided on the jack-shaft, by which it may be connected to either one of the quarter turn pulleys, making either of them the driver, while the other revolves idly. By this means the spindle may be reversed independently of the regular tapping attachment handle, so as to make the three fast reverse speeds available for drilling.

As a tapping machine, the tool would seem to have unusual advantages. The spindle pulleys are driven by a continuous belt, insuring a steady drive. The frictions are self-adjusting, allowing any tension to be put on that the operator may desire. The driving of the spindle by friction clutches minimizes the danger of breaking taps, since they may be so set as to permit the friction to slip, well within the breaking strength of the tap. The arrangement also permits a rapid starting, stopping and reversal of the spindle without shock or jar, whether in drilling or tapping work. An adjustable screw for the specially made endless belt is provided to increase or lessen its tension as required.

The drill has a total height of 79 inches, or of 99 inches

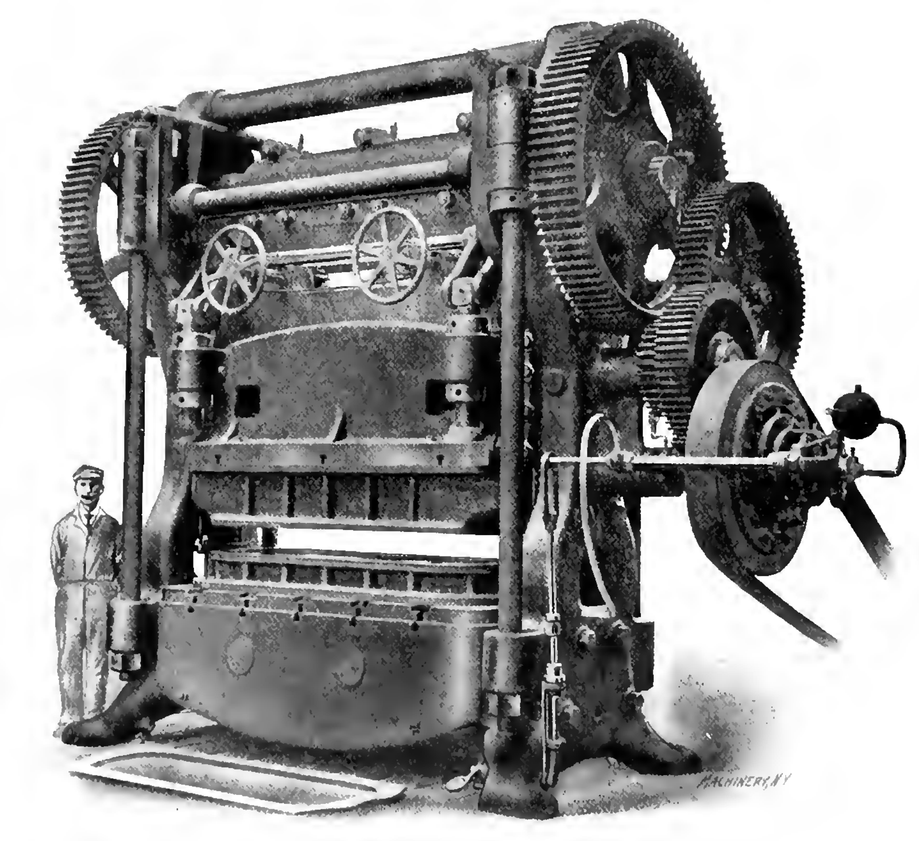
with the spindle extended. The spindle, which is counterbalanced, has a movement of 5½ inches. A driving socket for No. 2 Morse taper is provided. The table is 12½ by 14 inches, and is of the square type with a surrounding oil groove. The machine is also provided with a cup center and V-block. Both table and head are vertically adjustable on the column of the machine. The machine drills to the center of a 15-inch circle. Its net weight is 425 pounds.

FERRACUTE DOUBLE-CRANK TOGGLE-JOINT DRAWING PRESS

Presses for drawing seamless sheet metal shells are commonly designed with an outer ram or blank-holder, and an inner ram or plunger, thus making a double-acting press, as distinguished from the single-acting press which has but one ram. The outer ram may be held in position after having been moved down by various mechanical devices. The method most commonly used is to employ cams on the main shaft, and for certain shapes and sizes heavy springs are employed. A better and more modern device, however, is the use of a toggle- or knee-joint, which enables the pressure between the blank-holding surfaces of the dies to be taken more directly by the frame. This obviates the loss of power resulting from friction when the pressure is sustained by the crank-shaft. The press shown in the accompanying illustration is built on the toggle-joint principle, and has recently been placed on the market by the Ferracute Machine Co. of Bridgeton, N. J. It was designed by Mr. Oberlin Smith, president and mechanical engineer of the company.

The frame of the press is massive. The trussed bed, rests on shelves in the columns, to which it is securely bolted; each column is reinforced with two 4½-inch steel rods as shown in the illustration.

The ram and plunger have each an adjustment of 6 inches. The ram is adjusted by means of the round nuts shown in the engraving, and the plunger by means of the hand-wheels. The crank-shaft is forged from high carbon steel, and is 10 inches in diameter. It is reinforced by the long pitman-strap which unites the shaft and the plunger, the connection being made by two pitman stems. The latter are threaded and made to revolve simultaneously when adjusted by means of a shaft provided with two bevel gears. A link-belt joins the hand wheels, so that both revolve in the same direction when one is turned.



Double-crank Toggle-joint Drawing Press of Large Dimensions, built by the Ferracute Machine Co.

Two yokes, one on each side of the press, are attached to the plunger. These yokes have a vertical motion of 15 inches, the same as the stroke of the plunger. On the extensions of the middle toggle pins, rollers are provided, guided in slots in the yokes, the toggles being thereby straightened out at each stroke. The upper ends of the toggles are attached to the columns, and the lower ends to the outer ram.

The stroke of the outer ram is 6 inches, the plunger, as already mentioned, having a 15-inch stroke. The distance between the two columns is 100 inches, and the depth of the bed from front to back is 48 inches. The size of the hole in the bed is 60 inches by 18 inches. The distance from the bed to the outer ram at the top of the stroke, and in its extreme adjustment, is 32 inches, and to the inner ram or plunger, 35 inches.

The press is provided with triple gearing, the total ratio of which is 75 to 1; all gears are machine cut. The back-shaft is of unusually large diameter, and the large gears mounted on the main shaft are of the same size at each end, which relieves the shaft from torsional stresses. These gears are 5 feet in diameter and have a face 10 inches wide. The fly-wheel is 40 inches in diameter and has a face 7 inches wide, and runs at an average speed of 500 revolutions per minute. This gives a speed of from 6 to 7 strokes per minute to the press. A friction clutch is provided by means of which the ram may be stopped at any given point of its stroke. In the illustration the press is shown equipped with a positive knock-out.

The weight of the press is 91,000 pounds, the height being 13 feet, the width 16 feet and the length or depth 7 feet. The pressure exerted is 500 tons. It is designated by the makers as "Press SA175."

LE BLOND HEAVY-DUTY LATHE EQUIPPED FOR CRANK-SHAFT WORK

The heavy-duty lathe built by the R. K. Le Blond Machine Tool Co., of 4609 Eastern Ave., Cincinnati, O., described in the New Tools department of the September, 1909, issue of MACHINERY, was intended to produce a high output in a wide range of machine work. A modification of this design has been developed by the builders to meet the requirements of manufacturers who have large quantities of duplicate lathe work, but are unwilling or unable to invest their capital in attachments which, for them, would be useless.

The changes made in this simplified design (known as the "heavy-duty automobile lathe") relate, as may be seen from Fig. 1, principally to the spindle drive and feed mechanisms. The head-stock remains the same as on the machine previously referred to, with the exception of the back gearing. Two back gear ratios are provided as before, but the change from one to the other is made with a sliding key operated by the hand lever directly in front of the driving cone. This replaces the double friction clutch arrangement used and found necessary for quick changes on a general purpose tool.

The quick change gear box is replaced by one giving four rates of feed. The changes are obtained by sliding gears operated by the crank handle shown at the front of the box. The four changes are doubled by a reversible compound gear arrangement on the end of the bed, thus giving the operator a choice of eight geared feeds covering a wide range. As before, the apron is double walled and built of a single box section casting. The lead screw and split nut are removed, however, along with the quick change gear device.

The lathe is shown equipped with a set of tools of a type which has recently come into favor for automobile crankshaft work. The tools are best seen in Figs. 2 and 3, where a crank (in the rough, except for the two end journals) is having its four crank pins squared and turned. The device consists, as may be seen, of a special chuck, a tail-stock fixture, a double tool carriage and an automatic stop mechanism on the apron.

The crank-shaft is held in a split bearing in the chuck by one of the turned end journals, and is driven by the V-shaped jaw which is screwed down on the first crank arm. This jaw pivots at its back end, and is fitted with a spiral spring under the clamping screw to facilitate chucking. This work holding fixture is carried on a scraped slide on the face-plate, to which it is attached by a clamp and an adjustable gib. It is accurately positioned for the two crank centers by a hardened steel locking pin entering hardened steel bushings in the face-plate, after which it may be securely locked in position by the two T-bolts. A counter-weight is provided on the back of the face-plate which is fitted with stops for its two positions, thus enabling the operator to counterbalance the crank in either position practically simultaneously.

The other end of the crank-shaft is clamped at the turned journal in a split bearing in the tail-stock fixture. This fixture carries two hardened and ground bushings which are spaced the exact center distance of the crank throws; these bushings are alternately used as journals on the special tail spindle.

The tail-stock carries immediately in front of the main spindle, an auxiliary spindle, which is spaced the same distance apart as the journals in the fixture. This auxiliary spindle may be readily withdrawn by the lever shown on the tail-stock and serves a double purpose. In addition to affording a convenient means for changing the tail-spindle from one bearing to the other, it provides a means for accurately locating the tail fixture with relation to the crank throws when chucking. The alignment of the crank is accomplished by this auxiliary spindle in connection with a locking pin shown under and behind the face-plate (see Fig. 3) which enters a bushing in the head-stock.

The carriage is clearly shown in Figs. 2 and 3. The tool blocks are cast in one piece on a long slide which is mounted directly on the carriage. The rear tool block carries two tools set the proper distance apart for turning out the fillets, while the front block carries a round nose tool for removing the stock between the fillets. The movement of these tools is controlled by the stops shown on the slide, which enable the operator to duplicate diameters.

The longitudinal feed of the apron is controlled by the multiple stop-bar shown on the front of the bed in Fig. 1. The notches in this bar, which are spaced the same distance apart as the throws on the crank, engage a stop lever on the apron. In operation the carriage is, in turn, run up against each of these stops, bringing the back tools into exact position for turning out the fillets. The carriage is then returned, the front tool is run in, and the automatic feed is engaged. When the stop lever strikes the notch on the bar it operates a clutch on the feed rod and automatically throws out the feed. For crank-shaft work the stop bar is made as here shown to reduce the setting up time. When this feature is applied to a regular lathe, the stops are made independent, so that they may be set at any desired point within the range of the carriage travel.

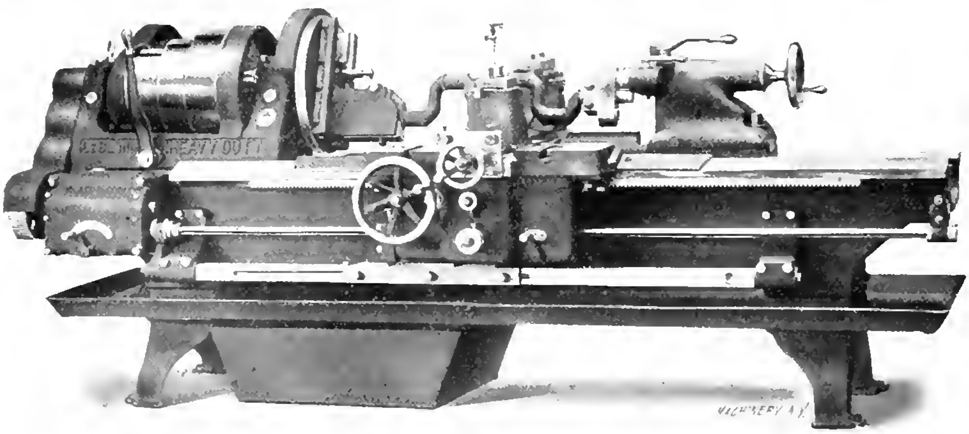


Fig. 1. Le Blond Heavy-duty Lathe arranged for Crank-shaft Work

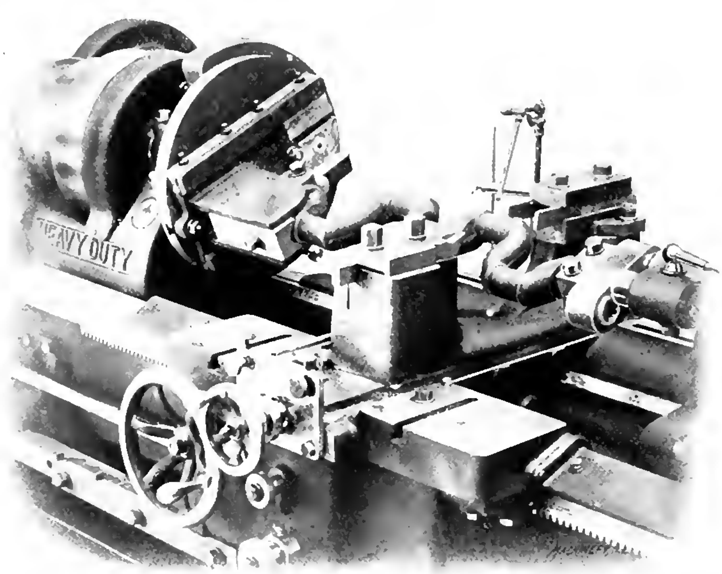

Fig. 2. Detail View, showing Special Holding Device and Tool Stops

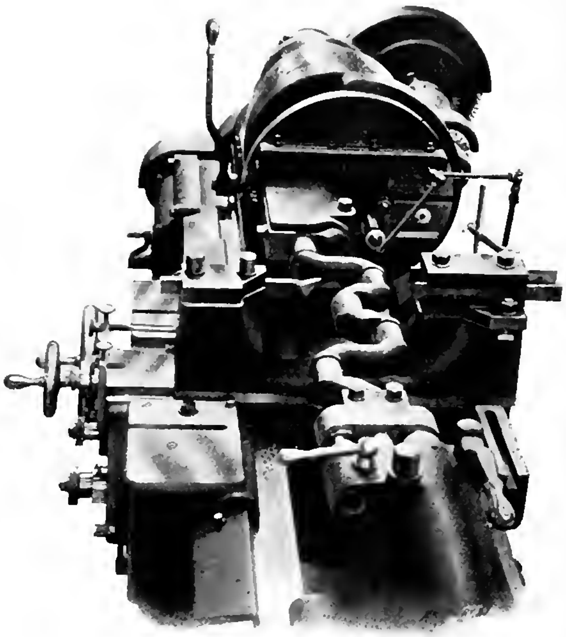

Fig. 3. The Arrangement of the Tools for Cutting the Fillets and Turning the Crank-pins

This construction affords a convenient method for turning shafts with a number of shoulders, and the manufacturers claim that on many classes of work it gives a higher production than the more complicated and expensive turret machinery, usually installed for such work.

This simplified form of heavy duty lathe is built in 16, 18 and 20-inch swings. The machine shown in the accompanying illustrations is the 20-inch size.

BERTSCH COMBINED MULTIPLE PUNCH AND SHEAR

The framework and operating mechanism for a multiple punch and for a gate shear resemble each other closely, the only difference, practically, being in the cutting tools themselves. Advantage of this fact has been taken by Bertsch & Co., Cambridge City, Ind., to develop a combined machine which has practically the efficiency of a separate tool for either of its combined functions. This combination multiple punch and shear is herewith described and illustrated.

The frame is of the gate type, having a wide cross-head operated by eccentrics at either end. The main shaft bearings are provided with adjustable split boxes; a third center bearing of patented construction is also employed, as shown. The clutch is reliable, positive, noiseless and easily operated. It has steel-faced jaws and a cast-steel switch ring, acting against a hardened steel roller on a vertical steel plunger.

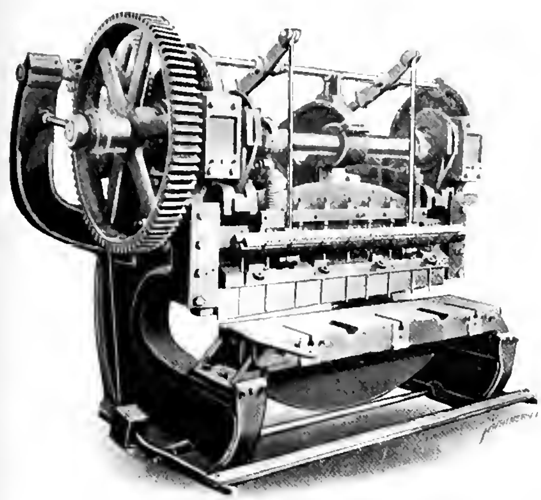

Fig. 1. Combined Punch and Shear as arranged for Plain Shearing

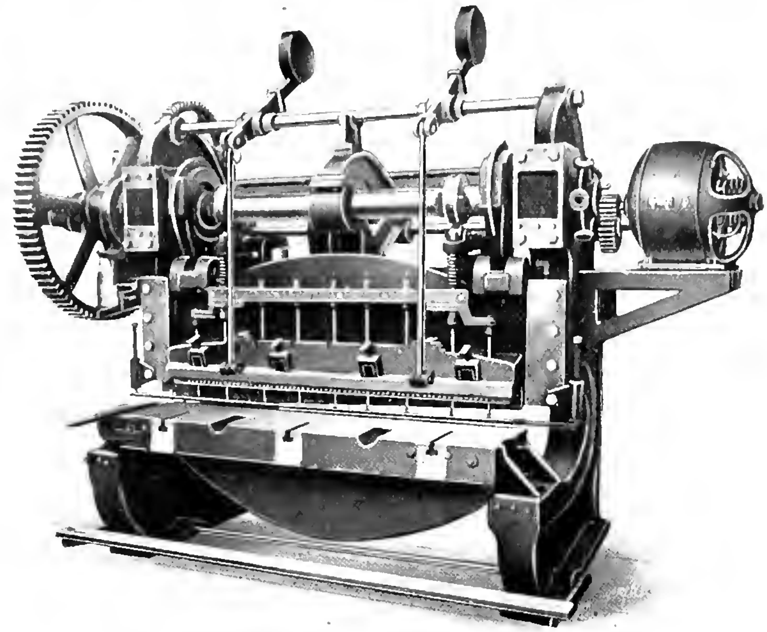

Fig. 2. Combined Machine with Cross-head swung down into Position

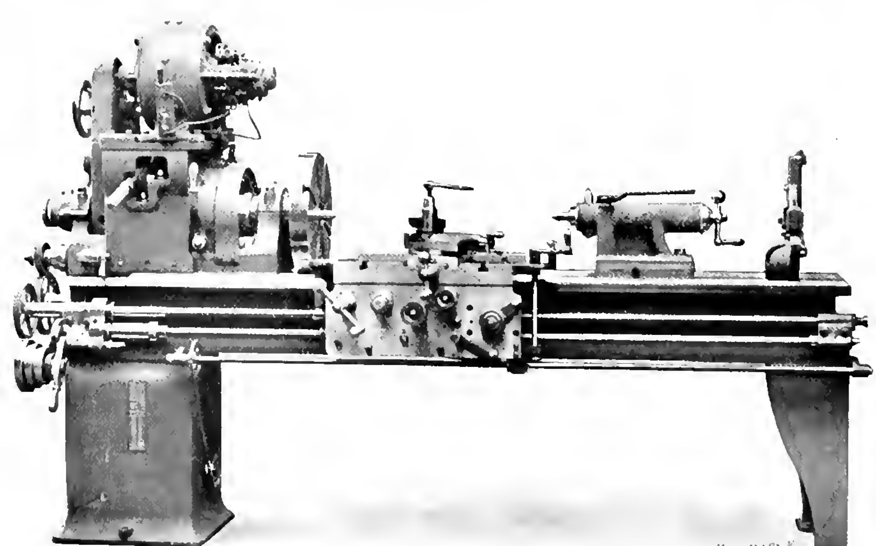
The machine is shown in Fig. 1 set up for use as a shear, and in Fig. 2 with the multiple punches in position. The latter, it will be seen, are mounted on a supplementary cross-head, hinged to the main cross-head, allowing them to be swung down into position or raised at will. Counterbalance weights are provided to facilitate this change. When engaged, this supplementary or punch cross-head is securely locked, and has a square shoulder fit along the entire length of the main cross-head which takes all the strain, none being transmitted to the hinge pins. End bearings are also provided for locating it longitudinally. The punches have either independent or universal adjustment. In the latter case they are set in an adjustable dove-tailed, steel punch-holder bar, so that the entire lot can be removed or replaced together. The punch and shear may be used together for piercing holes and trimming at one operation. The tool may be used as a simple shear as shown in Fig. 2, or as a punch only, with the upper shear blade removed.

A mechanism is provided which operates as a stripper when punching, and as a positive hold-down when shearing. This mechanism is operated by two cams mounted on the main shaft near the eccentrics. These bear down on rollers mounted on rock-shafts connected through the springs and rods shown, with a frame carrying a number of vertical rods. These latter serve as hold-downs for plain shearing work, and are of such construction as not to obscure the vision of the operator. They are of material assistance in safeguarding him when working on narrow strips. These rods also serve to support the stripper bar, as shown in Fig. 2, when punching is being performed.

This machine is made in a variety of sizes ranging from 3 feet to 12 feet in length, and with maximum capacities of 11 gage to ½-inch plate. It will be furnished for either belt or motor drive.

BRADFORD 16-INCH MOTOR-DRIVEN ENGINE LATHE

The accompanying illustration shows a regular 16-inch by 8-foot Bradford engine lathe as built by the Bradford Machine Tool Co., Cincinnati, Ohio, provided with individual motor drive. In applying the motor drive, the head-stock has been practically re-designed and adapted for the special requirements presented. The motor is placed on a frame which encloses the head-stock gearing. This arrangement is of special advantage as it puts the motor in a place where it is out of the way, makes it part of the machine, and at the same time makes it easily accessible to the operator. The connection between the motor and the lathe head-stock is through spur gears. The motor is of the 2 to 1 variable speed type, and as three speeds can be obtained by means of the gearing in the head-stock when the back-gearing is not thrown in, and three speeds with the back-gearing in operation, twelve speeds in all can be obtained. By using a rheostat, any intermediate speed from the lowest to the highest is also obtainable. The lathe is provided with a friction drive for the direct gear speeds, and a positive clutch for the back-gear speeds, and



Sixteen-inch Motor-driven Engine Lathe built by the Bradford Machine Tool Co., Cincinnati, Ohio

either can be thrown in while the lathe is in motion without danger of breakage. The motor speeds are operated by means of the smal lever at the right-hand end of the apron. The controller is inclosed in the cabinet leg of the lathe and is connected through sprockets, a splined shaft and bevel gearing with the lever which is operated over a graduated dial attached to the apron, as shown in the illustration. This arrangement makes all the controlling parts easy of access; at the same time, means are provided for stopping the lathe mechanically if required, independently of the electric equipment.

The lathe is in all other respects the same as the regular type of the Bradford lathes. The swing over the bed is 16¼ inches, the swing over the rest being 9 inches, and over the carriage 10¾ inches. The lathe with an 8-foot bed illustrated herewith takes 4 feet 1 inch between centers. A 1 11/16-inch hole is provided through the spindle. The spindle speeds obtainable vary from 5 to 340 revolutions per minute. The motor is 2 horse-power, but any style or make of motor can be fitted, if required; the speed of the motor can be varied from 600 to 1,200 revolutions per minute. The lead-screw has four threads per inch, and the lathe cuts threads from 2 to 40 per inch, including 11½ threads per inch. The weight of the lathe having an 8-foot bed, as illustrated, without motor, is 2,600 pounds net.

WELLS MOTOR-DRIVEN AUTOMATIC SCREW MACHINE

The accompanying illustrations, Figs. 1 and 2, show an automatic screw machine with individual motor drive, placed on the market by the F. E. Wells & Son Co., Greenfield, Mass. This machine is, in general, of the same design as the regular automatic screw machine built by the company, including the patented method of camming, and independent cross slides. In addition, however, this machine is provided with the advantage of direct motor drive, the power being transmitted through a speed changing device, involving the use of sliding gears, by means of which three changes of speed for the spindle are obtainable. The change gearing is shown in the rear view, Fig. 2. This speed changing device can, of course, also be used for driving the machine directly from a pulley on the main line-shaft by belting directly to the pulley which is now driven from the motor; the same number of speed changes are then obtainable. The advantage of being able to easily change the speed enables greatly increased production on an automatic machine.

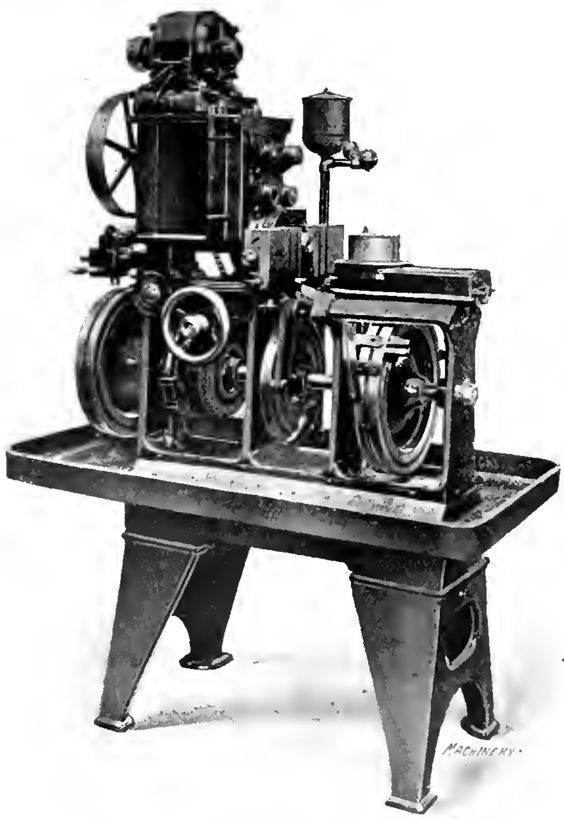


Fig. 1. Front View of Motor-driven Automatic Screw Machine, built by the F. E. Wells & Son Co., Greenfield, Mass.

Another novel feature is the method of transmitting the power from the motor to the main driving pulley without appreciable loss through the slipping of the belt. This method has been used for some years past on some classes of woodworking machinery, but has not been in vogue on metal working machines. Pins are set into the small driving pulley on the motor and the driving belt is provided with small corresponding holes. This prevents the belt from slipping when running over the small pulley, although the center distance between the two pulleys is small and the difference between their diameters marked.

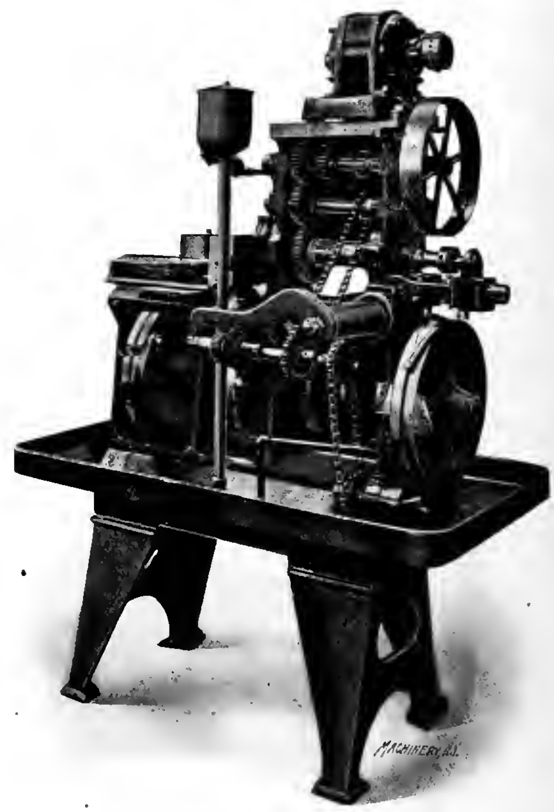

Fig. 2. Rear View of Wells Automatic Screw Machine, showing Driving Mechanism

AMERICAN TWO-FOOT AND THREE-FOOT RADIAL DRILLS

In the April, 1909, issue of MACHINERY, a 2-foot sensitive radial drill, built by the American Tool Works Co., 300-350 Culvert St., Cincinnati, O., was illustrated and described. This machine has proved very popular, and the firm has been forced, on account of the large demand, to bring out special designs of this drill in addition to the original design previously described. In Fig. 1 is shown one of these special designs, illustrating the 2-foot radial drill provided with motor drive and tapping attachment. As will be seen from the illustration, a Lincoln variable speed 3 to 1 motor is mounted beneath the box table. The speeds of the motor vary from 525 to 1,575 revolutions per minute, and the motor is under perfect control of the operator by a hand-wheel shown conveniently placed under the table in front of the motor. The tapping attachment is directly connected with the main belt drive and is controlled by the lever shown at the base of the column. The arrangement of the belting from the driving pulley in the rear at the left-hand side of the machine, to the vertical driving shaft is of particular interest, providing as it does on the one hand a convenient drive in a case where short center distances and the angularity of the drive make the arrangement rather difficult, and on the other a simple drive for the tapping attachment. It will be noted that there are no gears in this drive, either at the base or at the top of the machine, the power being transmitted throughout by belts. Means are provided for regulating the tension of the belts both overhead and below. The frictions in the tapping at-

tachment are of the American Tool Works patented type, and cannot become disengaged accidentally after they have once been thrown in. They are of ample proportions to transmit the maximum power the machine is intended for. The machine has a capacity for high-speed twist drills up to 1-inch diameter, and 1-inch standard taps. It may be fitted with a tapping chuck, making it particularly adapted for tapping small holes. The general design of the machine in all other details is identical with that described in the April, 1909, issue.

In Fig. 2 is illustrated the 3-foot American radial drill mounted on a pedestal base and not equipped with a box table. This type of machine is particularly convenient for drilling a great number of holes in work which can be conveniently moved on a truck, or otherwise, beneath the spindle of the machine. This arrangement eliminates to a considerable extent the handling of the work, and permits of its being moved from the drilling department to the next department with the least possible delay. The machine will be found of particular advantage in automobile and gas-engine manufacturing plants, and it is due to the requirements of manufacturers of this class of machinery that this type has been designed. When drilling with a jig the work can be carried out very rapidly, as the arm is easily swung to any position desired and the head rapidly moved to any point along the arm. A spindle speed as high as 900 revolutions is available, but this may be increased or diminished to suit special requirements. The bearings are all of the ball-bearing type, and the drill will run up to a speed of 2,000 revolutions per minute without signs of distress, but of course no twist drill would hold its edge long at such a speed.

In its general details the design of this machine is identical with the 2-foot drill, excepting, of course, that the dimensions are proportionately larger. The two machines illustrated show interesting examples of the possibility of adapting standard machine tools, built on the unit plan system, to different requirements by simply changing some of the details.

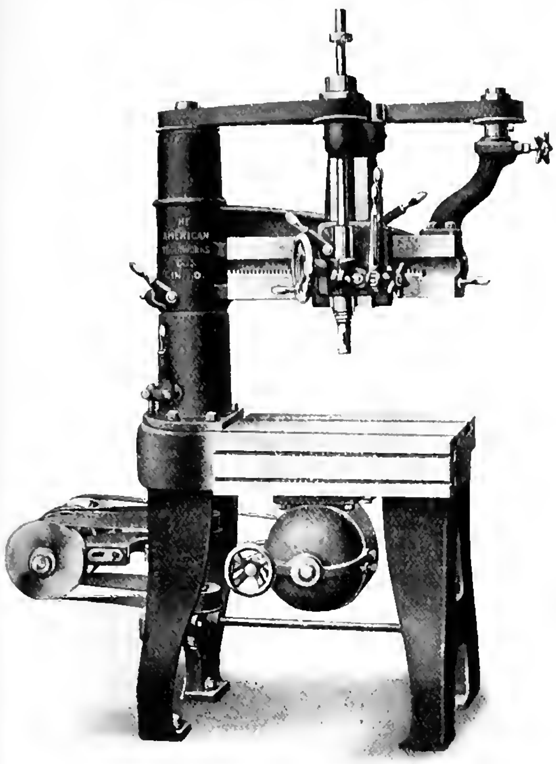

Fig. 1. American Tool Works Co.'s 2-foot Radial Drill with Motor Drive

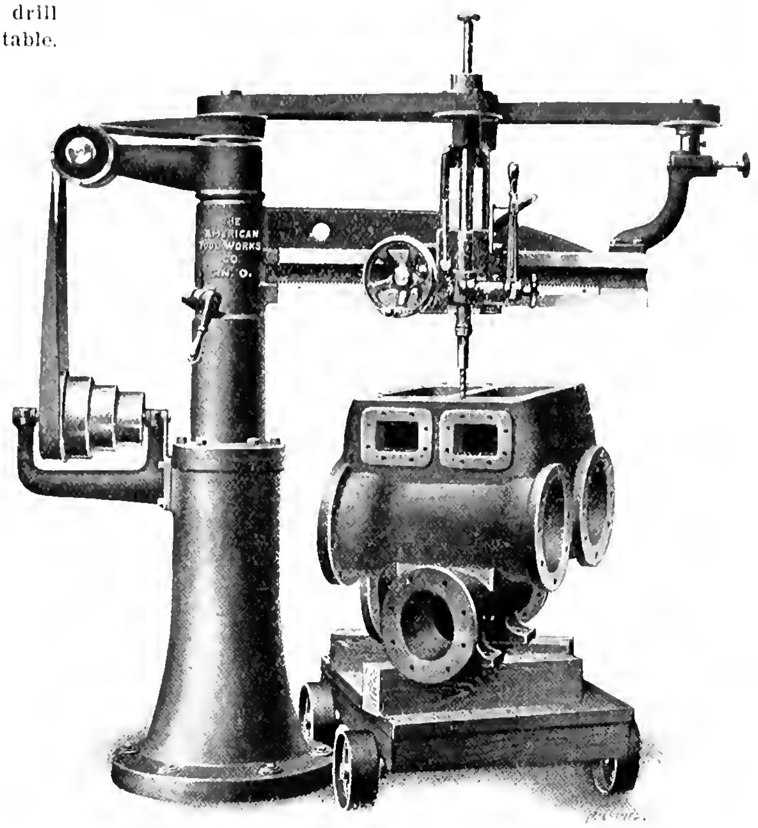

Fig. 2. Sensitive 3-foot Radial Drill, especially adapted for Automobile and Gas Engine Manufacture

DRILLING TEST—AMERICAN SENSITIVE RADIAL DRILL

Diam. of Drill, inches	Speeds		Feeds		Net Horse Power	Remarks

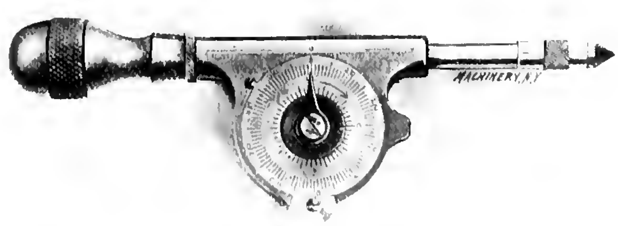
The accompanying table gives some results obtained in drill tests undertaken with this machine. The table gives the diameter of drill, the revolutions per minute, the cutting speed, and the feeds per revolution and per minute, stating as well the horse-power required for driving.

BROWN & SHARPE SPEED INDICATOR

A new speed indicator has been brought out by the Brown & Sharpe Mfg. Co., Providence, R. I. The new indicator is provided with two features which, in particular, will make it valuable. In the first place the indicator is equipped with a dial for registering the speed, on either side of the case. One side is used for ascertaining the velocity of shafts and spindles running in the right-hand direction, and the other side for determining the speeds of shafts running in the left-hand direction. The confusion and errors which are not uncommon when all readings are taken from one dial are thus avoided. The indicator registers revolutions in units, tens



Improved Brown & Sharpe Speed Indicator, with Dials on Both Sides of the Case

and hundreds. The second feature of importance is a small knurled wheel on the side of the case which provides a means for quickly readjusting the device after the reading has been taken. This wheel when turned revolves the disk indexing hundreds back to the starting point. This feature is of value when a series of readings is to be taken, as it saves a considerable amount of time and makes rapid and exact readings possible.

The indicator is small and light and provided with a polished wooden handle. The working mechanism is encased, and protected from dirt and injury by a heavily nickel-plated cover having a dull finish. The point is of hardened steel, and can easily be removed when worn, and replaced if required.

GORTON HEAVY-DUTY CUTTING-OFF MACHINE

A heavy-duty cutting-off machine has recently been placed on the market by the George Gorton Machine Co., of Racine, Wis. As may be seen by referring to the illustration of the machine, Fig. 2, it is exceedingly stocky and rigid in its design, and the aim of the builders has been to produce a tool capable of feeds and speeds heretofore unattainable. The bed and cutter head are both exceptionally massive, and chatter and vibration, which are inevitable in improperly designed machines of this type, have been eliminated. In addition to the rigidity, the large diameter of the main driving gear and the directness of the drive add largely to the efficiency of the tool.

The bed is a one-piece casting, heavily ribbed internally, which has its entire bottom cast solid, thus forming a reservoir for the cutter lubricant. Mounted upon this bed is a heavy cutter slide which contains the large driving gear, shown in Fig. 1, to which is attached the cutter blades and cutters. The cap which forms the upper half of the large drum bearings for this main driving gear, is bolted to the slide as shown. Cast integral with this cap are the brackets for the motor, and at the left are located the bearings for the main driving pinion which meshes with the main driving gear. The pitch diameter of the main gear is 60 inches and its face width $3\frac{1}{2}$ inches, while the pitch diameter of the driving pinion is 5 inches and the face width 4 inches. The driving pinion is forged integral with its 3-inch crucible steel shaft, and the angle of the drive is such that comparatively little pressure is placed on the cutter drum bearings. Attached directly to this cutter drum, which is made of fine-grained metal (25 per cent steel), is the cutter blade of 0.60 carbon steel. This cutter blade fits accurately over ten hardened and ground steel studs which are driven into the drum, and it is additionally secured by ten $\frac{7}{8}$-inch special screws as shown. For belt-driven machines, the driving clutch pulley is mounted directly upon the main pinion shaft. The lever which operates this clutch is seen at the front side of the machine directly over the stock vise. It is connected with the cone which expands the clutch by a rod passing through the pinion shaft, which is hollow. When the machines are electrically driven this clutch pulley is replaced by a clutch gear. The lever by which the clutch is operated is used to start and stop the machine.

This machine is designed for cutting off round stock from $1\frac{1}{2}$ to 6 inches in diameter, and square bars with widths from $1\frac{1}{2}$ to $5\frac{1}{2}$ inches. If necessary, round stock up to 8 inches in diameter may be severed by back feeding 2 inches by hand. The bars are held in the powerful clamping vise shown, which is equipped with hardened tool steel jaws. In addition to this vise there is a trolley for supporting the outer end of the bar. This trolley runs on a track, consisting of two 7-inch channels, which on a standard machine is 22 feet long. If required, special tracks 32 or 42 feet in length will be furnished. The trolley is provided with a positive measuring arrangement which permits the stock to be cut off to the required lengths. When a piece is severed it is forced through a trough at the rear into a truck, onto the floor, with little effort on the part of the operator.

The feeding mechanism on the standard machine is driven by 7-step cone pulleys, and a change of feeds is available which ranges from $1\frac{1}{2}$ to 6 inches per minute. It has been the experience of the makers that this method of driving is preferable to the all-geared drive. The lower cone pulley is connected with a gear-box containing forward and quick return feed clutches which are operated either by hand, or automatically with a positive knock-out at the extremes of the stroke, adjustment being provided for various diameters of stock.

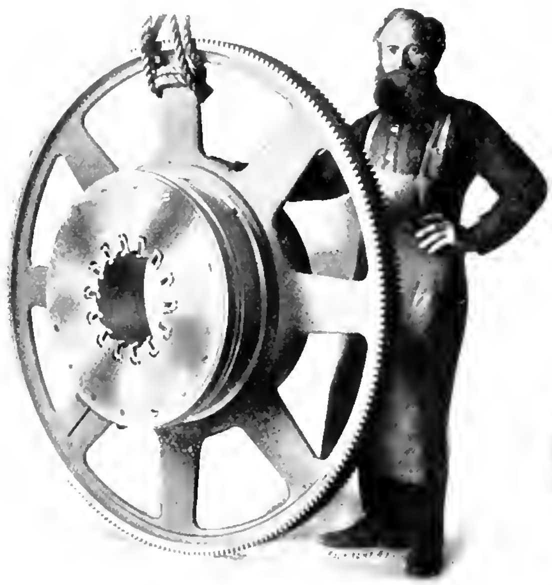


Fig. 1. Main Driving Gear of the Gorton Cutting-off Machine

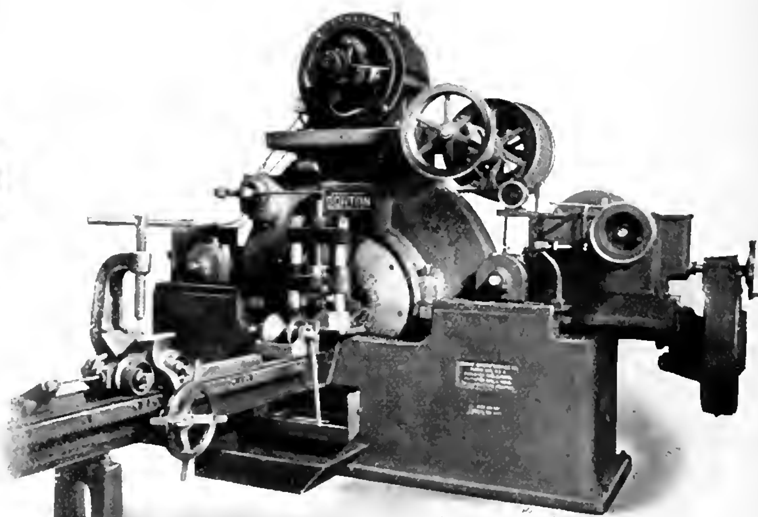

Fig. 2. Heavy-duty Cutting-off Machine, built by the George Gorton Machine Co.

Particular attention has been given to all lubrication details throughout the machine. The large cutter drum bearings which are of lumen bronze and interchangeable are flooded with oil, which is delivered into cored ways on the inside of the upper drum cap. The box-shaped extension for this oil may be seen just above the cutter blade, and in it there is a removable felt pad through which all oil entering the bearings must filter. This provision insures a lubricant which is free from grit. The main pinion bearings are equipped with a ring-oiling device, and are also flooded from the main driving gear. All the mechanism in the upper front gear case operates entirely below the surface of the oil.

Three standard cutter blades of different thicknesses are carried in stock, all of which are interchangeable. One of these blades is 7/16 inch thick, contains twelve 7/16 inch high-speed cutters, and is adapted for work ranging from 4 to 6 or even 8 inches in diameter. For cutting off stock ranging from 2 to 6 inches, a blade $\frac{3}{8}$ inch thick is recommended; this contains fourteen $\frac{3}{8}$ inch high-speed cutters and is the blade furnished with the machine unless otherwise specified. For smaller stock than that mentioned, a blade $\frac{1}{4}$ inch thick is provided

which contains sixteen ¼ inch high-speed cutters. If necessary, even this light blade can be used for severing stock up to 8 inches in diameter, but it will not stand the heavy feeds possible with the heavier blades. With each size of blade a cutter-setting gage is furnished for setting the re-ground cutters uniformly. It requires less than one minute to remove a broken cutter from the blade and replace it with a new one, and the breaking of a cutter while the machine is in use does not injure the blade.

The lubricant for the cutters is delivered by means of a geared pump, shown on top of the upper gear case. As a copious supply of lubricant should be used, the machine is equipped with a nozzle which will deliver a stream about four inches wide and one-quarter inch thick directly onto the saw cut. The chips fall on suitable screens which are contained in the chip pans shown in the side openings of the base. These screens effect the separation of the cutter lubricant from the chips which are raked from them into pans on the floor. All the collars, levers, hand-wheels, yokes, etc., on this machine are of steel, and all the nuts and screws are finished and case-hardened. The parts are all interchangeable, and the makers guarantee the workmanship and finish equal to that of the best machine tools built.

MECHANICS' MACHINE CO.'S 20- AND 26-INCH UPRIGHT GANG DRILLS

The accompanying illustrations show two sizes of upright gang drills brought out by the Mechanics' Machine Co., Rockford, Ill. In Fig. 1 is shown what is known as the 20-inch gang drill. In this, the individual drill heads with their frames, cone pulleys and gearing are mounted on a box column as indicated, the drills being built in gangs of 2, 3, 4, 5 or 6 spindles. Each drill is independent and can be stopped, started, or its speed changed, without interfering with the other drills, each having its own individual counter-shaft, operated through a foot lever, shown in the front of the machine. The work table slides on ways on the main column, and is supported on its edge by adjusting screws as indicated.

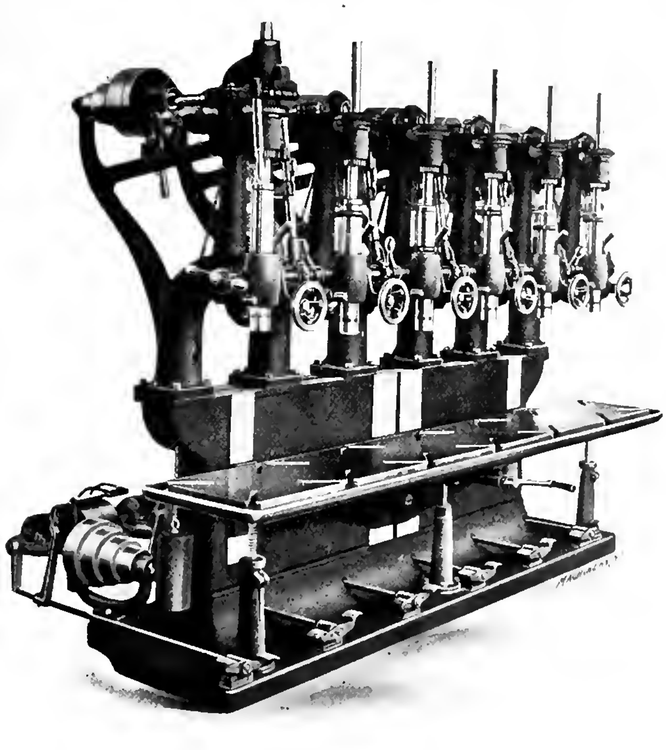

Fig. 1. Twenty-inch Six-spindle Gang Drill, built by the Mechanics' Machine Co., Rockford, Ill.

The maximum height of the drill with the spindle in its highest position is 84 inches, and the minimum height 75 inches. The distance from center to center of the spindles is 16½ inches, and the distance from the center of the spindle to the column is 10½ inches. The spindle, which is provided with a No. 3 Morse taper, has a diameter of 1⅜ inch and a vertical travel of 11 inches, and the spindle speeds are 0.005, 0.008, 0.011 and 0.014 inch per revolution of spindle. The size of the planed surface of the table for a 2-spindle machine is 11½ by 32½ inches, with an additional 16½ inches in length for each spindle added. The vertical travel of the table is 13 inches, and the maximum distance from the spindle to the table is 26½ inches, the minimum distance being 4 inches. The floor space required for the 2-spindle drill is 55 x 34 inches, for a 3-spindle drill 55 x 51 inches, an additional 17 inches in length being required for each spindle added. The weight of the 2-spindle machine is 1,900 pounds net, with an approximate addition of 800 pounds for each spindle added.

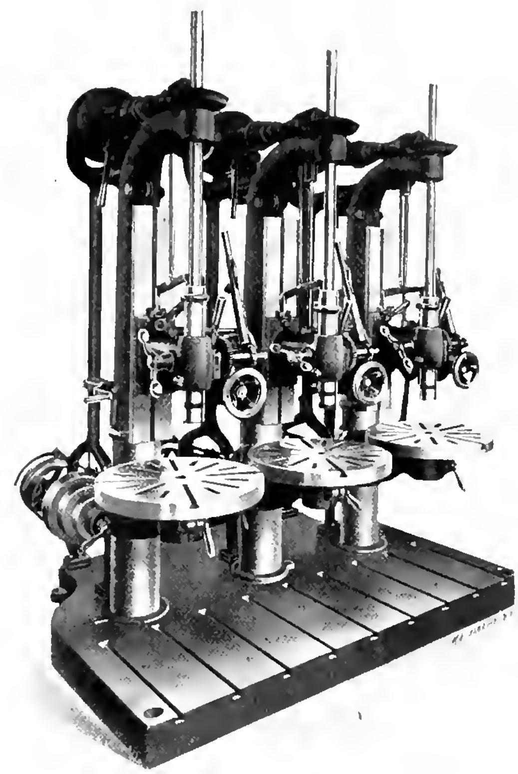

Fig. 2. Twenty-six inch, Three-spindle Gang Drill

The 26-inch gang drill in Fig. 2 is, as shown, of different design, it consisting of several practically complete upright drills mounted on a common base-plate. The design of the individual drills is also different from the design of the smaller drills shown in Fig. 1, these drill presses having sliding heads as indicated in the illustration. The 26-inch drill is supplied in gangs with 2, 3 or 4 spindles on the same base, and is furnished either with the ordinary round tables shown in the illustration, or with square tables having an oil groove or receptacle around the edges. These drills are furnished with back-gearing and positive feed; a geared tapping attachment or friction clutch tapping attachment can be furnished with one or more spindles, as required.

The maximum height of the 26-inch drill press with the drill spindle in its highest position is 87 inches; the maximum distance from the spindle to the base is 50 inches and the minimum distance 17 inches. The maximum distance from the spindle to the individual round table is 37 inches, the spindle being capable of reaching completely down to the table when in its lowest position. The distance from the column to the center of the spindle is 13 3/16 inches, the vertical feed of the spindle is 11½ inches, and the movement of the sliding head is 23 inches. The distance from center to center of the spindles is 24 inches. The floor space required for a drill press with two spindles is 48 by 67 inches, for three spindles 72 by 67 inches and for four spindles 96 by 67 inches. The net weight of the two-spindle 26-inch gang drill is 3,400 pounds, with approximately 1,700 pounds added for each additional spindle. A 24-inch and a 32-inch drill are also made in gangs, the same as the 26-inch drill. The general design of these two sizes is the same as that of the 26-inch drill.

"PEERLESS" PORTABLE ELECTRIC CHIPPING HAMMER

The electric hammer herewith illustrated and described is made by the Cincinnati Electrical Tool Co., 650 Evans St., Cincinnati, O. So far as we know, this is the first strictly electric hammer to be put on the market, there being in this tool no interposition of mechanical or pneumatic mechanism between the ram of the hammer and the source of the current.

The tool receives its current supply from an attachment connected with an ordinary direct current lamp socket. From

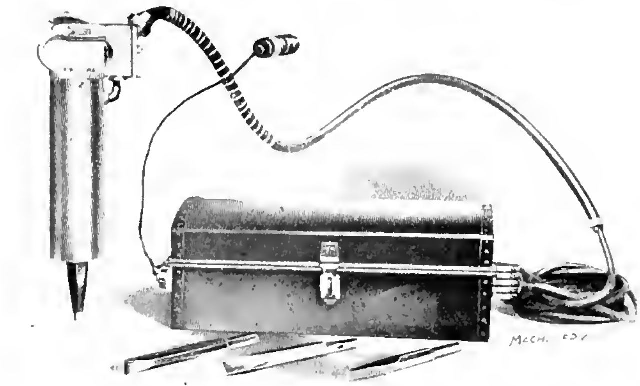

Fig. 1. An Electrically-operated Chipping Hammer, arranged with Lamp Socket Connection

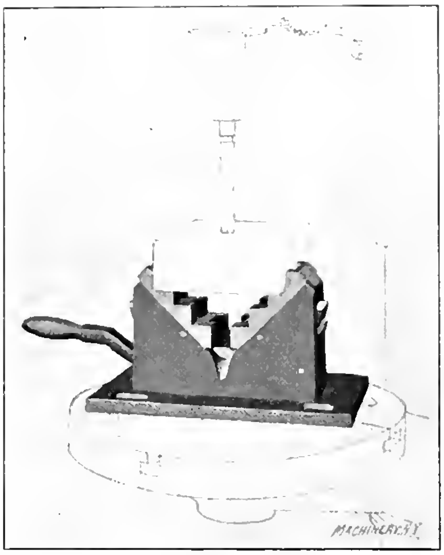
here it is led to the box shown, which contains an automatic switch mechanism for controlling the current movement throught the triple cable leading to a pair of solenoids contained within the hammer casing. When one of these solenoids is energized, the ram is raised; the energizing of the other draws the ram down again. The action of the ram or plunger on the chisel is identical with that in a pneumatic hammer. The same general appearance, and the same style of grip is retained, a switch being provided in the handle of the tool for controlling it in the usual manner.

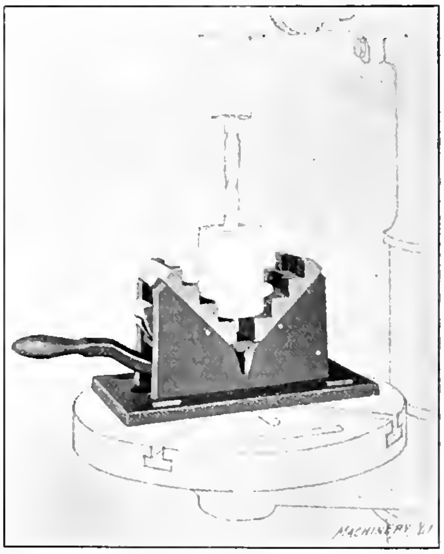
The device is light enough so that it can be carried around the shop by a boy. The box containing the switch weighs 38 pounds, and the hammer 19. The former takes a space of $7\frac{1}{2}$ by 20 inches. The hammer itself is $14\frac{3}{4}$ inches long by $3\frac{1}{2}$ inches in diameter. It will cut armor-plate up to $\frac{1}{2}$ inch thickness.

MITCHELL-PARKS DRILL PRESS VISE

The accompanying illustrations, Figs. 1 and 2, show the general design and action of a new drill press vise brought out by the Mitchell-Parks Manufacturing Co., 612 So. 6th St., St. Louis, Mo., and known as the "Gravity" vise. The device has been designed with a view of producing a drill press vise which would be extremely simple and rapid in its operation and that would, at the same time, hold the work being drilled firmly, and which could be used on work of any size or shape. The whole vise consists of only five parts and is not provided with springs of any kind, nor does it require any special parts for special work. When the handle shown in the illustrations is raised, it brings the jaws resting on the angle guides to which they are fitted, apart. A maximum opening between the upper steps of the jaws of 8 inches and between the lowest steps of the jaws of $2\frac{1}{2}$ inches can be obtained. When the work is placed in position between the jaws, its weight forces them downward along the guides, so that a firm hold is obtained on the work. When the drill enters the work, the pressure of the drill forces the jaws still further downward, and the work is gripped tighter the greater the pressure exerted on it by the drill. The jaws can therefore be said to automatically clamp the work as soon as it is placed in position. At the moment when the drill passes through the work, and the pressure of the drill on the work thus is decreased, a slight pressure on the handle will hold the work tightly so as to prevent turning at this time. Raising the handle will release the work between the jaws.

The vise may be placed loose on the drill press table except in extreme cases. When required, however, it can be easily bolted to the drill press table by means of the slots provided in the base plate of the device. The vise will hold round work from $\frac{1}{2}$ inch up to 8 inches in diameter, and work of other shapes in the same proportion. The size of the base plate of the device is $7\frac{1}{2}$ by 14 inches.





Figs. 1 and 2. The Gravity Vise, made by the Mitchell-Parks Mfg. Co., St. Louis, Mo.

MILWAUKEE SIXTEEN-INCH LATHE

In the June, 1908, issue of MACHINERY a lathe built by the Milwaukee Machine Tool Co., Milwaukee, Wis., was illustrated and described. The accompanying half-tones and line engraving show an improved design of the company's 16-inch lathe, recently placed on the market. In designing this lathe particular attention was given to provide an even distribution of metal, and an effort has been made to place the metal wherever it will do most good. Careful attention has also been given to produce a high-grade lathe as far as materials and workmanship are concerned. The lathe is especially adapted for general manufacturing purposes, it having the strength and power necessary for heavy work, and at the same time provision is made for convenience and adaptability for lighter jobs. The bed is heavier than in the previous designs, and is reinforced throughout with heavy cross ribs. The V's, which are planed at an angle of 45 degrees, have large wearing surfaces. The alignment of lead-screw and feed-rod has been taken care of when planing the bed, the bearing pads for these parts being planed and grooved to templets, the bearings being carefully fitted to the bed.

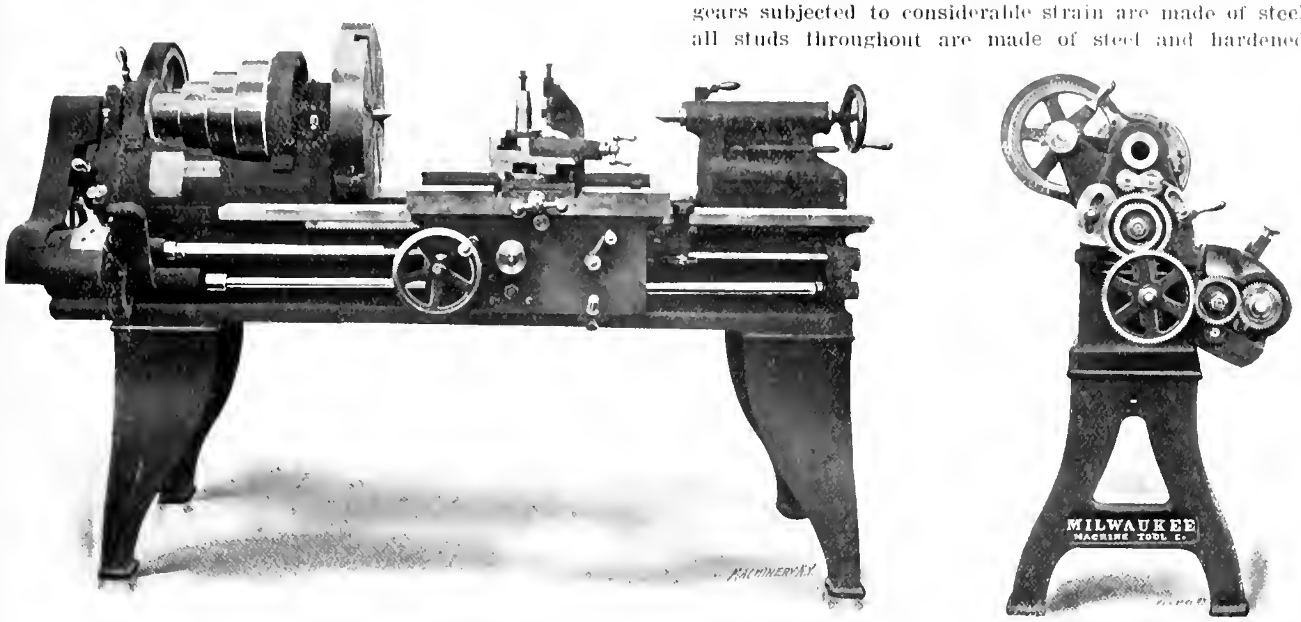
The Head- and Tail-stock

The design of the head-stock has been improved, it being more massive. The cone pulley has four steps instead of five as in the previous design, the width of each of the steps of the pulley having been correspondingly increased in order to permit a sufficient amount of power to be easily transmitted to the machine. The back-gearing is also made correspondingly heavy and of higher ratio. A patented spring cone stop is located in the face-gear and makes it very convenient for the operator when changing from the open belt speed to the back-gear drive. The spindle is provided with a 1 9/16-inch hole through its entire length and is drilled from the solid. It is made from crucible steel containing 0.60 per cent carbon, and is accurately ground. The bearings for the spindle are large, and are made of phosphor bronze and scraped to a bearing by hand. Two large oil reservoirs are located directly beneath each bearing, and the oil is carried to the spindle by means of a wick, which, on the one hand, keeps the spindle constantly wiped free from grit and dirt, and on the other hand affords ample lubrication regardless of speed.

The tail-stock is of correspondingly heavy design and has a long bearing surface on the bed. It is designed so as to permit the compound rest to be turned at an angle of 90 degrees, even when turning the smallest diameters. Screws are provided for setting it over sideways for taper turning, if required. The diameter of the tail-stock spindle is two inches, and the centers are provided with a No. 4 Morse taper.

and both slides are provided with taper gibs for adjustment, thereby avoiding the necessity of manipulating more than one screw when adjusting the gib. Graduated feed collars are provided for the feed screws for both the cross-slide and the compound rest.

The apron is carefully brazed and is tongued-and-grooved into the carriage and securely bolted to it. All pinions and gears subjected to considerable strain are made of steel, and all studs throughout are made of steel and hardened and



Figs. 1 and 2. Side Elevation and End View of Milwaukee Machine Tool Co.'s Improved 16-inch Lathe

ground, except in such cases where bronze bushings are provided. The rack is of steel, and cut in one piece. A safety locking device for the half-nuts is one of the features of the lathe.

The lathe is also furnished with a thread chasing dial, a feature which should be greatly appreciated. The dial is

The Carriage and Apron

The carriage has a bearing of 23½ inches on the ways, and is gibbed to the bed for its entire length. The bearing surface on the bed is not recessed, but is in full contact from end to end with the entire depth of the V's. This eliminates to a great extent the difficulty met with in regard to vibrations or "chattering." Instead of an inside V on the front of the lathe a flat surface is used. This shortens the bridge of the carriage, and affords a solid bearing directly under the tool-post. Large T-slots are provided for clamping work to the carriage. The cross-slide and compound rest have been made heavy in proportion to the remainder of the machine,

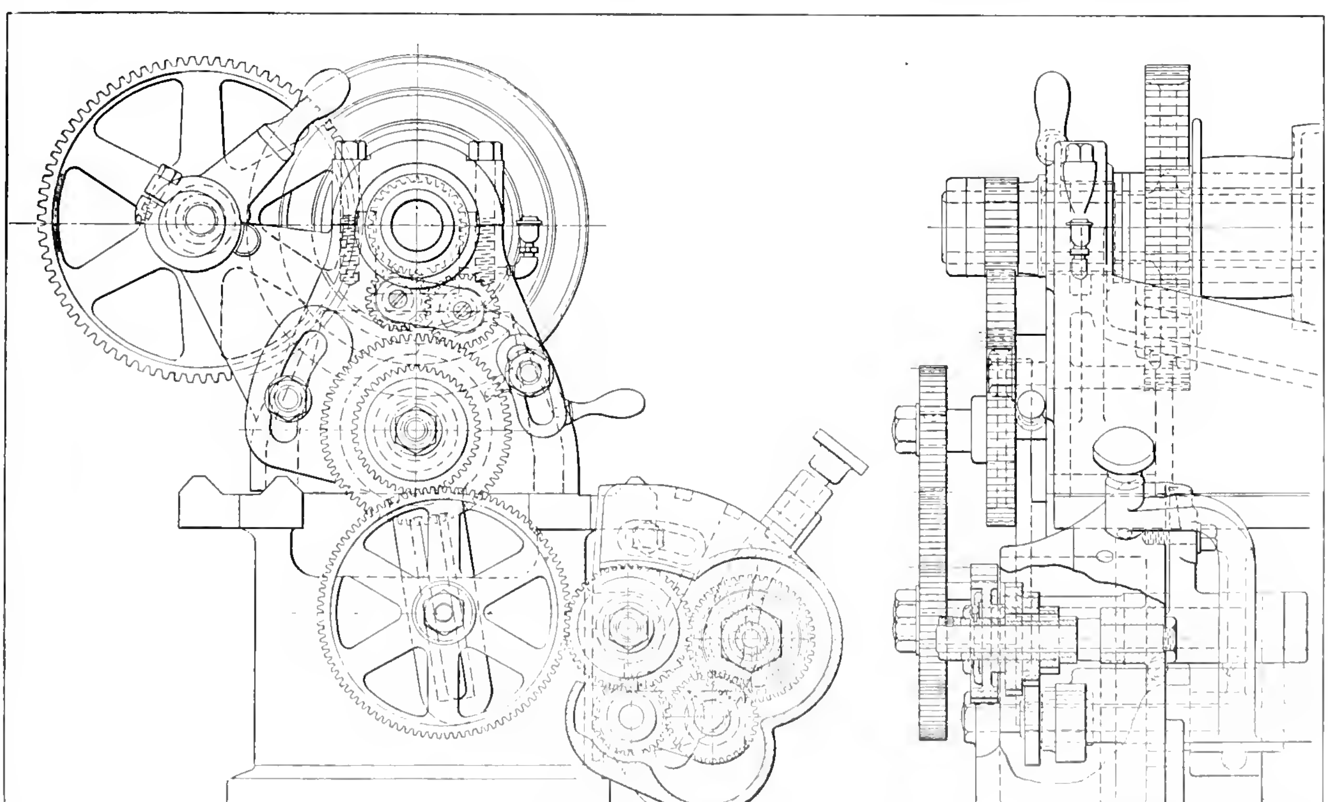


Fig. 3. Design of Feed Box and Gearing, Milwaukee Machine Tool Co.'s 16-inch Lathe

graduated to indicate the rotation of the lead-screw, and enable the operator, when cutting screw threads, to return the carriage quickly by hand, and throw in the nut at the proper moment. This feature alone saves a considerable amount of time when cutting long screw threads, as anyone having used such an attachment will appreciate.

The Change Gear Box

The lathe is provided with a change gear box which gives four practically instantaneous changes of feed through the operation of one lever, as shown in Fig. 1. The drive to the gear box and its general arrangement are shown in the line engraving, Fig. 3. Through the use of change gears supplied with the machine and this gear box, a practically unlimited range of feeds and threads per inch, within the capacity of the machine, can be obtained. The construction of the gear box is very simple, it consisting merely of a cone of gears and a sliding gear which can be brought into mesh with either of the gears in the cone. A friction disk is applied to the gear drive. It is adjustable, and can give any amount of tension desired. It will eliminate to a great extent the breaking of apron parts, etc., due in many instances to carelessness on the part of the operator.

Special attention has been given to the question of gear guards, all gears in any way exposed having been properly covered with guards. In the end view, Fig. 2, some of these guards have been removed merely in order to show the gearing, but they are well in evidence in Fig. 1. Considering the increasing requirements of the law, and the realization of the necessity of protecting the operator from possible injury, this feature is of considerable importance.

A double friction counter-shaft is supplied with the machine in which all the wearing surfaces on the clutch are accurately ground. The bearings are of the ring-oiling type, and are made of pressed steel. The hangers are made of the same material, which adds to a great extent to the strength and lightness of the construction.

The net weight of the machine with the six-foot bed is 2,200 pounds, and the approximate weight of the bed per each additional foot in length is 120 pounds.

PEERLESS AIR-COOLED PORTABLE ELECTRIC DRILLS AND GRINDERS

The tool shown in Fig. 1 (made by the Cincinnati Electric Tool Co., 650 Evans St., Cincinnati, O.) is exceptional for its lightness of weight, as compared with the size of drill it will use. Its actual weight (including the chuck) is only 4½ pounds, and it will drill holes up to 3/16 inch in steel. The style shown is made for direct current, but a similar tool is made for use with various voltages of alternating current.

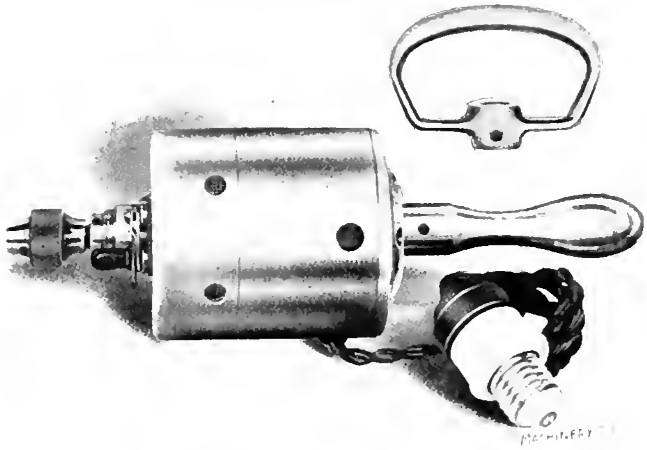

Fig. 1. "Midget" Air-cooled, Electric Drill

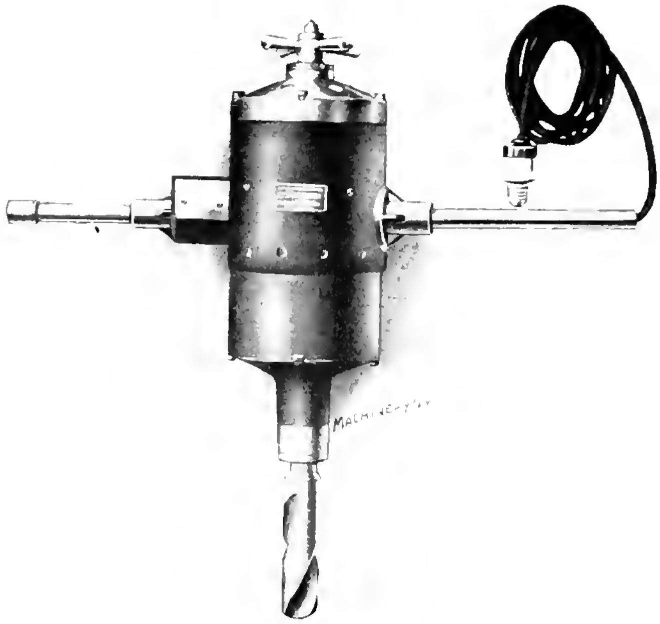

Fig. 2. Heavy Portable Drilling and Reaming Machine

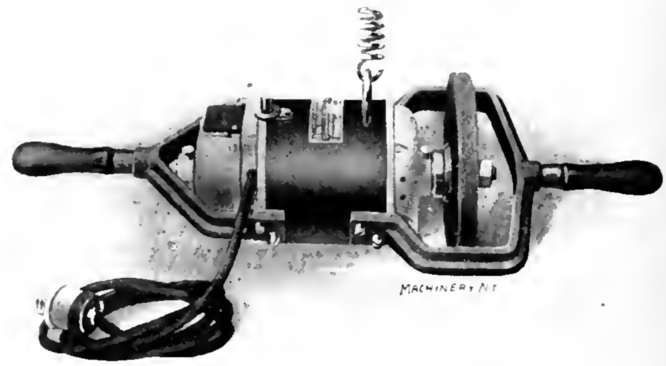

Fig. 3. A Suspended or "Aerial" Grinder for Heavy Duty

The largest size of portable drilling and reaming machines made by this firm is shown in Fig. 2. This machine is designed to drill holes in steel up to 1½, 2 or 2¼ inches, depending on which of three sizes is furnished. These three tools are fitted with Nos. 3, 4 and 4 Morse taper sockets, respectively. The smallest one weighs 63 pounds and the largest 86. Twenty feet of cable are provided, the leads entering one of the handles. A quarter turn of the latter starts and stops the machine. The motor, in common with all others in this line of portable tools, is air-cooled, and can be kept under heavy duty all day without getting heated. A fan mounted directly on the armature shaft provides the circulation for this.

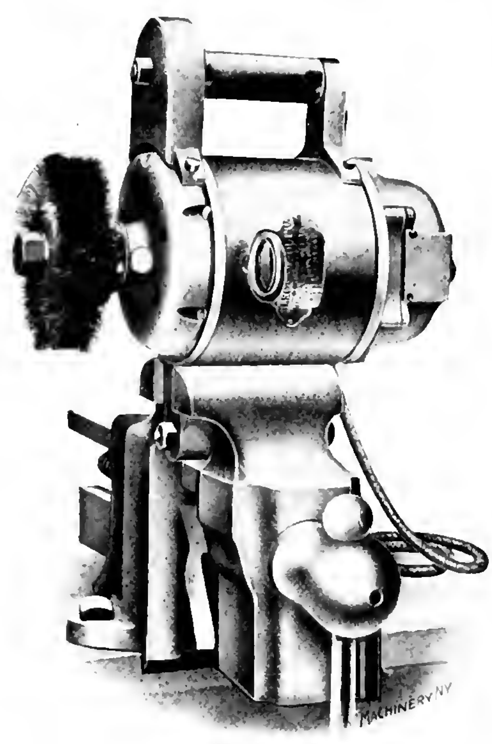

Fig. 4. A Light Aerial Grinder held in the Vise and used for Buffing and Polishing

The grinder shown in Fig. 3 is particularly adapted for smoothing off heavy castings. It is known as an "aerial" grinder, being hung on a spring suspension from the ceiling. The two handles hold it on the line of the center of gravity, and make manipulation of the tool easy. This direct current grinder is made in two sizes, for wheels 8 by ¾ inch and 10 by 1 inch respectively; it is furnished for alternating as well as for direct current.

Fig. 4 shows another type of aerial or portable grinder for lighter work than that done by the tool shown in Fig. 3. Here, however, the grinder has been caught in the vise, so as to make of itself a convenient bench buffing or polishing lathe. The starting switch is controlled by the knurled handle, a quarter turn of which serves to start or stop the machine.

One of the various lathe grinding attachments is shown in Fig. 5, where it is provided with an extension support and

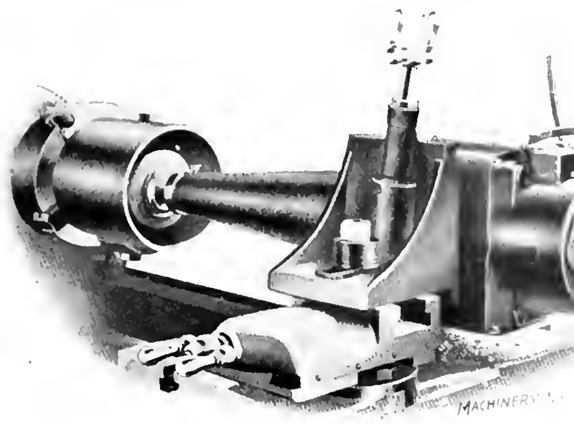

Fig. 5. Lathe Grinding Attachment, with Extended Spindle for Internal Work

spindle, particularly adapted to internal grinding. The use of such a device will bring the ordinary engine lathe into strong competition with the special grinding machine for toolroom and similar occasional work.

The various motor-driven tools just described are wound, as mentioned, for either direct or alternating current, and will be furnished for special voltages and cycles as may be required by the purchaser.

JARVIS DRAW-IN ECCENTRIC COLLET CHUCK

The accompanying half-tone shows an interesting device known as the Jarvis draw-in collet chuck, placed on the market by the Chandler & Farquhar Co., 34 to 38 Federal St., Boston, Mass. The chuck consists of a casing made in two parts, *A* and *B*, the upper part being graduated on the top surface. This casing is recessed eccentrically on the inside, and contains a cylindrical part on which worm-wheel teeth are gashed, this cylindrical part fitting in the eccentric recess of the casing, and being provided with an eccentric stem which is central with the casing when in the zero position, and into which fits

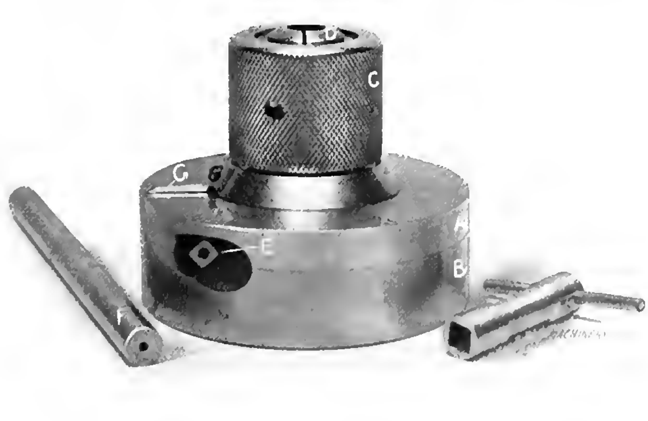

Fig. 1. Jarvis Draw-in Collet Chuck, placed on the market by Chandler & Farquhar Co., Boston, Mass.

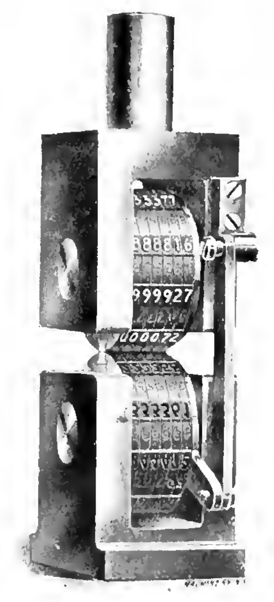
the collet *D*. The stem is threaded on the outside, and over it fits the chuck closer *C*. The worm teeth on the eccentric disk, fitted inside the casing, mesh with a worm *E*. It is obvious that when the worm is revolved by means of a socket wrench being applied to its square head, the eccentric disk inside the casing will revolve, and will, in turn, move the collet chuck out of its true center.

The chuck will be found useful for many purposes. It can be placed either on the lathe face-plate or in a holder, and can be used for holding either the work or boring tools. It can also be used on a milling machine, grinder, or any other machine where its special features would be advantageous. It has an eccentric throw of 1/4 inch from the center, and the face is graduated to read to 0.001 inch, so that it is easy to determine how much the center of the chuck will be out of its true center when the eccentric worm-gear has been turned a certain amount. A special test bar *F* is provided to be placed in the chuck in order to test when it is running true. It should, of course, be clamped to the face-plate of the lathe so that it runs absolutely true when the pointer *G* is at the zero position. If this is the case, the test bar can be removed, the work put into the chuck, the chuck moved out of center by turning the worm, and returned to an accurately central position by merely returning the pointer to the zero position. This feature will be found useful for drilling, boring or grinding eccentric bushings, or making eccentric cams. It is also useful when boring holes to size, as the boring tool can be placed in the chuck and the amount that the boring tool is fed into the work can be read off on the graduations on the face of the casing *A*. It will be found very convenient when boring jigs and fixtures in the milling machine. The chuck collets furnished have a capacity of from 1/16 inch to 1/2 inch, varying by 64ths or 32ds, as required.

BATES METAL NUMBERING MACHINE

The accompanying illustration shows one of the many types of numbering machines made by the Bates Numbering Machine Co., 696-710 Jamaica Ave., Brooklyn, N. Y. This machine is designed for embossing numbers on soft metal tags, strips, etc. The machine is operated in a power press, the upper part of it, of course, being attached to the plunger, and the lower part to the die block. It consists, as shown, of male and female dies, and can be made with 5, 6, 7 and 8 wheels, according to the number of figures required. When at work, it will number the work consecutively and automatically, there being a connecting pitman or link, as shown, between the upper and lower dies, so that they will index simultaneously. The height of the figures provided can be made either 3/16, 1/4, 3/8 or 1/2 inch, and intermediate sizes between these can be furnished if desired. The machine is an interesting example of the development of automatic numbering machines for embossing numbers on metal.



Bates Numbering Machine for Embossing Numbers on Metal

BRIDGEFORD BEVEL GEAR TURNING LATHE

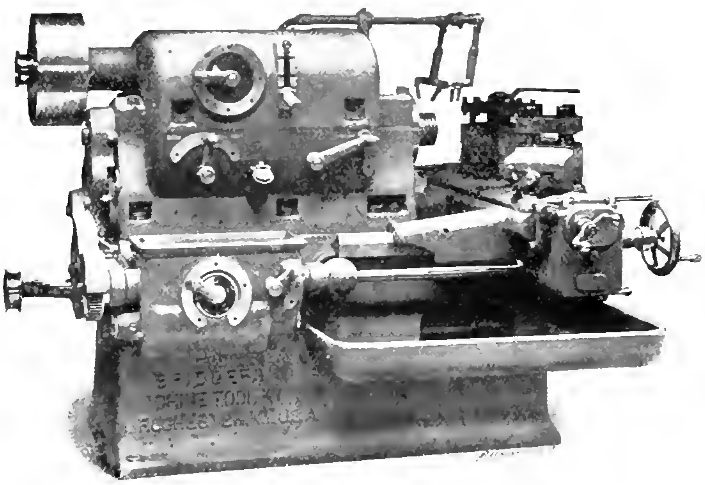
In the accompanying illustrations Figs. 1 and 2 are shown front and rear views and in Fig. 3, end view, of a lathe for turning bevel gears, which has just been placed on the market by the Bridgeford Machine Tool Works, Rochester, N. Y. This machine has been designed specifically for turning simultaneously the face, front and back angles of bevel pinions and gears up to 18 inches in diameter. Besides these turning operations, the boring and the facing of the back of the gears is also done advantageously in the machine.

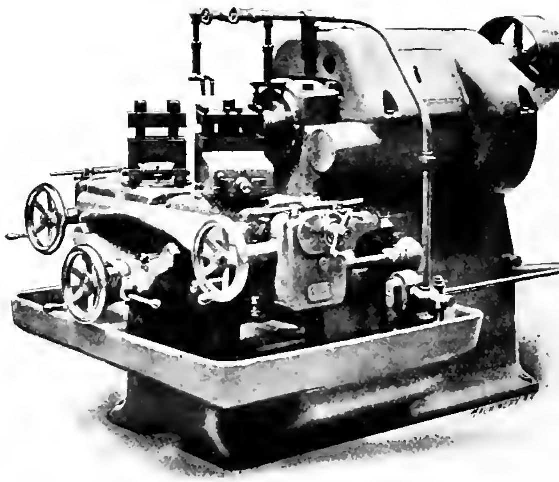
As will be seen from the illustrations, the frame, oil pan and oil reservoir are cast in one piece. The top of the frame or bed is provided with ways similar to those on engine lathes, and the head-stock of the machine is of a design similar to that used on the Bridgeford heavy duty geared head engine lathe, which was illustrated and described in the March, 1908, issue of MACHINERY, in the department of New Machinery and Tools. The drive to the geared head is through a constant speed pulley, 15 inches in diameter, as shown, with a width for a 6-inch belt and running at 140 revolu-

tions per minute. The gearing in the head provides for twelve spindle speeds ranging from 5.8 to 214 revolutions per minute. The design gives sufficient pulling power to enable three cutting tools to be used simultaneously, all cutting up to their full capacity. All the gears within the head are made of steel and run in oil. The bearings are self-oiling to prevent accidental heating and frictional losses.

The carriage is similar to that provided on a lathe, but is of a duplex construction, having an apron both in the front and in the rear of the machine, and is provided with two cross-slides carrying the angle turning rests, the right-hand cross-slide having a turret tool-holder. The carriage cross-slides and angle rests have power feed and automatic stops. The required hand-wheels are arranged within easy reach of the operator when in a working position. The machine is provided with a feed box as shown in Fig. 1, which gives ten feeds ranging from 0.005 to 0.190 inch per revolution of the spindle. The gears in this feed box are also made of steel and run in oil. From the feed box the power is transmitted by splined shafts to the aprons, the same as in a lathe, the power being carried to the rear of the machine by means of bevel gearing and a shaft which passes through the frame or bed. The machine is provided with an oil pump as shown in Fig. 2, and with properly arranged piping for carrying lubricant to the cutting tools. The oil pump is driven by a belt from a pulley on the end of the main driving shaft, as shown. All gearing has been carefully covered by suitable guards, and the machine offers a pleasing appearance on account of its well proportioned and uniform lines. The total net weight of the machine is 7,300 pounds.

The operation of the machine will undoubtedly be of interest. The first operation consists of boring the hole and facing the back of the gear. During this operation the blank is held in a universal chuck and the hole is bored out with the tool held in the left-hand rest, while the facing is done with tools held in the turret of the right-hand cross-slide. The second operation, consisting of turning the face, front and back angles, is the one where the prominent features of the machine come more particularly into play. During this operation the blank is either held on a special hub or on an arbor in the taper hole in the spindle, which is provided with a split bushing. The left-hand turning rest carries a roughing and a finishing tool for the face angle, and the turret on the right-hand cross-slide a set of roughing and finishing tools for the front and back angles. As these tools work simultaneously, bevel gears can be finished very rapidly. Two of the machines are already in operation in a gear manufacturing plant, and have made it possible to save considerable time over that required when turning the gears with ordinary engine lathe and turret lathe methods. At the same time, more accurate work can be produced than can be done with forming tools.





Figs. 1 and 2. Front and Rear Views of Bevel Gear Turning Lathe, built by the Bridgeford Machine Tool Works

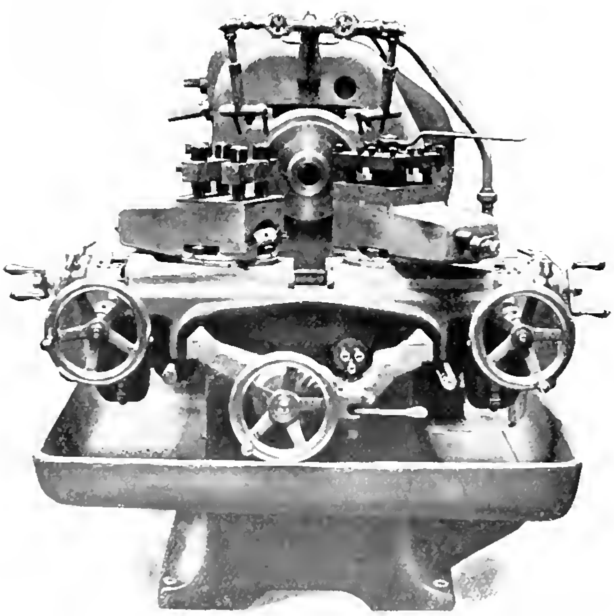


Fig. 3. End View of Bevel Gear Turning Machine

DECIMAL EQUIVALENTS ON THIMBLE OF MICROMETER CALIPER

The accompanying illustration shows an improved thimble of the micrometer caliper manufactured by the J. F. Slocomb Co., Providence, R. I. The improvement consists of a complete table of decimal equivalents of eighths, sixteenths and thirty-seconds of an inch, rolled on the thimble. It should prove very handy to the machinist to have the decimal equivalents directly on the thimble, it being possible to make the figures large and distinct and easy to find and read.

Thimble of Slocomb Micrometer, with Decimal Equivalents

* * *

The seventy-fifth meeting of the British Association for the Advancement of Science was opened August 25 in Winnipeg, Canada, with 600 delegates present from the United Kingdom, the United States and Canada. The twelve sections of the association remained in session for a week. One of the principal addresses, dealing with a variety of matter of interest to scientists and scientific educators, was delivered by Sir J. J. Thompson, the president of the association.

NEW MACHINERY AND TOOLS NOTES

Adjustable Work Clamp: Howell & Murray, Waverly, N. Y. This is a convenient tool of simple construction for holding work on the drilling machine table. The clamp jaw is adjusted and held in position by notches on an upright which is held down to the work and table by a bolt and nut, the bolt having a square head fitting in the T-slot of the table.

High-Speed Steel Twist Drill: New Process Twist Drill Co., Taunton, Mass. This drill, known as the Reliance high-speed twist drill, is made from flat bar stock twisted while hot. The twisted blade is then inserted into the tool shank, and brazed to the shank, so that the drill when finished is practically as strong as if made from one piece of steel.

Automatic Screw Machine: L. Wollstein & Co., 16 John St., New York City. This machine is adapted for making small screws and other parts commonly made in automatic screw machines. Instead of a turret, however, it carries a sliding spindle for holding a drill or other tool. When external threading is to be done the spindle can be removed and an opening die of special construction put in its place.

Small Gear Hobbing Machine: Schuchardt & Schütte, 90 West St., New York City. This machine has been designed in response to the demand for a machine to cut small gears for water meters, clocks, etc. It has a capacity for hobbing gears up to 24 diametral pitch, with an outside diameter of 4 inches and a face of 6 inches. The cutter spindle runs at 600 revolutions per minute. The machine is entirely automatic, but hand feed can be used if desired when cutting small worm gears.

Ring Oiling Bushing: Brown Engineering Co., 123 North 3rd St., Reading, Pa. This ring oiling bushing for loose pulleys and clutches is particularly adapted for use in machine shops. It will run from four to six weeks without having its oil supply replenished, and it is claimed that the bushing will save over 75 per cent of the oil ordinarily required. It can be operated at speeds as high as 2,000 revolutions per minute. The bushings are made with all the standard bores from 1 3/16 inch to 2 15/16 inches.

Oil Cup: United States Metallic Packing Co., Philadelphia, Pa. This accessory has been designed with a view of making an oil cup of maximum strength. The shank of the oil cup is of machine steel, and the cover is of pressed steel, attached to the body of the oil cup by a steel chain so as to prevent losing it. It is furnished either with a needle or wick feed, and with shanks of any desired diameter and number of threads. The standard cup, however, has a ¾-inch diameter shank and 14 threads per inch.

Universal Ball Bearings for Shafting: United Bearings Co., Bradford, Pa. These ball bearings are adapted for heavy loads and allow an end movement of the bearing. They consist of an outer casing proportioned to fit any standard hanger and containing a hardened and ground steel case at each end for receiving the ball bearings. The inner ball race is of hardened steel provided with a lining of good anti-friction metal fitting over the shaft. Thus the bearing is in fact a combination plain and ball bearing, so that if the ball bearing should be subjected to injury the bearing still is serviceable as a plain bearing.

Bench Cutting-Off Saw: Taylor-Shantz Co., Rochester, N. Y. This machine is intended to be placed on a bench or stand, and to do the work, generally, of a power hack-saw. It is designed particularly for tool-room use. Due to the fact that a blade with a thickness of only 3/64 inch is used, considerable material is saved, which is important when cutting up high-speed steel or other expensive stock. On large work a saw 5/64-inch thick may be used. The machine weighs 160 pounds and occupies a space of 14 by 14 inches. It has a capacity for cutting off 2½ inches square, 2¾ inches round, and 4 by 2 or 4½ by 1 inch flat stock.

Heavy Swaging Machine: Langelier Mfg. Co., Providence, R. I. This machine is adapted for tapering heavy work. It swages solid stock up to 2 inches in diameter and tubing up to 3 inches, and is especially intended to meet the requirements of manufacturers of heavy tubing for the automobile trade. The machine takes dies from 4 to 8 inches long; the spindle is of large proportions, its head being 10⅝ inches in diameter by 10⅝ inches long and the bearing part 6 inches in diameter by 23 inches long. The machine should run at a speed of 240 revolutions per minute and be connected to the counter-shaft by a 7-inch belt. The floor space required is 42 by 48 inches.

Saw Table: Silver Mfg. Co., 317 Broadway, Cleveland, O. This machine is adapted for small pattern shops or woodworking shops on account of being inexpensive and simple. It is equipped with a safety guard and pivoted auxiliary frame for vertical adjustment of the saw, and while adapted for fine accurate work, it is amply strong enough for rough and heavy work as well. The saw is 12 inches in diameter, and when raised projects three inches above the table. Saws up to 14 inches in diameter can be used. The ripping fence tilts to any angle up to 45 degrees. The floor space of the machine is 44 by 66 inches, the size of the table 31 by 38 inches, and the height 32 inches.

Under-Belted Disk Grinder: Gardner Machine Co., Beloit, Wis. The improvement in this grinder over the Gardner grinder illustrated and described in the July, 1908, issue of Machinery, consists mainly in the drive and a slight modification of the frame, so that the belt can be passed over the machine spindle pulley, down through the base of the machine, and through the floor to a motor mounted in the ceiling below or in the pedestal of the machine. The spindle pulley and belt are entirely enclosed so that the whole machine offers a compact substitute for the direct motor-driven disk grinder, which presents the difficulty that grinding dust is liable to get into the working parts of the motor.

Double Crank Press: E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. This machine is adapted for heavy cold bending, drawing and forming operations in thick sheet steel manufacture. It is particularly intended for work of large dimensions, such as automobile engine crank cases, frame members, channels, etc., and for heavy cutting and perforating. The machine is capable of exerting a safe working pressure of 800 tons. The width between the frame columns is 74 inches, and between the gibs 67 inches. The stroke of the slide is 14 inches and the distance from the bed to the slide, the stroke down and the adjustment up, 20 inches. The adjustment of the slide is 6 inches.

Hardening Furnaces for High-Speed Steel Tools: American Gas Furnace Co., 24 John St., New York City. These furnaces are the results of a series of experiments undertaken to determine the best means for hardening different kinds of high-speed steel tools in gas blast furnaces. Different types of furnaces have been adopted for various kinds of tools, each type being, of course, used for a considerable variety. For instance, a special furnace is made for heating reamers, drills, taps and other tools of considerable length but small diameter. Small cylindrical work is suspended by the shanks in the heating space and is removed after heating without coming in contact with the lining of the furnace or the supports, thus preventing injury to the fine cutting edges.

Electric Pyrometer: Bristol Co., Waterbury, Conn. This pyrometer is intended for high temperatures and is designed to permit quick readings. An advantage of the instrument is that its construction substitutes an inexpensive metal for the expensive platinum-rhodium for the larger part of the couple. The tips of the couple, however, are of platinum-rhodium, and may be exposed to a temperature of 3,000 degrees F. without danger of the temperature at the junctions between the tips and the remainder of the couple exceeding a safe limit. The complete instrument is portable and temperatures up to 2,500 degrees F. can be obtained in a few seconds. By using a special form of tip, the instrument can be used for measuring the temperature of hot metal surfaces.

Forty-Ton Duplex Chain Block: Yale & Towne Mfg. Co., 9 Murray St., New York City. This chain block has been brought out to meet the demands of the trade for a dependable hand hoist for handling very heavy loads in cases where the installation of an electric crane or steam hoist would be out of the question. It is composed of two 20-ton units with equalizing bars at top and bottom, thus providing for a single point of suspension and a single point of attachment of the load. Provision is made for swiveling each unit at top and bottom. The hand chains are arranged to permit two, four or eight men to work effectively. When the load is larger than 40 tons, it can generally be handled by two of these hoists working together, giving a double capacity of 80 tons.

Motor-Driven Sensitive Drill: Willey Machine Co., Jeffersonville, Ind. This drill press has been built heavier than former designs, and has a square table instead of a round one as previously used. The motor is connected to the spindle by a belt and cone pulley, and three changes of speed are provided. The motor is adjustably mounted for tightening the belt, and the starting switch is placed within the motor frame, eliminating connections outside of the motor. The distance from the center of spindle to the column is 12 inches, the maximum distance between the spindle and table 38 inches, the vertical motion of the spindle 3 inches, and the size of the table 11½ inches square. The total height of the drill is 67 inches, and the weight of the machine 200 pounds. It requires a 1/3 H. P. motor.

Vertical Keyseat Milling Machine: Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa. This machine is adapted particularly for keyseating, and is built along the lines of a vertical milling machine. The spindle is mounted in a vertically adjustable saddle, so that a minimum distance of 6 inches and a maximum distance of 18 inches between the end of the spindle and the top of the table is obtainable. The spindle speeds vary from 142 to 395 revolutions per minute with the back-gears in, and from 430 to 1,194 revolutions per minute when driving direct with the back-gears thrown out. The work-table is 11 inches wide and 40 inches long, surrounded by an oil pan. It has an automatic power feed motion of 36 inches in either direction. The feed motion is obtained by a feed box giving nine changes. The machine occupies a floor space of about 4 by 5 feet.

Three Head Reaming and Tapping Machine: Niles-Bement-Pond Co., 111 Broadway, New York City. This machine is adapted for work on cast iron T- and L-shaped pieces up to

18 inches, and steel T's and L's up to 12 inches. It is provided with three heads mounted on a T-shaped bed, and has a stationary table to which the cradles for holding the work are clamped. Each of the three heads has independent hand adjustment and drive, as well as independent power feeds suitable for reaming and tapping, the feeds obtainable being 1/32, 1/16 and 1/8 inch per revolution. The maximum distance from the center of the machine to the ends of the spindles is 26½ inches; the distance the centers of the spindles are above the work-table is 15 inches. The spindle speeds are from 3¼ to 14 revolutions per minute. The power for each head consists of a 12½ H.P. variable speed motor.

Inclinable Rotary Furnace: Rockwell Furnace Co., 26 Cortlandt St., New York City. This furnace, intended for smooth round work, has a rotating cylinder or drum lined with a standard hard refractory brick with a smooth internal surface. The furnace is capable of being inclined, and the gradual incline causes the material to feed forward. The degree of pitch may be adjusted through a hand-wheel so as to regulate the progress of the material through the furnace to the required time of heating. This automatic continuous heating provides for a uniform heat in all the pieces, none of them being likely to be overheated or not sufficiently heated, as is the case in stationary furnaces. These furnaces can be built to suit different requirements, and in sizes to handle up to 2,000 pounds of stock per hour.

Universal Boring Tool-Holder: The Robinson Tool Works, Waterbury, Conn. This tool-holder differs from other holders intended for the same purpose particularly in that it passes over the lathe tool-post instead of passing through the tool-post slot. It is clamped by means of the regular tool-post wedge and screw, the tool supporting ring or washer being removed from the tool-post. The advantages claimed in connection with this tool-holder are that it elevates the boring tool horizontally, that tools of any diameter and of any kind of round stock can be used, and that it is always possible to have the tool projecting the right length from the holder. It is made in five sizes, the smallest size adapted to a No. 1 watchmaker's lathe, and the largest to lathes having 20 to 36 inches swing and taking boring bars to 1¼ inch in diameter.

Variable Speed Counter-shaft: Hawkeye Mfg. Co., Cedar Rapids, Ia. This device depends for the variations of speed on the greater or less amount of slipping in the frictional contact between the constant speed driving pulley and the shoes of a spider carrying the driven pulley. It is claimed that uniform speeds are obtained, due to the fact that the principle of the centrifugal governor is introduced in the mechanism. The essential parts of the device are driven pulley and a friction clutch of the drum and brakeshoe type, having an adjustable contact controlled by a lever, or a sheave with drop chain, with which the pressure of the shoes on the wheel face can be regulated. Not only the cone pulley, but also the tight and loose pulleys, are eliminated from the drive. A continuous range of speeds from the maximum to the minimum is obtainable.

Surface and Tool Grinder: Robinson Tool Works, Waterbury, Conn. This grinder has been designed for grinding the faces of small dies and punches and for surface grinding of other small parts occurring in tool work. It can also be used as a regular tool grinder, and is provided with holders for grinding twist drills and milling cutters. It consists of a head carrying two wheels, one at each end. A table or platen is provided under one of the wheels. The other wheel is provided with an adjustable tool-rest and a fixture for holding twist drills, this latter having a capacity for drills from ⅛ inch up to 1½ inch diameter. The machine is either adjustably mounted on a column or furnished as a bench grinder. The diameter of the surface grinding wheel is 5 inches and of the drill grinding wheel 6 inches. The net weight of the machine, including counter-shaft, is 180 pounds.

Rivet Spinning Machines: Grant Mfg. & Machine Co., 80 Silliman Ave., Bridgeport, Conn. Three new riveting machines have been brought out by this company, two being riveters of the noiseless type equipped with flat and horn tables, and designed for work requiring a great depth of throat; work 11½ inches from the edge can be riveted. On the riveter provided with a flat table, fixtures can be mounted for different classes of work. The machine with the horn table is especially adapted for the manufacture of railroad lamps, signal lamps, metallic doors, etc. A small double spindle riveting machine for rivets ⅛ inch in diameter and less and adapted for light work such as small hinges, jewelry novelties, etc., has also been brought out. It heads simultaneously both ends of a plain wire passing through the work. This machine may be mounted on a bench or pedestal and is operated by a treadle attached to the floor. The maximum capacity between the spindles is 1½ inch.

High-Speed Drilling and Tapping Machine: Cincinnati-Bickford Tool Co., Cincinnati, O. This machine has been designed to meet the requirements of a high-speed and high-powered machine, particularly adapted for high-speed steel twist drills. It is also provided with a slow speed for tapping and with a quick return for withdrawing the tap. It is of the upright type, motor or belt driven as required, and provided with special bracing in the back of the column to provide additional strength. The head is vertically adjustable on the column; the spindle is provided with ball bearings, and jam nuts for adjustment, and an automatic stop so that a number of holes may be drilled to a given depth. A geared feed box is located on the sliding head and provides for six feeds varying from 0.006 to 0.039 inch per revolution of the spindle. The lever for manipulating the back gear when placed in a neutral position will stop the spindle. The machine is provided with gear box drive when belt driven, but in the variable speed motor driven machine the motor takes the place of the gear box. The gear box provides for 18 different speeds, giving, in connection with the back-gears, 36 spindle speeds varying from 38 to 534 revolutions per minute. The machine is provided with the company's patented geared tapping attachment, and a high-speed attachment, desirable for drilling small holes, may also be used in connection with this drill. The machine is built in sizes from 24 to 42 inches.

* * *

THE SALE OF THE IRON AGE

The sale of the *Iron Age*, the formal transfer of which was made the latter part of September, transfers to new owners the oldest and best-known trade publication in this country. The publication will be continued by the David Williams Company, with Charles T. Root, President, Charles Kirchhoff, Vice-President, and W. H. Taylor, Secretary and Treasurer.

In his valedictory, which is given the leading editorial place in the last number, Mr. Williams says:

The conductors of *The Iron Age* have always felt their responsibility as publishers of an organ of important information to which the trade looked for impartiality and fairness. Its reputation (even in other hands) is dear to us, and on no account would we have entertained a proposition to allow the paper to get into the hands of men whose ideals of journalism were not high. Fortunately this is not the case here. The purchasers are men of standing and eminently qualified for the task they have undertaken. I have known Mr. Root for many years, and entertain for him a profound respect and regard, not only as a peculiarly able publisher, but as a charming and high-minded man. His associates are publishers of character, experience and skill. I feel that *The Iron Age* is safe in their hands and wish them all possible prosperity and success.

The opinion Mr. Williams holds of the gentlemen who now control the *Iron Age* is shared by all who know them, and especially by trade paper publishers whose knowledge is more intimate and personal. Under their management the *Iron Age* will undoubtedly advance along new and aggressive lines, to even greater prosperity than it attained under its former owners.

* * *

WORCESTER TRADE SCHOOL

Plans for the proposed Worcester trade school have been prepared by the architects, and submitted for consideration. The academic building has a frontage on Grove St. of 200 feet and runs south on Concord St. to Prescott St. It is to be built of brick with limestone trimmings and the estimated cost is $275,000. Fronting on Grove St., is the academic section of the wing, 57 feet by 52 feet, three stories and basement. Attached to the academic section and fronting on Concord St. is the shop, 214 feet long and 42 feet wide, two stories and basement. The first and second floors of the academic section will be occupied as class rooms, and on the third floor is a large drafting room. The basement and first story of the shop section will be given up to the machine shop and the second floor will be devoted to the wood-working department. At the south end of the shop, fronting on Prescott St., will be the power plant in the basement and on the opposite side is the blacksmith shop. The moulding room will be on the first floor under these departments. A department for bookkeeping and cost accounting is provided for, where the pupils will be taught the cost of production. The wing about to be constructed will accommodate about 300 boys, and the estimated cost is from $50,000 to $60,000.

* * *

The central idea that the boy gets at college is training, training of the mind, storing the mind full of things. Now I say, without the slightest hesitation, that for success in life, intellectual training comes second or third. Without question, character comes first; good sense, second; and intellectual training, third.—*F. W. Taylor.*

THE VERNAZ CIRCULAR CUT FILE*

The Vernaz file has been previously illustrated and a general description presented in the March, 1907, and the September, 1908, issues of MACHINERY. In the latter of these issues it was referred to as the "Vixen" file, this name being the American trade name. The file is the result of an effort on the part of Mr. Alexis Vernaz of Yverdon, Switzerland, to save from the scrap heap a large number of accidentally hard castings. Proving itself successful, it was patented in nearly all industrial countries. The most prominent feature of the file, apparent to the casual observer, is that the teeth of the file are cut circular as shown in Fig. 1.

The essential feature of the Vernaz file, outside of the circular cut, is the form of the tooth itself, the section of the teeth being similar to that of the teeth in a milling cutter. The included angle of the teeth is 60 degrees, with a front rake of 1½ degree. The number of teeth per inch varies from 6 2/3 to 16, according to the purpose for which the file is intended. The teeth are cut one at a time with an end mill made in the shape of a hollow cylinder, having a diameter of from 2½ to 3 inches, and the edge beveled off to an angle of 60 degrees. This end mill is set at an angle of 1½ degree with a line at right angles to the plane of the file. In the manufacture of the files, automatic machines rotate the cutters, feed them into the file blanks to the proper depth, withdraw them, index or move the file the length of the pitch, and then repeat the same action for the next tooth.

At first it would seem that the inclination of the axis of the cutter would produce a cutting edge on the file which would not be flat, but concave. This, of course, is true of the bottom of the cut, but the shape of the top or edge, being produced by the intersection of the conical (beveled) face of the cutter with the cylindrical surface made by the preceding cut, is rather doubtful at first sight. In Fig. 2 the true shape of the edge has been determined by drawing it in a scale several times the true size. In this illustration lines *C* and *D* are corresponding elements of the cylindrical and conical surfaces of the tooth at the edge of the file, and determine the corner *A* of the tooth. The point *A* at the outer edge of the file falls distinctly below the surface of the blank. The top of the file, consequently, is very slightly convex, which is probably an advantage. The convexity is very slight, amounting to only about 0.002 inch on a file 1¼ inch wide.

It has been found that the circular cutting edges cut properly whether the file is pushed straight or at an angle, and also that the relatively large pitch and depth of teeth prevent clogging and the necessity of cleaning, and produce exceptionally smooth surfaces. The surface produced on steel is smoother than that from an ordinary second-cut file, due to the fact that the latter has a tendency to retain small chips between the teeth which scratch the surface filed. On fibrous and tenacious materials, such as wrought iron, mild steel, brass and aluminum, the improvement over ordinary files is very marked. That the action is a cutting one and not an abrading or grinding action, is shown by the chips, which under the magnifying glass are curled up and look as if they were made by a lathe or planer tool.

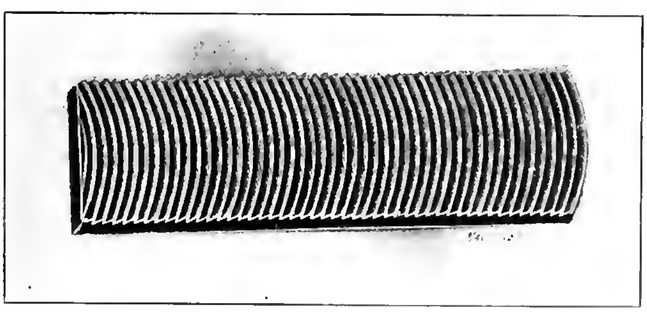

Fig. 1. A Section of the Vernaz File, known in the United States as the "Vixen" File

Tests have been undertaken on these files at the works of Wm. Sellers & Co., Inc., and by Tinius Olsen & Co., Philadelphia, Pa., using a file-testing machine built by Edward G. Herbert, Ltd., of Manchester, England. (This machine was described in the December, 1907, issue of MACHINERY, engineering edition, and also referred to in the September, 1909, issue of MACHINERY, engineering edition, in an article entitled "The Testing of Files and Tool Steel.") In making comparative tests of twenty-nine files from eleven different makers, it was found that twenty-eight out of the twenty-nine regular commercial files, when tested on cast iron, removed from 0.7 to 20.6 cubic inches, while only one file removed 73 cubic inches. These tests also bore out the results of experiments made by Edward G. Herbert himself, showing that the two sides of a file often show extreme variation in cutting capacity. In the tests referred to, the worst case of this kind was a file which removed 20.6 cubic inches by one side and 0.4 cubic inch by the other. Four Vernaz files have been tested on cast iron. The poorest one removed a total of 48.2 cubic inches, using both sides, and the best 143.75 cubic inches, the variations between the two sides being very slight, the worst case being a file removing 49.1 cubic inches by the one side and 34.9 by the other. On high carbon steel the minimum and maximum figures for ordinary commercial files were 3.6 and 6.4 cubic inches, and for the Vernaz files 9 and 25.8 cubic inches. In this case, however, two out of three Vernaz files showed a marked difference on the two sides.

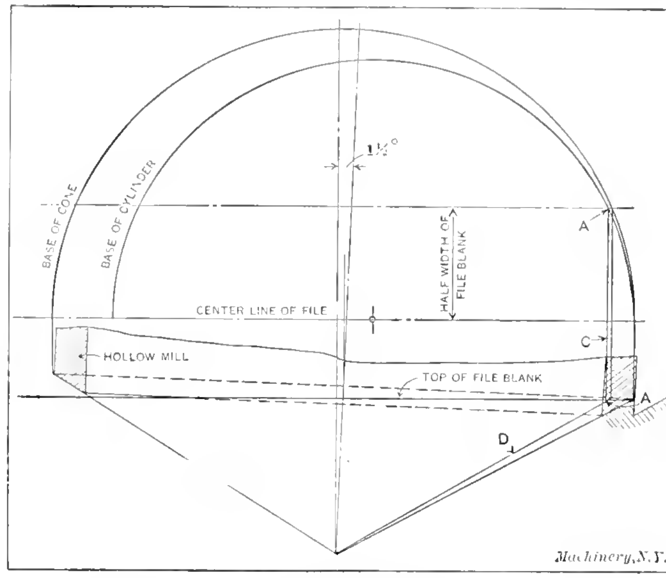

Fig. 2. Diagram used for showing that the Top Surface of the Vernaz File is Convex

The committee of the Franklin Institute reporting on the Vernaz file considers that this invention is the first radical improvement in files for generations, and that the inventor has done the industrial world a marked service, not only in presenting a new and efficient cutting tool for metals, but also in the impetus which the introduction of the tool will give to improvement in cutting capacity and endurance of the regular type of files. The committee, therefore, recommended that the inventor be awarded the Elliott Cresson medal as an appreciation of his achievement.

* * *

Santos-Dumont, the Brazilian aviator who attracted the attention of the world to himself some years ago by his dirigible balloon experiments and exploits, lately built an aeroplane of diminutive size that flew at a speed of fifty-five miles an hour near Paris, September 11. It weighs together with pilot only 260 pounds, and has only nine square yards of wing surface as against twenty-two square yards in the Curtiss aeroplane, twenty-six square yards in the Bleriot machine and fifty-three square yards in the Wright machine. The motor is a two-cylinder gas engine developing 30 horsepower at 1,800 R. P. M. The machine, which is of the butterfly type, is so constructed that it can be used both as an aeroplane and a motor car, rising at will from the road, and descending again to run on the ground. Santos-Dumont expects to reduce the distance required to rise to about forty or fifty yards. The trials at St. Cyr required only seventy to eighty yards to start.

* Abstract of a report of the Franklin Institute, through its Committee on Science and the Arts, published in the *Journal of the Franklin Institute*, September, 1909.

PERSONAL

Charles S. McCarthy has taken the position of superintendent with the Warner Mfg. Co., Toledo, O.

O. J. Sundstrand has been elected secretary and treasurer of the newly-organized National Machine & Tool Works, Rockford, Ill.

William M. Grove has been given full charge of the Cleveland territory for the product of the Ingersoll Milling Machine Co., Rockford, Ill.

T. F. Meek, for twenty-one years with the Detroit Steel Casting Co., is now vice-president and general manager of the Toledo Steel Casting Co., Toledo, O.

C. C. Wais of the C. C. Wais Machine Co., Cincinnati, Ohio, has sold his business, and is now connected with the Covington Machine Co., Covington, Va.

F. G. Kernan, formerly Eastern sales agent for the Fox Machine Co., Grand Rapids, Mich., has been made general sales manager of the company, with headquarters at Grand Rapids.

M. T. Lanse has been made secretary and treasurer of the Foglesong Machine Co., Dayton, Ohio, succeeding A. C. Jackson, who is now cashier of the North Dayton Savings Bank.

Henry Bowman, formerly with the Detroit Steel Casting Company, has taken the position of superintendent of the Toledo Steel Casting Co., which firm succeeds the C. E. Sutton Company.

Perley E. Harvey, who recently resigned from the position of assistant superintendent at the Chapman Valve Mfg. Co., Springfield, Mass., has taken a position with the Fore River Ship Building Co., Quincy, Mass.

W. S. Chase, sales manager of the National-Acme Mfg. Co., Cleveland, Ohio, sailed September 11 for a two months' business trip in Great Britain and on the Continent. He was accompanied by his wife.

Frank Salomon, representative of the engineering staff of Alfred Schütte, Cologne, Germany, is on a visit to America in the interests of his house. His American address is Alfred H. Schütte, 90 West St., New York.

The name of the heating and ventilating engineer of New York, referred to in the article by Mr. C. M. Ripley, "Pure Air Law for Workmen" in the September number, engineering edition, is Percival Robert Moses.

Edwin Cedarleaf, formerly superintendent of the Rockford Machine & Shuttle Co., is now general manager of the National Machine & Tool Works, a concern which succeeds to the old Dalin Bros.' shop and business in Rockford, Ill.

Adolph W. Gilbert has been elected president and general manager of the Chapman Valve Mfg. Co., Springfield, Mass. Mr. Gilbert recently resigned from the position of general manager with the Pratt & Cady Co., Hartford, Conn.

Charles M. Robertson, superintendent of the Colburn Machine Tool Co., Franklin, Pa., resigned his position September 1 to become a salesman with the E. L. Essley Machinery Co., of Chicago and Milwaukee, agent for the Colburn boring mill.

T. W. Warner has been elected president and general manager, and E. S. Janney, secretary-treasurer of the newly organized Warner Mfg. Co., maker of automobile gears and transmissions, which occupies a part of the old Pope plant in Toledo, Ohio.

Frank H. Hill, formerly in the sales and engineering departments of the New York office of the Sprague Electric Co., has been made manager of the Atlanta, Ga., branch office, and assumed his new duties September 1. Mr. Hill succeeds Mr. F. V. L. Smith, resigned.

P. P. H. Conover, secretary and treasurer of the Miami Valley Machine Tool Co., Dayton, Ohio, returned in September from a two months' trip in Europe. He visited England, France, Germany, Italy and Switzerland. The trip was partly on business and partly for pleasure.

P. T. Wingo, for twenty-two years with the Brown & Sharpe Mfg. Co., Providence, R. I., on work relating to gearing and special machinery, has resigned and is now connected with the Cadillac Motor Car Co., Detroit, Mich., in a general mechanical engineering capacity.

A. W. Lewin was advanced September 1 to the position of manager of the New Orleans office of the Sprague Electric Co., New York. Mr. Lewin is a member of the American Institute of Electrical Engineers, and has had extensive commercial and engineering experience in the electrical business in both North and South America.

James H. Norris, for the past nine years business manager of the John F. Allen Riveting Machine Co., 370-372 Gerard Avenue, New York City, resigned his position, his resignation having taken effect September 1. It was Mr. Norris' intention to take a rest of about two months, part of which time was to be spent on an extended trip.

P. J. Hoenschied, for several years vice-president and mechanical manager of the National Twist Drill & Tool Co., Detroit, Mich., has disposed of his interests in that concern and expects to start a new company for the manufacture of automobile parts. The Hoenschied stock was purchased by members of the National Twist Drill & Tool Co.

C. E. Wust, of C. E. Wust & Co., Seebach, Zurich, Switzerland, is in America to establish licensees for making the Wust herringbone gearing (see MACHINERY, engineering edition, April, 1908, page 515) and to make a contract with some maker of American machine tools to build the Wust herringbone gear-cutting machine. The Grand Union Hotel, New York, is his headquarters.

M. M. Shepherd has just been appointed shop instructor at the James Millikin University, Decatur, Illinois. Mr. Shepherd has had wide experience both as a mechanic and as an instructor in designing, drafting, pattern-making, forging, foundry and shop work. He was for three years teacher of manual training in the city schools of Providence, R. I., and four years in similar work in the high schools of Milwaukee, Wis.

F. H. Banbury, engineer of the Acheson-Oildag Co., Niagara Falls, N. Y., sailed for Europe on the steamship *St. Louis*, September 25. Mr. Banbury is an Englishman by birth; he came to America about five years ago and became connected with the Acheson-Oildag Co. over a year ago. His European trip is taken in the interest of the company to introduce deflocculated graphite, the discovery of Edward G. Acheson, president of the company.

W. E. Wickenden has been appointed assistant professor of electrical engineering of the Massachusetts Institute of Technology, Boston, Mass., and will assume the duties vacated by Prof. G. E. Shaad, who has gone to the University of Kansas to take charge of the electrical engineering department there. Mr. Wickenden is a graduate of Dennison University, and is a member of the electrical engineering staff of the University of Wisconsin. He is the author of a book on photometry and illumination.

* * *

OBITUARIES.

James Denver, formerly master car builder of the N. Y., N. H. & H. R. R., died August 19, and was buried in Springfield, Mass.

Walter E. Andrews, president of the Williams Typewriter Co., died at his home in Shelton, Conn., September 7 of arterial trouble, aged fifty-nine years. Mr. Andrews was a native of Vermont, and, when a young man, went West and resided in Des Moines, Iowa, for many years, where he became president of the Western Newspaper Union. He came East to Brooklyn and about nine years ago removed to Shelton.

Russell Markham died at the home of his son, E. R. Markham, Cambridge, Mass., August 24. Mr. Markham, during war times, worked on rifles for the United States government at the old Jones & Lamson shop, Windsor, Vt., and the Massachusetts Arms Co., Chicopee Falls, Mass. After the close of the civil war the Lamb Knitting Machine Co. bought the Massachusetts Arms Co. plant and Mr. Markham entered its employ as foreman, which position he held for nearly forty years, retiring only four years ago on account of advanced age.

Robert Hoe, 3rd, head of R. Hoe & Co., printing press builders, New York and London, died in London, September 22, aged seventy years. Mr. Hoe was the third in line of printing press builders. His grandfather, Robert Hoe, came to America from Leicestershire, England, in 1784, and in 1803 started a printing press plant with his brothers-in-law, Matthew and Peter Smith. Mr. Hoe was succeeded by his two sons, Col. Richard M. Hoe and Robert Hoe, 2nd. Robert Hoe, 3rd, was a son of the latter, and succeeded to the management in 1884. At the time that Robert Hoe, 3rd, entered the business, the cylinder press invented by his uncle, Richard M. Hoe, had a capacity of only 9,000 sheets of four pages each per hour, which had afterwards to be folded by separate machinery or by hand. Hoe presses are now built that are fed with eight rolls of paper at once, and produce 166,000 16-page newspapers per hour, folded ready for delivery. While Mr. Hoe was remarkable for his inventive capability, it is said he never took out a patent in his own name. He was an organizer of ability and systematized his factory thoroughly in all departments. Mr. Hoe also had some reputation as an author, having written several books on book-binding, evolution of printing presses, etc. He gave a great deal of attention to the education of apprentices, and every boy apprentice to R. Hoe & Co. was compelled to attend school, one hour of his working time and one hour of his own time being devoted to this purpose every week day evening. The Grand Street factory, New York, employs about 2,500 men, and the London factory about 800 men.

* * *

The Zeppelin airship has found a serious rival in the Schütte airship, which will undergo thorough trials within a few months. This navigable balloon will have a lifting capacity of five tons, and its chief interest centers in the fact that the inventor has devised means for storing the gas forced out of the balloon by the ascent into high altitudes, or by the expansion due to the heat of the sun's rays. This fact

will enormously extend the possibilities of remaining in the air, as the gas can again be supplied to the balloon as required. The plans have been submitted to leading aeronautic experts and are said to have met with their encouragement. Prof. Schütte retains the rigid frame of the Zeppelin airship but employs wood instead of aluminum, and the cover has a lining of gold-beater's skin. From these new features important advantages are anticipated. The airship will be lighter and more elastic, the loss of gas will be reduced to a minimum, and the absence of metal in the framework will render ignition from lightning less probable. At the same time, the absence of metal enables a wireless telegraphy outfit to be carried in the car without danger.

* * *

COMING EVENTS

October 3-9.—St. Louis Centennial Week, St. Louis, Mo. Balloon, airship and aeroplane races will be arranged under the auspices of the Aero Club of St. Louis.

October 4-8.—Annual joint convention of the American Street and Interurban Railway Association, American Street and Interurban Railway Accountants' Association, American Street and Interurban Railway Engineering Association, American Street and Interurban Railway Claim Agents' Association, American Street and Interurban Railway Transportation and Traffic Association, American Street and Interurban Railway Manufacturers' Association, at Denver, Col. Bernard V. Swenson, secretary and treasurer, 29 West 39th St., New York.

October 12.—Monthly evening meeting American Society of Mechanical Engineers at the Engineering Societies Building 29 West 39th St., New York. Calvin W. Rice, secretary, 29 West 39th St., New York.

October 12-13.—Semi-annual convention of the National Machine Tool Builders' Association at the Hotel Astor, New York. P. E. Montanus, secretary, Springfield, Ohio.

October 14.—MACHINERY's seventh annual outing.

October 19-21.—Annual convention of the American Railway Bridge and Building Association, Jacksonville, Fla. S. F. Patterson, secretary, Boston & Maine R. R., Concord N. H.

April 1-June 30, 1910.—American Exposition in Berlin to stimulate trade relations with Germany and American export business generally. The exposition will be held in the Exposition Palace, having 110,000 square feet floor space. Max Viewger, American manager, 50 Church St., New York.

December 1-13.—Annual convention of National Association for the Promotion of Industrial Education, Milwaukee, Wis. J. C. Monagham, secretary, 20 West 44th St., New York.

NEW BOOKS AND PAMPHLETS

INVENTIONS, PATENTS AND DESIGNS. By G. Croyden Marks. 116 pages, 4¾ by 7 inches. D. Van Nostrand Co., New York. Price $1.

This work contains the full text of the British patent and designs act of 1907 and will for this reason be particularly valuable to Americans who are interested in British patents. The general text treats of fostering industries, the meaning of patents, what is patentable, surrender and revocation of patents, licensing of inventions, infringement of patents, patent working in America, legal proceedings, applying for an injunction, how to work patents, designs, etc.

POCKET MANUAL OF ENGINEER'S SOLAR TRANSIT. 53 pages, 4½ by 6½ inches, 9 illustrations. Published by Keuffel & Esser Co., 127 Fulton St., New York, and Hoboken, N. J.

The manual describes the Keuffel & Esser engineer's solar transit, its adjustments and method of use. A table of mean refractions is included, also rules for taking the sun at any latitude or longitude, determining the meridian by direct observation on the sun and determining the meridian by observation on Polaris. While the manual is designed for engineers and others fully familiar with the use of the transit, it will also be found of considerable interest to amateurs and others who would like to know how the polar explorers Cook and Peary located the pole or how navigators verify their position in mid-ocean.

MACHINE SHOP DRAWING. By Fred H. Colvin. 139 pages, 4½ by 6¾ inches, 91 illustrations. Published by the McGraw-Hill Book Co., New York. Price, $1 net.

This book is intended to help those who do not understand the reading of drawings rather than to teach drawing itself. It is a fact that many good mechanics are "shy" on reading blue-prints, and this treatment of the subject has been with a view of explaining to this class the principles of mechanical drawing, illustrating the same with examples of common objects found in machine shop practice. The contents by chapters are: Reading Drawings, Drawing of a Monkey Wrench, Some Examples of Drawings, Laying Out Spur Gears, Laying Out Bevel Gears, The Worm and Worm-wheel, and Sketching.

HENDRICKS COMMERCIAL REGISTER OF THE UNITED STATES FOR BUYERS AND SELLERS. 1,220 pages, 7½ by 10 inches. Published by S. E. Hendricks & Co., 74 Lafayette St., New York. Price $10, express charges prepaid.

This well-known directory of the architectural, mechanical, engineering, electrical, construction, railroad, iron, steel, mining, mill, quarrying, exporting and kindred industries has passed into the eighteenth edition. It contains over 350,000 names and addresses and has 35,774 classifications, fully listing manufacturers and dealers in the industries mentioned. The comprehensiveness of the directory may be inferred from the statement made by the publishers that it lists for railroads everything from a track bolt to a locomotive; for mining, everything from a miner's lamp to a stamp mill of steel tipple; for the machine shop, everything from a tool-holder to a boring and turning mill or traveling crane; for foundries, everything from a molder's flask to a cupola; for contractors, everything from a pick or shovel to a hoisting engine or steam shovel; for the drafting room, everything from a drawing pencil to a blue-printing machine; for power transmission, everything from a belt fastener to a complete system including the latest specialties in right angle transmission and variable speed countershafts. The directory is one that we heartily recommend to all who desire comprehensive lists of concerns in the various industries. The lists are conveniently arranged for circularization, etc.

CATALOGUES AND CIRCULARS

FREDERICK O. DRAKE & CO., Fisher Building, Chicago, Ill. Catalogue of mechanical books for home study.

MODERN TOOL CO., Erie, Pa. Leaflet of universal grinding machines made in two sizes, 9 x 26 inches and 13 x 32 inches capacity, respectively.

AMERICAN RAILWAY STEEL TIE CO., Harrisburg, Pa. Circular describing the composite steel and asphalt filling tie made under the John G. Snyder patents.

PHILLIPS PRESSED STEEL PULLEY WORKS, 4th St. and Glenwood Ave., Philadelphia, Pa. Leaflet illustrating the Elliott Cresson medal awarded to Ferdinand Phillips, October 2, 1907, for his machinery for manufacturing pressed steel pulleys.

WELLS BROS. CO., Greenfield, Mass. Circular of machine screw taps and dies of the American Society of Mechanical Engineers standard. The A. S. M. E. sizes are being adopted by many manufacturers, and it is probably only a matter of a few years when the V thread machine screws will become obsolete.

FRANK MOSSBERG CO., Attleboro, Mass. Five full size illustrations of Mossberg screw wrenches, namely: Midget, Sterling No. 2, Sterling No. 3, Sterling No. 14, and Sterling No. 50. The half tones reproduce the beautiful mottled effect of case-hardening and are very attractive examples of half-tone illustrations.

ELECTRICAL ALLOY CO., Morristown, N. J. Catalogue No. 2 of resistance materials in every variety of wire, sheet and ribbon, nickel steel alloy, nickel copper alloy, ferro nickel alloy, nickel-chromium alloy, German silver alloy, for use in the manufacture of arc lamps, resistance controllers, car heaters, measuring instruments, rheostats, etc.

CLEVELAND TWIST DRILL CO., Cleveland, Ohio. Leaflet on drill grinding, reproducing MACHINERY's shop operation sheets Nos. 100 and 101 on grinding flat and twist drills. The company supplies a model drill point in die-cast metal which is intended to serve as a guide to the proper grinding of drills. This will be found valuable by all users of twist drills. The price is $1.

NEW ERA GAS ENGINE CO., Dayton, Ohio. Catalogue of New Era auto-cycle which is designated as a two-wheeled automobile, and is operated similarly to an automobile. It has no pedals and is driven by an air-cooled 3½ horse-power single-cylinder motor through a two-speed gear that enables the rider to ascend the steepest hills found on the ordinary highways.

KEUFFEL & ESSER CO., 127 Fulton St., New York, and Hoboken, N. J. Price list of blue-print papers which are supplied in three grades as regards time: regular, requiring from four to eight minutes' exposure in bright sunlight; quick, for work required on short notice and where no good light is available, and electric quick, for use with electric light and electric printing machines.

WESTERN ELECTRIC CO., 463 West St., New York. Bulletin of tungsten miniature low voltage incandescent lamps, 1.5 to 20 volts. These lamps vary in efficiency from 0.9 watt per candle power to 1.33 watts per candle power, and are desirable for use on automobiles, flash-lights, signs, dental, optical and surgical instruments, etc., and in fact in any place where small low-voltage power lamps are used.

MIAMI VALLEY MACHINE TOOL CO., Dayton, Ohio. Catalogue F of Miami Valley engine lathes made in 13-inch and 16-inch sizes, 13-inch stud lathes, sensitive drills, plain cutter and reamer grinders, No. 2 universal grinder with automatic feed, No. 2 universal surface grinder, No. 1 universal cutter and tool grinder. The operations of grinding a form cutter, gear cutter, blanking punch, spiral cutter, T-slot cutter, side milling cutter, etc., are illustrated.

INGERSOLL-RAND CO., 11 Broadway, New York. Bulletin No. 4009 of Temple Ingersoll "electric air" rock drills. The Temple Ingersoll "electric air" rock drill apparatus comprises an electric motor and a two-cylinder air pump and the rock drill proper. The air pump is connected with the rock drill by two hose and the pulsations of the pump work the drill in unison, using the same air continuously.

CHAPMAN ENGINEERING CO., 917 Land Title Building, Philadelphia, Pa. Catalogue of casehardened, corrugated copper flange gaskets, adapted to all kinds of steam service, working equally efficiently under superheated steam, high pressures or low pressures. These gaskets are guaranteed not to burn or blow out, to stand 500 pounds steam pressure and superheated steam of any practicable working temperature and to make an absolutely tight joint on a rough or pitted surface.

NORTON CO., Worcester, Mass. Booklet entitled "Facts Worth Knowing about Grinding Wheels," containing valuable information for users. The Norton grinding wheels are made by three processes—vitrified, silicate or semi-vitrified, and elastic, and in grades suitable to all classes of work. Suggestions for ordering are given which will be found valuable by those who are not fully aware of all the factors that enter into the selection of grinding wheels necessary to secure the highest efficiency.

NEWMAN-ANDREW CO., 107 West St., New York. Circular of "Toledo" high-speed steel manufactured by Jno. Hy. Andrew, Ltd., Toledo Steel Works, Sheffield, England. The circular gives directions for treating "Toledo" high-speed steel, ordering steel suitable for various purposes, such as cold chisels, boiler snaps, mint dies, rock drills, lathe tools, milling cutters, etc., and lists the various brands manufactured. A comparison of thermometric scales, and tables of weights of bar stock per lineal foot are appropriately included.

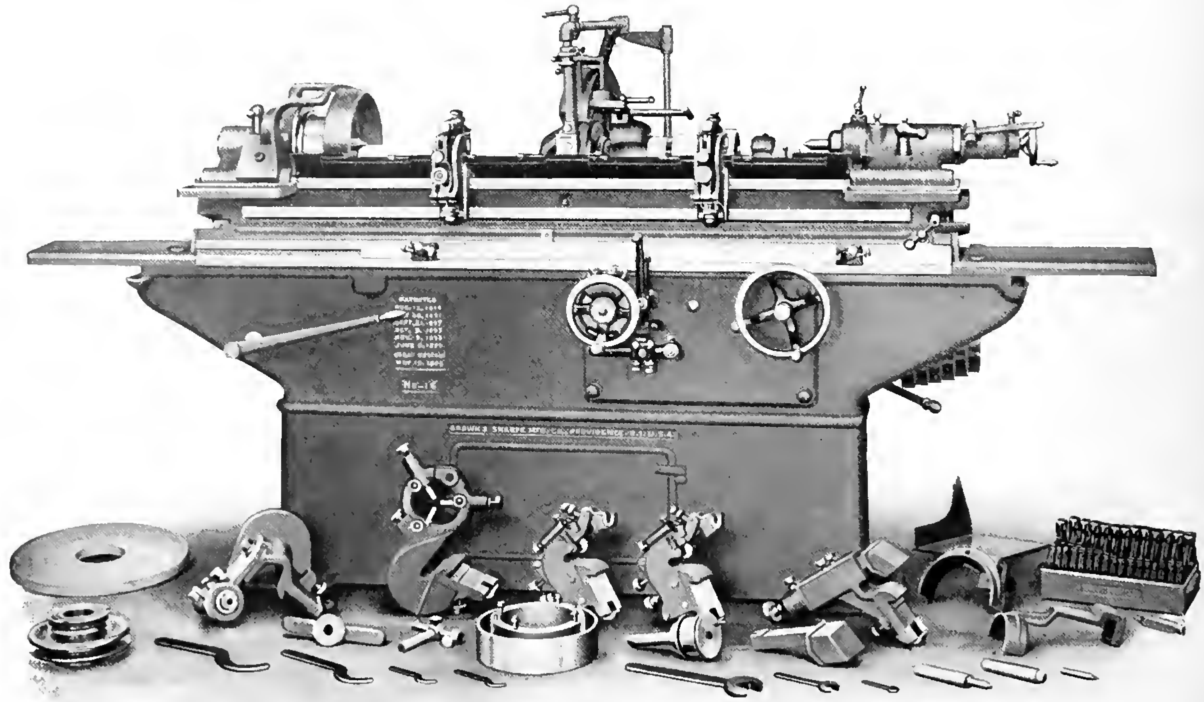
ELECTRO DYNAMIC CO., Bayonne, N. J. Circulars No. 29, 32, 34 and 35, illustrating the electro-dynamic interpole variable speed motors which have the following characteristics: 1. Constant speed at any controller position regardless of load. 2. Wide speed range by field control. 3. Freedom from sparking. 4. Compactness. 5. Reversibility. 6. Operation on any single voltage—110, 210, or 500 volts. The circulars describe the theory of magnetic action and illustrate the construction of the motors, and their application to machine tools, elevators, printing presses, crane trolleys, vacuum cleaning pumps, centrifugal pumps, etc.

W. S. ROCKWELL CO., 50 Church St., New York. Circular of Rockwell annealing and hardening furnaces, giving dimensions, fuel consumption of oil and gas, and other data required by purchasers. The furnaces are made in 13 sizes, the smallest having chamber dimensions of 10 by 13½ inches, and entrance to chamber, 9 by 5 inches. The largest furnace listed has a chamber 39 by 54 inches with entrance 36 by 18 inches. These furnaces are suitable for annealing, hardening, tempering and casehardening, but are not adapted for hardening high-speed steel.

NATIONAL FILE & TOOL CO., 2110 Allegheny Ave., Philadelphia, Pa. Catalogue of the "Vixen" patent hand milling tool. The Vixen file and milling tool was described in the May, 1909, number of MACHINERY. It differs from the ordinary file in the shape of the cut, the teeth being formed on the arc of a circle and so shaped as to give a smooth shearing action. It is claimed that the Vixen file and milling tools will cut from three to five times as fast as an ordinary file tool, and last from four to six times as long. They are particularly efficient on soft metals and alloys such as babbitt, lead, aluminum, etc., cutting rapidly and being self cleaning.

W. F. & JOHN BARNES CO., 231 Ruby St., Rockford, Ill. Catalogue No. 69 of upright drills and other machine tools, comprising bench friction disk drill, floor friction disk drill and regular upright drills of various patterns and designs from 15 inches swing to 50 inches swing, inclusive. These drills are provided with special attachments according to requirements, including gear tapping attachment, compound table, oil feeding device, multiple spindle head, etc. The Barnes horizontal radial drill is illustrated, and also the Barnes water emery grinder, adjustable screw press, universal sliding chuck attachment, and various features of design and construction of the upright drills

BROWN & SHARPE MFG. CO.,



B. & S. Grinding Machine Accuracy is Permanent

When a machine is new its perfect working condition and ability to produce accurate work are naturally expected. **The real test, however, is that of long continued service** and it is here that is manifested the **excellent design** and **high quality** of **workmanship** which characterize

B. & S. Grinding Machines.

In construction a sufficient amount of metal is correctly distributed in all parts to secure rigidity—a factor of utmost importance. The working parts are easily accessible and all levers and hand wheels are conveniently located so that the operator may have full control from the front of the machine. This, together with the employment of a special cross feeding mechanism that causes work to be ground automatically to within .00025 of an inch of a required size, enables **one operator** to **easily run two machines.**

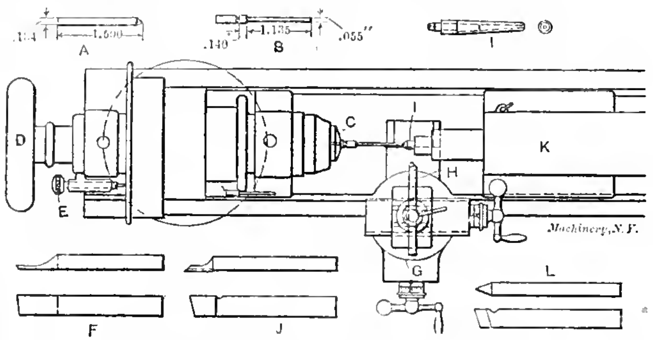
Another feature of great importance consists in the fact that the work speeds and table feeds are completely separated, permitting the correct table feed for any work speed to be obtained.

Supplement to MACHINERY, November, 1909

Operations for the Article in this number entitled "Machine Shop Practice—Jig and Die Work in the Bench Lathe—I"

SHOP OPERATION SHEET NO. 115.

A. L. Monrad. MACHINERY, November, 1909.



Accurate Turning in a Bench Lathe.

1. As the pin is to be turned to the dimensions given at *B*, secure a piece of say 0.134-inch wire which is the size of Stub's gage number 29. Insert split chuck *C* for this size wire in the lathe spindle, being careful that the tapering part of both chuck and spindle are clean. Push the wire through the chuck until it projects about 1⅝ inch, and tighten the chuck by turning the hand-wheel *D*.

NOTE.—Never use the indexing pin *E* in the holes of the pulley to prevent the latter from turning while tightening the chuck (unless a special index plate is used for that purpose) as by so doing the indexing holes will become worn.

2. If the wire extends far beyond the hand-wheel *D*, place a horse beneath the end of the wire to keep it from flying about when turning, or saw it off close to the lathe spindle.

3. Fasten a cutting-off tool *F* in the tool-post with the point as close as possible to the latter to prevent chattering. Set the tool so that it will cut off 1½ inch of stock, and with the belt on the smallest pulley and the foot on the treadle giving the slowest speed, cut the wire, using lard oil as a lubricant.

NOTE.—If a number of pieces are to be cut off, the tail center can be used as a stop for the stock by locating it 1½ inch from the cutting edge of the tool.

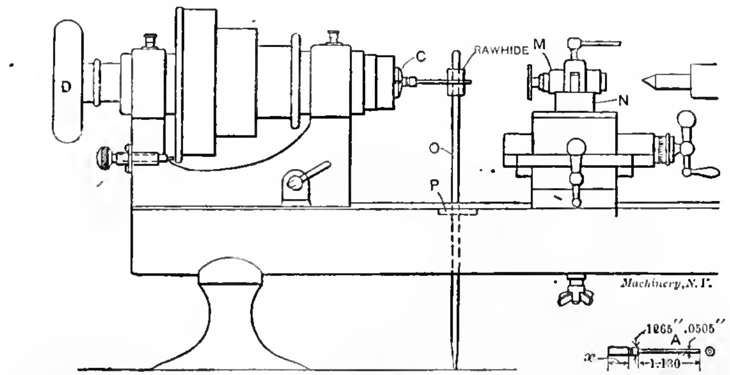
4. Set the slide rest *G* to an angel of 30 degrees, and fasten the piece of wire, previously cut off, into the chuck so that its end projects about ¼ inch. Set the cutting edge of a diamond pointed tool *H* to the height of the center of the work and turn the latter to a conical point as shown at *A*. Allow the wire to project about 1 5/16 inch beyond the face of the chuck and support it by a special female center *I* in the tail-stock *K*.

5. Rough turn the pin, using the diamond point tool *H*. Take a finishing cut with a side tool *J*, forming the pin as shown at *B*, and making it 0.055 inch in diameter and 1.135 inch long to the shoulder. When turning, shift the belt to the largest pulley and press down with the foot on the fast treadle. Cut a groove 0.140 inch from the shoulder with a sharp thread tool *L*.

6. After the pin has been hardened, polish it in the lathe, using a medium grade of emery cloth, and then draw the temper to a light straw color. Again polish the pin ready for the grinding operation.

SHOP OPERATION SHEET NO. 116.

A. L. Monrad. MACHINERY, November, 1909.



Grinding in a Bench Lathe

1. After the pin is turned and hardened as described in the preceding sheet, grind off the conical point by hand on an emery wheel making the distance from the end to the shoulder 0.130 inch as shown at *A*. Insert a chuck the proper size for the small diameter of the pin in the head-stock spindle.

2. Insert the small end of the pin in the chuck within 1/16 inch of the shoulder and tighten the chuck slightly by turning the handle *D*. If the work is gripped too tightly, it is liable to run out of true.

3. Fasten the grinding attachment *M* in the tool-post so that the axis of the wheel spindle is parallel with the axis of the work, and also so that the two axes are in the same horizontal plane. Adjustments for height may be obtained by inserting a ring *N* beneath the attachment. Dress the face of the wheel, which should be of fine carborundum, to an angle of about 5 degrees. Cover the slide rest with a piece of cloth to protect the bearings from the abrasive when grinding, and grind the part x of the pin perfectly true.

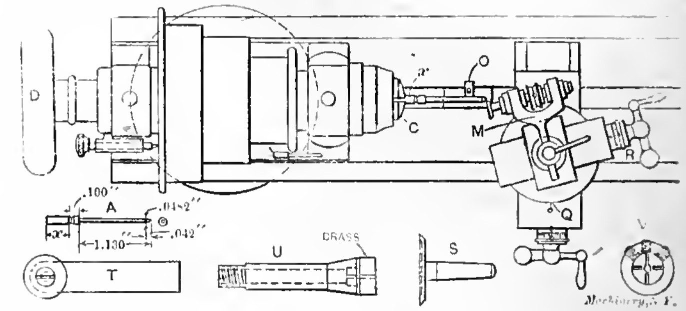
4. Place a larger chuck *C* in the spindle and reverse the pin, gripping it by the part just ground. If the outer end of the pin runs out it may be trued by inserting a narrow strip of tissue paper between the taper of the chuck and the spindle.

5. The steady-rest *O* is next adjusted to the work. This must be done very carefully so as not to spring the pin when grinding. First move the brass plate *P*, up between the ways of the lathe bed, and then adjust the rawhide support until it is in line with the work. Next stick the wire point into the bench, as shown in the illustration, so that the rawhide just barely touches the pin.

6. Grind the pin up to the shoulder to a diameter of 0.0505 inch, allowing 0.0005 for lapping. Be sure that the work is parallel before taking the finishing cut. Keep the wheel sharp and run with the belt on the second pulley and the foot on the fast treadle. Feed moderately, grinding off 0.001 inch at a time. Grind the head to a diameter of 0.1265 inch. Allow the steady rest to remain in position for the succeeding operation.

SHOP OPERATION SHEET NO. 117.

A. L. Monrad. MACHINERY, November, 1909.



Grinding with a Diamond Wheel

1. Loosen the screws in the slide rest and swing it around to an angle of 4 degrees, using the graduations at *Q*.

2. Grind the end of the pin true, and then set the feed-screw thimble *R* to zero. Next grind a taper on the end 0.042 inch long and 0.049 inch diameter.

3. Remove the emery wheel from the tool-post grinder, drive a diamond wheel *S* in the grinder collet and screw it into the spindle. The spindle should be driven direct from the main shaft, using the smallest pulley, to obtain the slowest speed. Distribute some number 2 diamond dust mixed with sperm oil over the face and side of the wheel and then charge the latter by holding a hardened roller *T* against its face and side for say five minutes.

4. Change the belts so that the grinder runs at the fastest speed while the pin revolves very slowly, and finish grind the end of the pin. Set the thimble *R* on the feed-screw to zero, and grind the taper end to 0.0482 inch diameter at the largest part, as shown at *A*, leaving a sharp corner and a shoulder which is to be 0.001 inch on a side after the work is finished by lapping.

5. Move the slide rest and the steady rest *O* to one side, and with a lap *V*, lap the two diameters of the pin to 0.050 and 0.126 inch, respectively, using the finest emery and sperm oil. To lap the pin round and straight, do not move the lap slowly, but draw it back and forth moderately fast, for by so doing a perfectly straight and round surface is obtained. Finish with a clean lap and use machinery oil for draw-lapping to obtain a very brilliant and shining surface. Move the slide rest back in position, and with the hand resting on the slide rest, draw-lap the taper of the pin, using a flat copper lap and fine emery, or white oil-stone dust and sperm oil until it is reduced to 0.048 inch at the largest part.

6. Reverse the pin in the chuck so that the end x projects, and break off this end. Insert a chuck *U*, to which a brass piece has been soldered, in the spindle. Drill and bore a hole, in which the small part of the pin will be a push fit, in this brass piece, and push the pin through the plate. Solder the pin to the plate. Replace the diamond wheel with an emery wheel and adjust the latter until its axis is in the same plane and at right angles with that of the work. Face the head of the pin to a length of 0.100. With a side tool remove the solder and withdraw the pin.

CHAIN-MAKING EXTRAORDINARY IN A SCRAPLESS PRESS-ROOM

CHESTER L. LUCAS*

TWENTY-FIVE thousand links of steel sprocket chain, automatically punched, formed and assembled complete in one day of 10 hours! This is the remarkable, though everyday performance of each of the many automatic chain presses in the factory of the Locke Steel Belt Co., of Bridgeport, Conn., manufacturers of steel belt or sprocket chain.

This chain is made primarily for two classes of work: agricultural machinery, such as planters, mowing machines, harvesters, etc., and for conveying and elevating machinery in the mining, grain and other similar industries. The chain is made to meet all requirements, being made in varying sizes from ½ to 3 inches in width, and in thicknesses from 0.045 to 0.250 inch. During the making of this chain not an ounce of the stock is wasted in scrap, excepting a small "scallop" at the beginning and another at the end of each coil of steel. The part of the link which is punched to form the opening in the center is curled around and serves to connect the link with the one following. Thus, 100 feet of steel ribbon enters the press from one side and emerges on the other side as 95 feet of completed chain—the slight shrinkage being due to the bending of the steel in forming the link. The steel used is of low carbon, and comes in large coils ready for the press, having been rolled to the right width for the size chain into which it is to be made; therefore all sharp edges that would result from sheared stock are eliminated. The chain is easily parted at any desired point by simply bending a link backwards as far as possible and slipping it out edgewise.

* Address: Saugus Station, Lynn, Mass.

The Automatic Chain Press

The principal feature of the making of this chain is the automatic chain press shown in Fig. 1. This type of machine was specially designed and built for the work, and as the results will testify, it has been highly satisfactory. In general, it resembles and in fact is, a heavy, powerfully-geared, triple-action press. At the right of the illustration may be seen a roll of stock being fed to the press, and just outside of the housings of the press is located the feeding device which is patterned after the familiar grip feed. The main point of this feed is its positive action, which is absolutely necessary on account of the construction of the dies themselves. If, for example, the stock and partly completed links should, through failure of the feed, be advanced but half the required distance, the dies would be badly damaged at the next stroke of the press. Fig. 2 shows the feed in cross-section, and its operation is as follows: As the connecting-rod *A* descends (actuated by a crank on the driving wheel) it causes link *B* to recede, carrying with it part *C*, which upon reaching lug *D*, pulls back the feed finger *E* in conjunction with slide *F*, of which it is a part. When the end of the stroke is reached, the forward motion throws the feed finger *E* with its jaw, into the stock, forcing it hard against the corresponding jaw in the slide beneath the stock. Between these two jaws the stock, with the whole slide, is carried forward the distance required to form one link. To prevent the slide *F* from moving forward before finger *E* has gripped the stock, a spring pressure plate *G* is provided which bears against the slide. Before the steel ribbon enters the feed, it

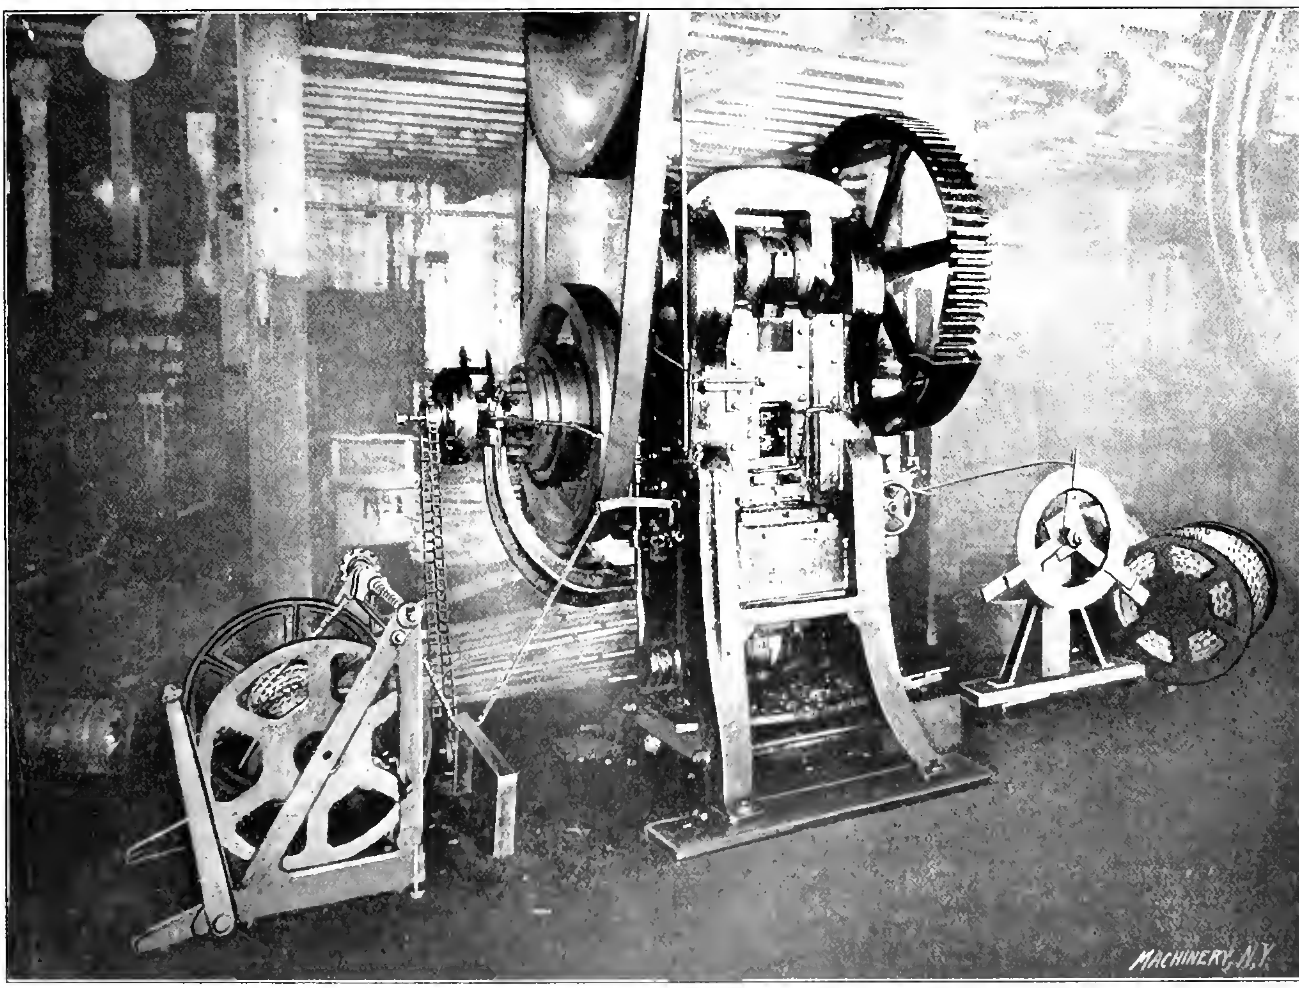

Fig. 1. Automatic Chain Press and Reel upon which Finished Chain is wound

passes between a set of straightening rolls that effectively removes any kinks or dents that would interfere with the action of feed or dies.

The Dies

The dies used in this chain press are very interesting. Although of a modified design, they are after the style of the ordinary follower die; several operations of the chain making being performed upon as many different sections of the stock at each stroke of the press. Another noticeable feature is that all wearing parts, such as punches, scoring chisels, etc., are so arranged in the dies that they may be easily removed without interfering with the rest of the dies, thus facilitating adjustment and renewal. The bodies of the first chain dies were made of tool steel; later machine steel was used, and at the present time machine steel case-hardened to a depth of 1/16 of an inch, is giving better satisfaction than either the unhardened machine steel or the tool steel.

The press tools for the making of the chain are shown in Figs. 3 and 4; these may properly be divided into four parts: the punch *A*, which is held and operated by the main ram of the press; the plate (or stripper) *B*, which is held and operated by the cam-slide; the principal die *C* (also shown in plan view in Fig. 4) fastened to the bed of the press; and the finishing die *D* held and operated by the triple-action mechanism beneath the bed of the press. The function of plate *B* is to hold the body of the chain while punch *A* with its sections *b*, *c*, *e*, *h* and *j* are performing their work on the links and also while finishing die *D* is at work on the under

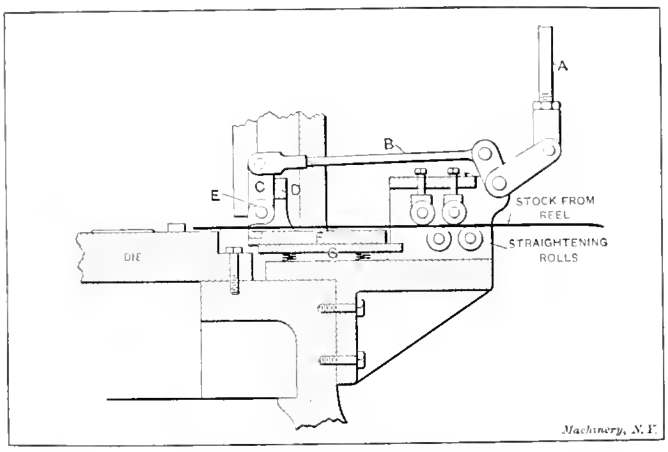

Fig. 2. Positive Feeding Mechanism which advances the Stock the Length of a Link at each Stroke

side of the stock, connecting the links. Just before punch *A* does its work, plate *B* is clamped upon the stock by means of a cam-slide, and held there until the upward stroke releases it.

After leaving the straightening rolls, the stock enters the feeding mechanism already described, and by it is advanced the length of one link under the dies. The first stroke of the press forms the stock over the rounding projection *a* in the die; at the same time, on the under side of the stock, scoring chisels b_1 in the die meet scoring chisels *b* in the punch, on the top side of the stock. While the hump is being formed over *a*, the scoring chisel *c*, located at the top of the hump in the punch, does its work, making a cut clear across and half way through the stock, to facilitate the separation of the links in a succeeding operation. The result of this stroke of the press is indicated by the letters *A* in the illustration, Fig. 5, which shows the appearance of the top and bottom of the stock. While the upward return of the press is under way, the feed is advancing the stock another link's length forward, bringing the hump just formed into position over projection *d* in the die. When the press comes down on the second stroke, scoring chisel e_1 in the die and *e* in the punch make opposite cuts that connect the first two cuts made, near their rear ends, thus outlining three sides of what is to be the open space at the center of the link. With this stroke, figure punch *f*, located in plate *B*, stamps the size of chain into each side of the face of the link. This stroke leaves the stock in the condition shown at *B*, Fig. 5.

The semi-completed links are again forwarded one length, bringing the first hump over shearing knife *g* in the die. On the third down-stroke section *h* in the punch separates the stock on the short scored cross line and pushes it in either direction into the die cavity *i*. This step is plainly shown at *C*. The stock is advanced again for the final operation of completing and connecting the links. As the punch descends, section *j* separates and pushes well down into the die, the center of the link, which operation takes but little pressure, as it has already been deeply scored on both sides. Simultaneously, section *k* of plate *B* severs the link where it has been previously scored. At this point, inverted punch *D*,

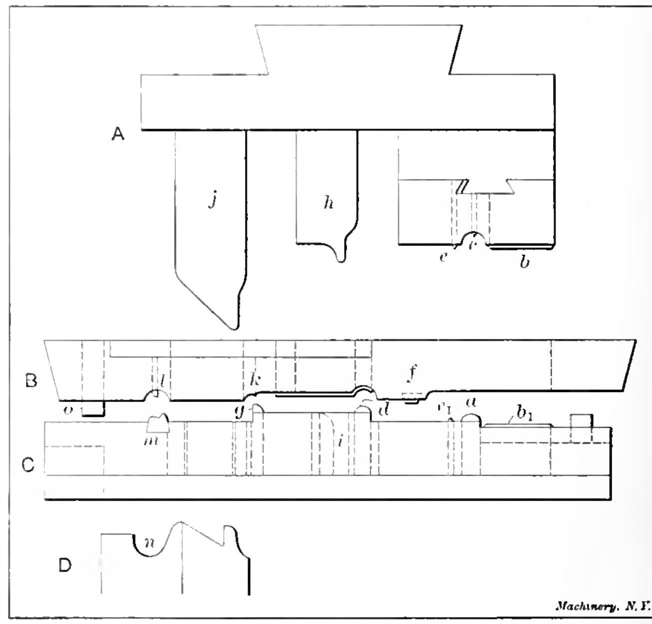

Fig. 3. The Dies used in the Chain Press

operated by the triple-action mechanism beneath the press bed, receives the link tongue in the section *n* and then rises, pushing the link tongue upward and through the center of the link ahead. At the end of its upward journey the tongue strikes the depression in plate *B*, which rounds it nicely into shape, thus connecting it with the forward link and completing the operation of making the chain. A projection *l* is placed in this recess to prevent the link from entirely closing, which would make separation of the completed links

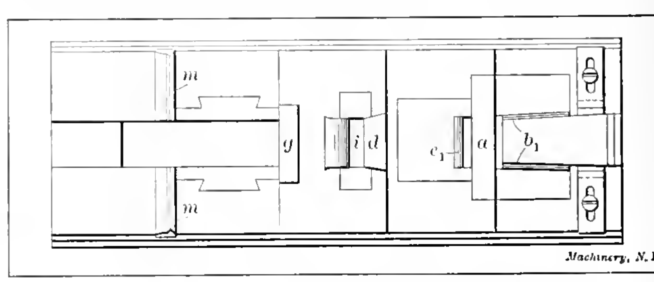

Fig. 4. Plan View of the Die shown in Fig. 3

impossible. During the linking operation, the balance of the stock, outside of the opening, is held by plate *B* against projection *m* and the rest of the die. Stop *o* is added to the dies to insure that the finished chain is pulled from the dies but one link at each stroke of the press. As the link nearest completion is severed from the balance of the stock, it is plain that it would be pulled too far by the winding mechanism if stop *o* did not drop into the opening of the preceding link and hold the link following in position for the linking operation.

While the operations just described have been taking place on the first link other links have of course been started, so that at each stroke of the press four different links are undergoing the various operations and one link is completed and connected with the finished chain that is being wound on the reel at the left of the press.

The Reel

As the completed chain leaves the press it passes under a cam-lever and thence to the reel at the left of the press, as shown in Fig. 1. The solving of the winding problem was not as simple a matter as it would at first appear. To begin

with, the reel weighs over 100 pounds empty and wound with chain, over 500 pounds; therefore the mechanism must be strong and simple, especially as the weight is constantly changing. Secondly, at the starting of the empty reel only about two feet of the chain is wound in one revolution, but when the reel is nearly filled, from eight to ten feet are wound in one revolution, consequently the reel winding must be intermittent. Thirdly, adequate means had to be provided for winding the chain in even layers in order that it might be easily unreeled in subsequent handling.

The reel is about three feet in diameter and made of heavy iron with the sides perforated to reduce the weight as well as to allow the oil better circulation in the tempering bath, which will be described later on. In use, the reel is supported on four small rollers at the base of its support; the rear set acts as driver and transmits the power for turning the reel. When the lever at the side of the reel is thrown down, the rear set of rollers drops back and allows the reel to roll out of the frame. The scheme for obtaining the intermittent motion to the reel-winding is simple. To the driving mechanism (which by the way is operated by power conveyed from the press by a Locke steel chain) is added a friction clutch, controlled by the cam-lever under which the chain passes on its way to the reel. When the chain is being wound too fast, it pulls up against the cam-lever, which by this upward motion disengages the friction clutch and stops the reel. After enough chain accumulates to allow the lever to drop and thus engage the clutch, the reel starts again. The chain is wound in even layers by the screw at the top of the reel which is made with a double (forward and reverse) thread. The carriage over which the chain passes is thus guided slowly backward and forward as the reel is wound, thereby producing a regular and evenly wound reel.

The Hardening Furnace

In many respects the most interesting part of this chain-making plant is the hardening room. To this department the reels of completed chain are brought, and by means of hardening furnaces like those shown in Fig. 6, the soft steel links are automatically hardened. As each link receives the same heat for the same length of time and is quenched in a bath of never-varying temperature, it is obvious that each link of the chain must be thoroughly and evenly hardened.

The illustration Fig. 7 shows a sectional view of the furnace and tank. The incline is lined with firebrick and the heat is supplied through four burners *B* which burn crude petroleum. The chain leaves the reel at the base of the furnace and passing over the sprocket wheel *A* enters the incline, through which it passes at the rate of from 6 to 10 feet a minute, entering the hardening tank shown at the foot of the incline in a bright cherry red heat. After dropping deep into the tank the chain is brought up and over sprocket wheel *C* and thence to the reel where it is wound in the manner already described. By referring to the illustration, it will be noticed that from the time the chain leaves the sprocket wheel *A* at the top of the furnace, until it reaches the sprocket wheel *C* at the end of the hardening tank, it comes in contact with nothing except the red-hot firebrick and water. In this way it is plain that there can be no danger of the hot links being stretched and thereby affecting the pitch of the chain. Provision is made for adjusting the heat in the furnace to suit large or small chain, and the machine is fitted with cone pulleys to regulate the speed at which the chain passes through.

With a line of red hot chain constantly entering the hardening tank, it does not take long to heat the water. To keep the water cool, a large supply pipe is steadily emptying cold water into the tank and at the side is an overflow pipe to carry away the warm water. One little kink on this machine deserves mention, and that is the utilizing of the exhaust heat to dry the chain as it comes out of the tank, dripping wet. As in the other reel drives, the power for this machine and its reel is transmitted by chain similar to that under process of making.

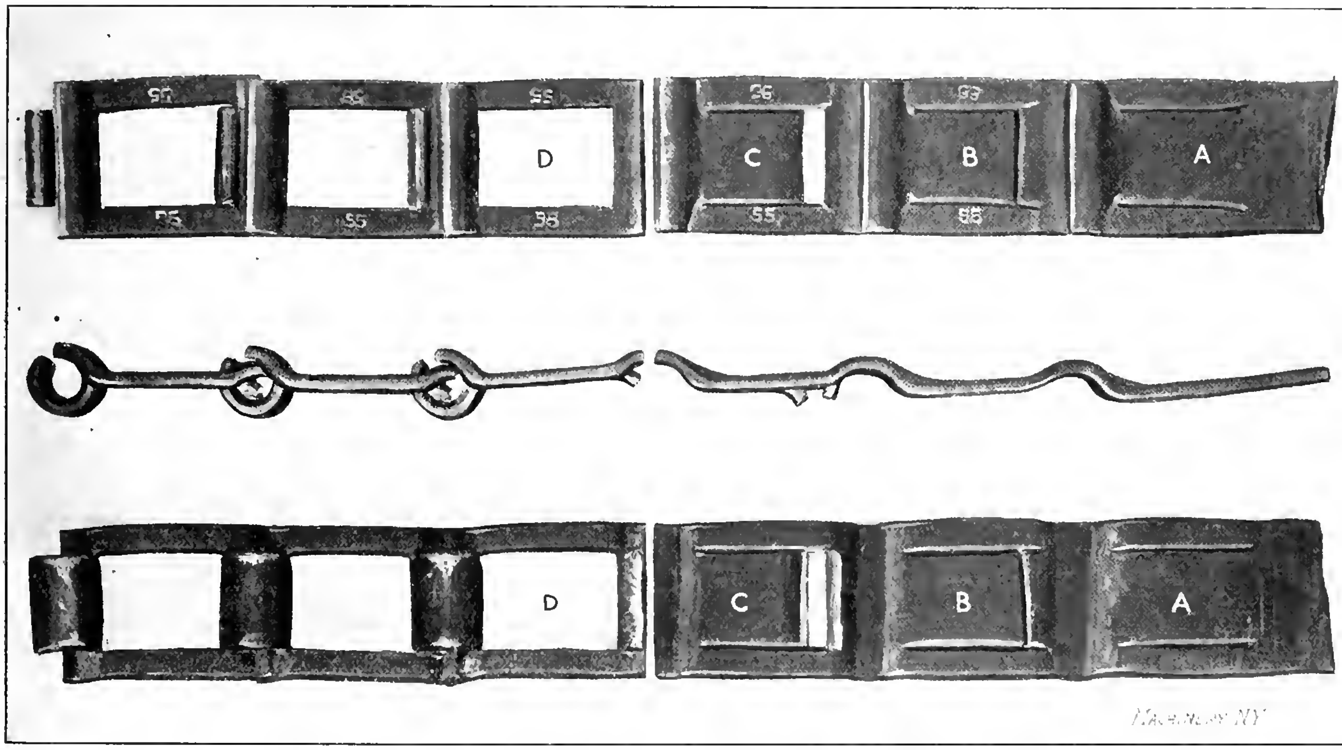

Fig. 5. The Four Successive Steps in making the Chain, and the Completed Links

Tempering

The hardened chain which is of course very brittle in its extreme hardness, now undergoes the tempering process. Great vats of neatsfoot oil are heated to a temperature of 620 degrees F. and into these the full reels of chain are lowered by means of cranes. In this hot oil the reels are left for half an hour, which reduces the temper to a point where the steel has its maximum toughness. Next, the reels of chain are placed on an iron plate which is kept continuously hot, and upon this plate they are left until the adhering oil is baked hard upon the surface of the chain.

Inspection

The tempering operation really completes the chain, yet it is put through a very rigid test which precludes the chance of a single defective link escaping. Fig. 8 shows a view of the testing department and testing apparatus. Here the chain is separated into 10-foot lengths or, if required, into special lengths, as may be seen in the background. Each of these lengths is stretched out upon the testing bench and compared with a standard 10-foot length of the same pitch. If it agrees within the required limits, one end is held by a hook

at the end of the bench and the other end attached to the testing apparatus shown. The main lever of this device is studded with pin holes, and by means of a pin and different weights the required testing pressures can be applied to the various sizes of chain. It is then again compared with the standard to detect stretching. As the chain is drawn from the reels, it is pulled through a series of sprockets to discover any stiff or otherwise faulty links that may be in it.

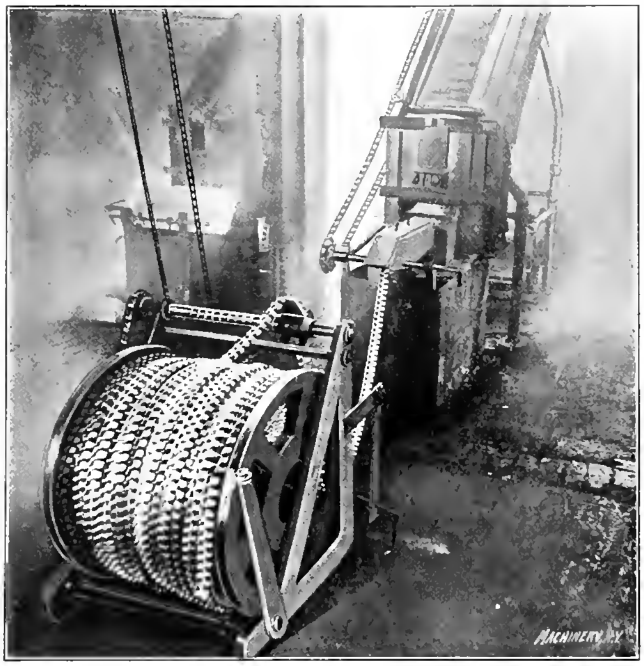

Fig. 6. Chain passing from the Reel into the Hardening Furnace

Each and every link undergoes this exacting examination, and, as two men will put 20,000 feet of the chain through the various tests in one day, the process is not as slow as it would at first seem.

It is not necessary to apply oil to the chain prior to shipment, as the oil tempering operation leaves the chain with a film of oil, baked on, which not only protects the steel from

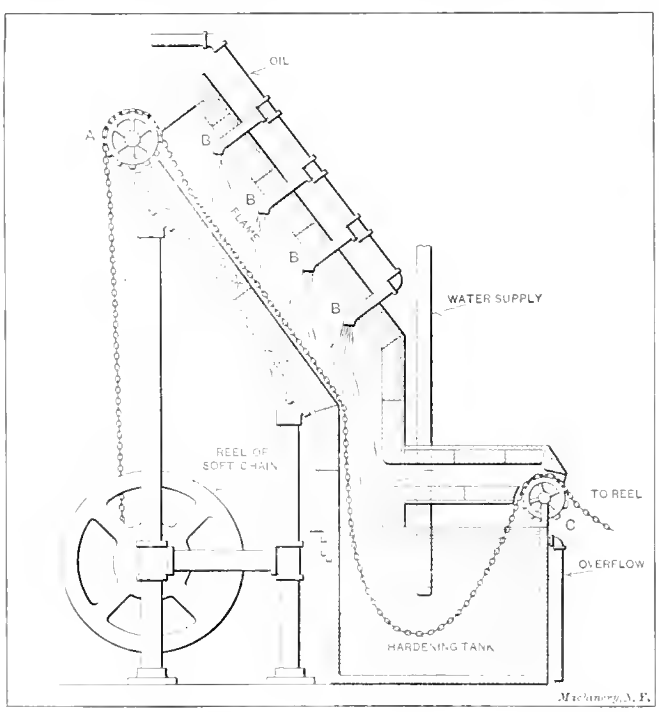

Fig. 7. Sectional View of the Automatic Hardening Furnace

the action of air and water, but gives the chain a durable glossy black finish that satisfactorily completes the manufacture of a superior sprocket chain.

* * *

A new aviation prize, offered by the French paper *Matin*, consists of a sum of $20,000 which will be paid for the first flight with an aeroplane from "city to city" before Aug. 1, 1910.

APPLICATION OF ELECTRICITY FOR PURIFYING AIR

New applications of electricity are being discovered daily but not every new application is of as much interest or importance as one recently developed for purifying the air of reading rooms, theaters, and other close places where large numbers congregate. The apparatus referred to is the ozone generator made by the National Air Filter Co., Chicago, a large installation of which was recently made in the Chicago Public Library to purify or ozonize the 10,000 cubic feet of air per minute that is forced into the main reading room. Dr. W. A. Evans, health commissioner of Chicago, declared that the air in the library building prior to the installation of the apparatus was entirely unfit for use, being foul and dangerous, and probably no other building in the city has been subjected to more condemnation because of its defective ventilating system than it. After the installation of the ozonizing apparatus it was found that the main reading room was completely deodorized, the air being freed of that disagreeable and deleterious odor which for years had so thoroughly permeated all papers, books, furnishings, etc., in this large room. The fresh sterilized "mountain" air in the room reduced the humidity during the hot, oppressive days of summer, and greatly increased the comfort of the readers and employes. The installation renders the disinfecting of all books, periodicals, papers, etc., on the shelves, racks, tables, etc., an automatic process, keeping them constantly in a hygienic condition.

Fig. 8. Department where the Chain is tested

The ozone generator is installed in the large air duct and measures 6 feet high, 11 inches thick and 1 foot wide; it consumes 6.5 amperes of current per hour while ozonizing 15,000 cubic feet of air per minute. A connection is made with a feed wire of 110 volts to a step-up transformer which discharges a current at a potential of 7,000 volts. The high-tension current feeds into a series of electrodes made in the form of ordinary hairbrushes. A static electrical discharge is maintained playing against a series of glass plates. Through this blue electrical discharge of 7,000 volts, air is forced, the result being that all bacteria, germs, etc., are electrocuted. When the filtering electrodes become dirty or clogged they are simply rubbed together and cleaned as one would clean an ordinary hair brush. The generator is placed between the fan and the spray of water used in washing the air, to prevent losing the ozone which the water would otherwise naturally take up.

The low consumption of current and consequent low maintenance cost makes the ozone generator feasible for purifying the air of shops, mills and factories where difficulty is experienced in supplying air in large volume free from odors. It is of commercial importance for preserving and restoring food and other products affected by odors or quickly tainted by decay. Ozone has been found to completely deodorize stale milk, cream, butter and other creamery products, and other uses for the process are constantly being discovered. It is being used for aging wine, curing tobacco, tanning hides, purifying water, etc.

CALCULATING THE SIZE OF BLANK FOR ROLLING SCREW THREADS

J. F. SPRINGER*

There are some interesting problems connected with screw threads which come into prominence when we take up the question of forming them, not by a cutting operation, but by a rolling process. In the process of thread rolling there is no cutting of the groove; the whole procedure depends upon pressing the metal down at one point and permitting it to protrude at another. There are no chips. The amount of metal with which one begins is the amount with which one ends. When cutting a thread in the lathe, the gage of the thread is the same as the gage of the blank; but this is not the case in thread rolling. The thread here projects out beyond the original surface, so that to make a screw thread of a particular gage, it is necessary to use a blank of less diameter. But how much less? To answer this question, it is necssary to determine just how much material is contained in a screw thread.

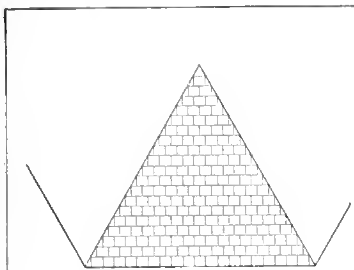

Fig. 1

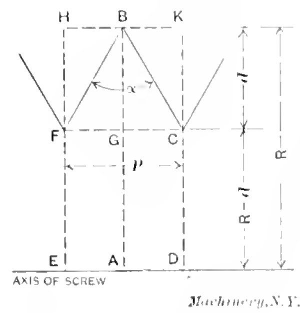

Fig. 2

Before taking up this question in a mathematical way, it may be well to point out how it might be solved experimentally. Suppose we wish to ascertain the exact volume of a sharp 60-degree V-thread ¾ inch in diameter, 10 threads per inch. Taking a ¾-inch rod of some homogeneous material, we first weigh it accurately. We next cut the required thread in the lathe, and measure the length of rod thus threaded. We may now weigh the rod again. The difference between this weight and the former one is evidently the weight of material removed in forming the groove. To get the weight of the thread itself, we may now turn off the threads and weigh the rod after the threads have been turned off. Still another method of getting the volume of the thread depends upon the fact that the groove and thread combined form a cylindrical shell whose volume may easily be calculated (by subtracting the volume of the cylindrical core from that of the blank before threading). Therefore, when once we have ascertained the volume of groove or thread, the volume of the other may readily be obtained from the combined volume by subtraction. All methods of cutting and weighing, however, require very delicate scales and careful experimentation; besides, they have to be repeated for every size.

It is important, then, to consider how we may approach this subject mathematically. The simplest thread to calculate is the square thread. In this thread the amount of metal removed is exactly the same as that left in the thread. Consequently, to get the volume of either thread or groove, we calculate the volume of the cylindrical shell, between the core of the bolt and the original cylinder of the blank, and then divide by 2. Suppose the diameter of the blank is 2 inches and the depth of thread is 0.2 inch. Then the radius of the blank is 1 inch, and that of the core 0.8 inch. If the length of the threaded portion is 3 inches, we have for the shell:

$\pi \times 1^2 \times 3 - \pi \times 0.8^2 \times 3 = 3.393$ cubic inches.

As thread or groove is one-half the shell, we have, for either, the value 1.697 cubic inch.

If there are eight threads to the inch, then there are altogether in the three inches of length a total of 24 threads. Consequently, the volume of a single thread passing once around the screw is $\frac{1.697}{24} = 0.071$ cubic inch.

Now let us consider the case when square grooves and square ridges run around the bolts in planes perpendicular to the axis. Just as before, the volume of the ridges is just equal to that of the grooves, provided that ridges and grooves are the same in section. We must, however, have an equal number of grooves and ridges in order to calculate correctly. In three inches we should have 24 ridges and 24 grooves. Consequently, as before, we find that a single ridge or groove has a volume at 0.071 cubic inch. Consider now what this means. Provided the cross-section is the same in both cases, a square thread has the same volume whether the thread is a ridge in a plane at right angles to the axis or whether it winds as in a screw. This is a very important conclusion, as upon it depends our method for the calculation of other styles of threads. It does not matter, then, how much or how little a square screw thread is inclined, its volume is ever the same, provided no change in the axial section is made. To determine its volume, accordingly, we take it in its easiest position—that is, when it is a plain annular band. We can easily calculate this, by finding the volume of a cylinder whose base has the same diameter as the thread and whose height is one-half the pitch. From this we subtract the volume of the cylinder whose height is one-half the pitch and whose diameter is that of the thread less twice the depth of the thread. The difference between these two volumes will be the volume of one thread passing once aronnd the screw. Let $2R$ be the diameter of the original blank, p the pitch, and d the depth of thread. If we denote the volume of one convolution of square thread by V, we may write

$$V = \frac{1}{2}\left[\pi R^2 p - \pi (R - d)^2 p\right] = \frac{1}{2}\pi p\,(2Rd - d^2) \quad (1)$$

Let us now inquire whether this principle that the volume of a convolution is independent of the inclination of the thread is true for the ordinary V-thread. In Fig. 1 is represented in axial section a 60-degree V-thread. We may divide this triangle by a series of lines all parallel to the base and equally distant from one another. We further divide the several bands into which the triangle is thus divided by vertical lines

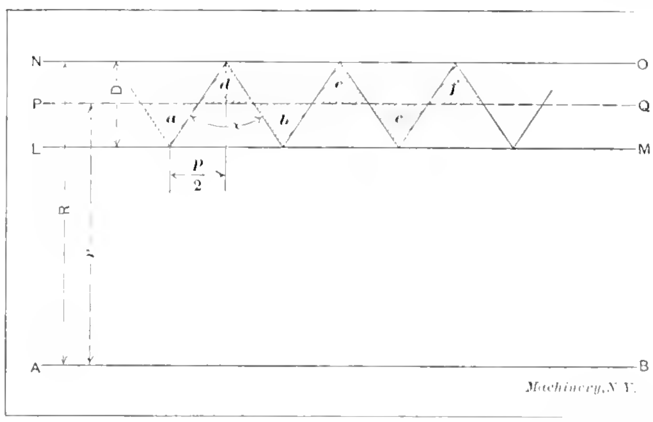

Fig. 3

into small squares all equal to each other. We have as the result a multitude of square screw threads. With the exception of the helical strips, one at the summit and one at each end of a row of squares, the cluster of little square threads will make up the large V-thread.

We now proceed to reduce the size of the section of the little square threads. Each one is made smaller, but each is kept square and all are kept equal. To do this, all we have to do is to draw all the lines closer together. The sum of the squares is now more nearly equal to the V-section, and the cluster of the small square threads becomes more nearly equal to the V-thread. If we continue to make the squares smaller, we get closer and closer to the V-section, and the cluster of square threads gets closer and closer to the V-thread. As there is no limit to our process of reducing the squares and, therefore, no limit to the closeness with which the resulting cluster of square threads approximates the V-thread, we conclude that the rule for square threads holds

* Address: 625 W. 135th St., New York City.

for the full V-section and the full V-thread. That is to say—we conclude that the volume of a V-shaped convolution may be found by ascertaining that of an annular ring having the same V-section. This is a very important conclusion.

A little consideration will soon convince one that precisely the same rule applies to any style of thread. For, by the same system of approximation, we may reach the same result.

Let us now derive the formula for the volume of a sharp V-thread. In Fig. 2, let a be the angle of the thread, p the pitch, d the depth, and R one-half the outside diameter. We must calculate the volume of an annular ring having the triangle BCF as its axial section. The volume of the annular ring may be determined by adding together the two conical frustums generated by rotating $ABCD$ and $ABFE$ on ED as axis and then subtracting the cylinder generated by rotating $FCDE$ on the same axis. We may write:

Frustum $ABCD =$

$$1/3 \times 1/2\, p\, [\pi R^2 + \pi (R-d)^2 + \pi R (R-d)].$$

Frustum $ABFE =$

$$1/3 \times 1/2\, p\, [\pi R^2 + \pi (R-d)^2 + \pi R (R-d)].$$

Cylinder $FCDE = p\,\pi\,(R-d)^2$.

Consequently, denoting the volume of the convolution of the screw thread by W, we have

$$W = \frac{p\,\pi}{6}[R^2 + (R-d)^2 + R(R-d)] + \frac{p\,\pi}{6}[R^2 + (R-d)^2 + R(R-d)] - p\,\pi\,(R-d)^2$$

$$= \frac{p\,\pi}{6}[2R^2 + 2(R-d)^2 + 2R(R-d) - 6(R-d)^2]$$

$$= \frac{p\,\pi}{6}[2R^2 + 2R^2 - 4Rd + 2d^2 + 2R^2 - 2Rd - 6R^2 + 12Rd - 6d^2]$$

$$= \frac{p\,\pi}{6}[6Rd - 4d^2],\quad W = \frac{p\,\pi}{3}[3Rd - 2d^2)$$

$$= \frac{p\,d\,\pi}{3}[3R - 2d] \qquad (2)$$

We may put this formula in a different form. By referring to Fig. 2, we may write

$$\tan\frac{a}{2} = \frac{GC}{BG} = \frac{\tfrac{1}{2}p}{d} = \frac{p}{2d},\ \text{or}\ p = 2\,d\tan\frac{a}{2}.$$

Substituting this in equation (2), we get

$$W = \frac{2\,d^2\,\pi\tan\frac{a}{2}}{3}[3R - 2d] \qquad (3)$$

Since $\tan 30° = \frac{\sqrt{3}}{3}$, we have for the sharp 60-degree thread:

$$W_1 = \frac{2\,d^2\,\pi\,1/3\sqrt{3}}{3}[3R - 2d]$$

$$= \frac{2\sqrt{3}}{9}d^2\,\pi\,[3R - 2d] \qquad (4)$$

Now, just as we found the volume of a convolution of the thread by adding two frustums and then subtracting a cylinder, so we may proceed with the calculation of the volume of a convolution of the thread groove. But we may take a different course; we observe that a thread convolution plus one of its adjacent groove convolutions has a volume equal to that of an annular ring whose axial section is the sum of those of thread and groove. By taking one-half of one adjacent groove and one-half of the other, we may reduce the annular ring to a cylindrical ring whose axial section is $FCKH$ (Fig. 2). The volume of this ring is obtained by subtracting the cylinder formed by rotating $EFCD$ from that formed by rotating $EHKD$. That is, the volume of the ring is $p\,\pi\,R^2 - p\,\pi\,(R-d)^2 = p\,\pi\,(2\,R\,d - d^2) = p\,d\,\pi\,(2\,R - d)$. If we subtract from this the volume of the thread (equation 2), we get for the volume X of a convolution of the V-shaped thread groove.

$$X = p\,d\,\pi\,(2R - d) - \frac{p\,d\,\pi}{3}(3R - 2d)$$

$$= \frac{p\,d\,\pi}{3}(3R - d) \qquad (5)$$

Since $p = 2\,d\tan\frac{a}{2}$

we have

$$X = \frac{2\,d^2\,\pi\tan\frac{a}{2}}{3}(3R - d) \qquad (6)$$

For the sharp 60-degree thread, we have

$$X_1 = \frac{2\sqrt{3}}{9}d^2\,\pi\,(3R - d) \qquad (7)$$

It is interesting to note that with V-shaped threads, where the grooves have equal but inverted sections, the volume of a groove convolution is greater than that of a thread convolution. Thus the groove convolution is (formula (5))

$$\frac{p\,d\,\pi}{3}[3R - d]$$

and the thread convolution (formula (2))

$$\frac{p\,d\,\pi}{3}(3R - 2d)$$

The first value is greater than the second. By subtracting, we ascertain that the excess of groove over thread is $\frac{p\,d^2\,\pi}{3}$.

In rolling a screw thread, a sharp ridge is pressed into the blank. As the metal being operated upon is not easily compressible, particles move away from the advancing tool, penetrating, under the pressure applied, into the body of the blank; but they cannot coalesce with the particles against which they press; nor can they sensibly find room through compression. Thus it comes about that a sharp ridge pressed into a steel blank accomplishes two results. First, it makes an indentation or groove. Second, it forms, indirectly, two adjoining ridges with a groove between them. Without going further into the process of thread rolling, enough has been said to make it clear that in threading a blank, the lower part of the groove is made by pressing suitable tool edges into the blank, and the upper part of the thread is due to material forced up out of the blank. Disregarding minute quantities, this bottom portion of the groove must equal in volume the extruded material. In Fig. 3, AB is the axis of the blank, PQ represents its original surface, LM marks the depth to which there is actual penetration of the forming dies, and NO defines the height to which there is extrusion of material. The problem that has to be solved is to determine $2r$, the diameter of the blank, when $2R$, the diameter of the desired screw, is given. The volume, then, of the grooves a, b, c, etc. must just equal the volume of the threads d, e, f, etc. By formula (3) we may express the volume of a convolution of the thread def. We replace d in this formula by its equivalent $R - r$, and obtain volume of thread convolution e (see Fig. 3).

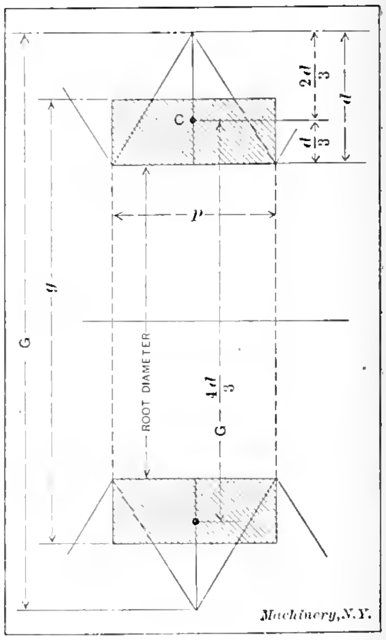

Fig. 4

$$e = \frac{2\,(R - r)^2\pi\tan\frac{a}{2}}{3}(R + 2r)$$

Similarly, by formula (6) we may express the volume of a convolution of the groove b; we must, however, replace R in this formula by r, and d by $D + r - R$ (see Fig. 3). We then have:

Volume of groove convolution

$$b = \frac{2\,(D+r-R)^2\,\pi \tan\frac{\alpha}{2}}{3}\,(2r - D + R)$$

Now thread convolution c must be equal to groove convolution b.

$$\frac{2\,(R-r)^2\,\pi \tan\frac{\alpha}{2}}{3}\,(R + 2r) = \frac{2(D + r - R)^2\,\pi \tan\frac{\alpha}{2}}{3}\,(2r - D + R)$$

or $(R-r)^2\,(R+2r) = (D+r-R)^2\,(2r - D + R)$.

From this we get, after performing the operations indicated and collecting

$$3\,Dr^2 = D^3 - 3\,D^2R + 3\,D\,R^2.$$

Dividing by $3\,D$,

$$r^2 = \frac{D^2 - 3\,D\,R + 3\,R^2}{3}$$

$$r = 1/3\,\sqrt{3\,(D^2 - 3\,D\,R + 3\,R^2)}. \qquad (8)$$

It will, perhaps, be more convenient to have this formula in terms of R and p instead of in terms of R and D. Referring to Fig. 3, we see at once that

$$D = \frac{p}{2}\cot\frac{\alpha}{2}$$

Replacing, by means of this value, the quantity D in formula (8), we get,

$$r = 1/3\,\sqrt{3\left(\frac{p^2}{4}\cot^2\frac{\alpha}{2} - 3/2\,Rp\cot\frac{\alpha}{2} + 3\,R^2\right)}$$

$$r = 1/6\,\sqrt{3\left(p^2\cot^2\frac{\alpha}{2} - 6\,Rp\cot\frac{\alpha}{2} + 12\,R^2\right)}$$

If $\alpha = 60$ degrees, then $\cot\frac{\alpha}{2} = \sqrt{3}$,

and we get,

$$r = 1/6\,\sqrt{3\,(3\,p^2 - 6\,\sqrt{3}\,R\,p + 12\,R^2)}$$

$$r = 1/2\,\sqrt{p^2 - 2\sqrt{3}\,R\,p + 4\,R^2} \qquad (10)$$

Formula (10) applies to the ordinary sharp V-thread of 60 degrees. The value $2r$ would be the diameter of wire that should be used on a thread rolling machine to produce a screw thread of an external diameter equal to $2R$. Let g be the diameter of blank wire and G the diameter of the finished screw thread. Then we may write,

$$g = \sqrt{p^2 - G\,p\,\sqrt{3} + G^2}. \qquad (11)$$

[The final formula above may be obtained in a simpler manner as follows: In Fig. 4, let

G = the outside diameter of thread,
g = diameter of blank,
d = depth of thread, and
p = pitch of thread.

The volume of one thread convolution equals the area of its section multiplied by the length of the path of the center of gravity of the section, if the section be rotated once about the axis of the screw. The center of gravity of a triangle is located one-third of its altitude from the base. Hence, C is the center of gravity, and the path of C when the thread section is rotated is a circle with the diameter $(G - \frac{4\,d}{3})$

The volume of the thread convolution then is

$$(G - \frac{4\,d}{3})\,\pi \times \frac{pd}{2}.$$

This volume must equal the volume of a hollow cylinder having an outside diameter equal to the diameter g of the blank, an inside diameter equal to the root diameter $(G - 2\,d)$ of the thread, and a height p (see Fig. 4).

Thus

$$\left(G - \frac{4d}{3}\right)\pi \times \frac{pd}{2} = [g^2 - (G - 2d)^2]\,\frac{\pi p}{4}$$

Solving for g^2 in this equation gives us

$$g^2 = \frac{4\,d^2}{3} - 2\,G\,d + G^2$$

or

$$g = \sqrt{\frac{4\,d^2}{3} - 2\,G\,d + G^2}$$

But for a 60-degree thread $d = p \times \cos 30° = \frac{p\,\sqrt{3}}{2}$.

Therefore, for a 60-degree thread

$$g = \sqrt{p^2 - G\,p\,\sqrt{3} + G^2}$$

This formula is the same as the one already found by the author's method.

While this formula is theoretically correct, it should be remembered that in thread rolling a great many factors enter which cannot be determined with absolute exactitude. Minute inaccuracies in the thread rolling tools, for instance, lack of homogeneity in the material, etc., would influence the size of blank required. The formula, however, will furnish a guide for selecting the approximate size of stock for thread rolling, although the final determination may have to be left to practical experiments.—EDITOR.]

HINDERING RECLAMATION WORK IN THE WEST

The reclamation work of the United States government in the arid regions of the West is done under the provision of the Reclamation Act which provides that the land benefited by the water provided shall be assessed for the cost of the work. The payment is made, not into the general fund of the United States Treasury, but into a special fund for reclamation work, and it again becomes available for further reclamation work in other sections.

The reclaiming of the arid regions was begun extensively under ex-President Roosevelt and his Secretary of the Interior, James Garfield. During the Roosevelt regimé settlers were permitted to work on the irrigation projects and the payment for the work was applied to offset assessments on their claims. This practice obviously was mutually beneficial to the settlers and the government. The settlers were able to employ their time profitably while waiting for the life-giving water and the government benefited inasmuch as it received payment on the assessments in advance, thus enabling other irrigation work to be begun long before it would have been possible had the settlers been obliged to wait for the returns received from the irrigated land before making payments.

Under the Taft-Ballinger regimé, the practice of applying the payments for work done by the settlers on future assessments has been stopped, because of an interpretation of the practice placing the government in the light of a debtor to the settlers for the work done on the projects. The *Engineering News* published a long editorial in its September 30 issue calling attention to the misrepresentation of an editorial in the *New York Times* accusing the Roosevelt Secretary of the Interior of being a socialist, etc. The *Engineering News* points out that the irrigation work, which is of enormous extent, has been done most efficiently and without the suspicion of graft, and it hints that this hindrance of further irrigation work is not in the interest of the general public. It is a pity that governmental red tape unwinding should be permitted to slow down one of the greatest projects ever undertaken for the common good.

* * *

The Department of the Interior of Canada has recently been estimating the available water power of the Dominion, and it is stated that there is 26,000,000 horse-power available in accessible localities, of which only 500,000 has hitherto been developed.

COMPRESSOR DESIGNING—THE DISTRIBUTION OF THE LOAD

FRANK RICHARDS*

The air compressor shown in Figs. 1 and 2 may be regarded as a standard machine for the special line of work for which it is adapted. There is that which is picturesque for the engineer as well as for the landscape gardener, and this is a picturesque and interesting machine, embodying a number

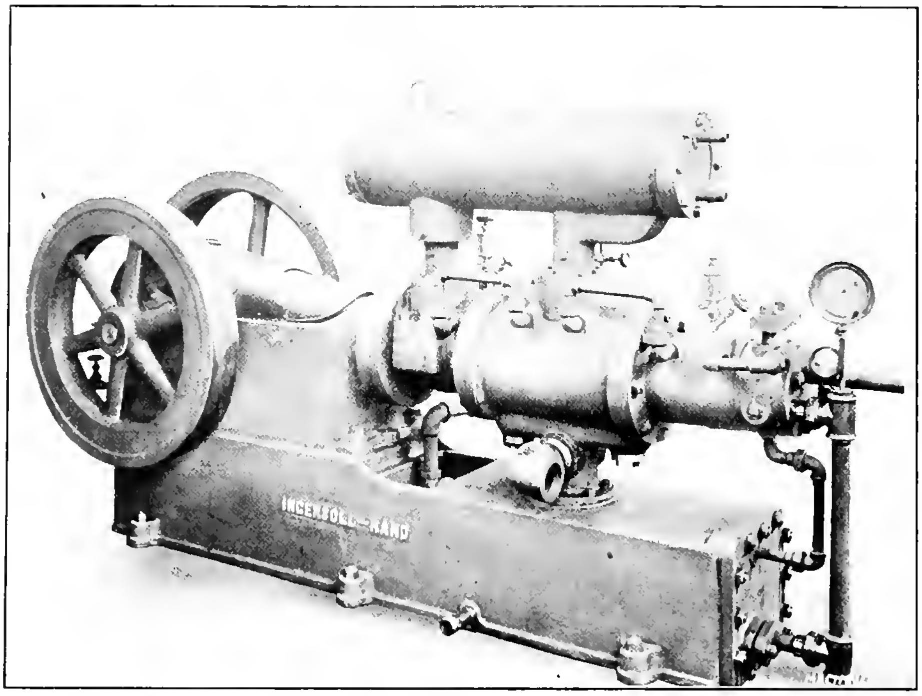

Fig. 1. Ingersoll-Rand Three-stage Air Compressor, designed to compress to 1000 pounds per square inch

of details of ingenious design which are well worth considering. The compressing of air is not in any case as simple an operation as the pumping of water, and when high pressures are required, involving, as in this case, multiple stage compression, the problem of equitably apportioning the work and the effect for each step of the operation, the providing for the easy flow and the efficient cooling of the air between the stages, the reduction of machine friction to a minimum, the providing for the proper lubricating of all the working parts, the arranging of all for ready accessibility when wear or accident makes it necessary, constitute in all an intricate problem, the solution of which is well worth looking into. Nothing, of course, is final, and everything achieved is a challenge to surpass it, so that doubtless later there may be a better machine than this, or than any we now know of, and we must note its points of excellence while we may.

This is a three-stage air compressor designed to work to 1,000 pounds gage pressure, with a free air capacity of about 50 cubic feet per minute. It is a power-driven machine, the type of power application being according to circumstances. As here shown it has a pulley for a belt drive, but it may also be driven by a chain, gearing, a Pelton wheel on an extension of the shaft, or by a direct-connected electric motor.

The dimensions of the cylinders are: 8-, 5- and 2¾-inch diameter, respectively, by 8-inch stroke, and the normal speed is 150 revolutions per minute, giving a piston speed of 200 feet. The low-pressure, or intake, cylinder is double-acting and the other two are single-acting. The three cylinders are in a straight axial line, one piston-rod extending from the crosshead through all the pistons. The low-pressure cylinder is between the other two, the intermediate cylinder being in front, or toward the crank, and the high-pressure cylinder at the back. The pistons of the intermediate and of the high-pressure cylinder are, in fact, plungers on each side of the low-pressure piston. The working area of the low-pressure piston on each side is, therefore, only that portion of the piston which surrounds the plungers, and these areas are quite different on the two sides of the piston on account of the different plunger diameters. This arrangement gets rid of all cylinder heads or partitions and stuffing-boxes between the cylinders. The only stuffing-box for the entire machine is that in the head next to the crosshead and opposed to the working pressure of the intermediate cylinder. The piston rings are the only packings required besides this one stuffing-box. The packing rings for the low-pressure and the inter-

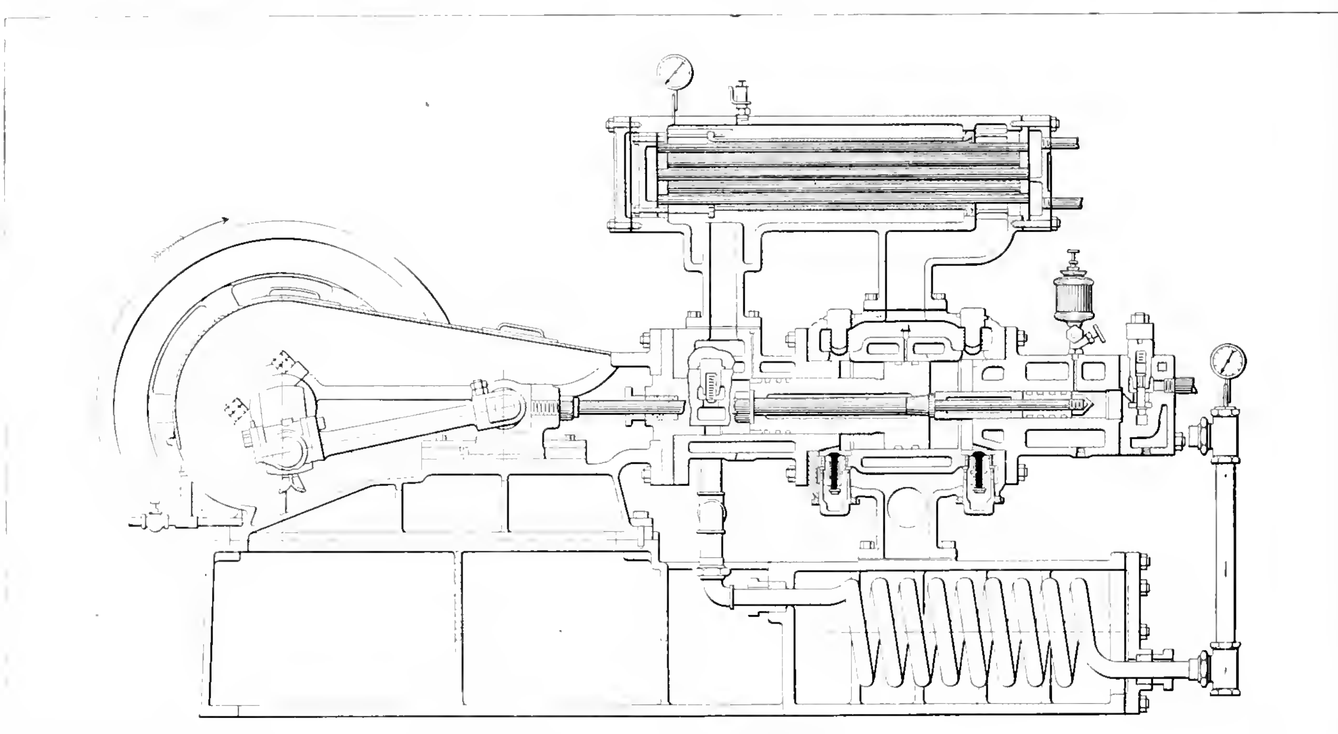

Fig. 2. Sectional View of the Three-stage Air Compressor

* Address: 229 W. 135th St., New York.

mediate pistons are sprung into grooves turned in the solid metal. In the high-pressure piston or plunger the grooves are not turned in the solid but are formed by removable sections which fit the piston-rod and also the cylinder bore, and which are cut away at the outer corner to form the grooves for the rings. When the main portion of this piston is in place in the cylinder, a packing ring is slipped in to fit against it; one of the movable sections of the piston is then slipped in against this, then another ring, then another piston section with a washer and nut outside, which secures all. The middle or low-pressure pisten has a taper fit on the rod, and is secured by a nut outside the intermediate plunger, which thus locates it precisely and holds it securely.

The actual working clearances of one of these compressors, as determined by the inspector, were: for the low-pressure cylinder, 3/32 inch and 3/32 inch; intermediate cylinder, 1/8 inch; high pressure, 1/8 inch. The distribution of the pressures and the apportionment of the work of compression throughout the cycle of operations of this compressor are such as to make the work for each stroke nearly the same.

On the forward stroke, or with the pistons moving toward the crank, the low-pressure piston and the intermediate piston are both compressing to their respective pressures, and the receiver pressure against the high-pressure plunger is assisting; that is, its thrust at practically constant pressure is to be deducted from the total work done by the other two pistons. On the backward stroke, the low- and the high-pressure pistons are compressing, and the receiver pressure against the intermediate piston is assisting in the work. By calculation based on the assumption that the compression is adiabatic, it is found that the horse-power required for the forward compression stroke of the low-pressure cylinder is 2.79, and for the same stroke of the intermediate cylinder, 8.52 H.P. The total horse-power resistance for the forward stroke is $8.52 + 2.79 = 11.31$ H.P. The intake pressure against the high-pressure plunger which is approximately constant, is sufficient to develop 3.13 H.P. which is to be deducted from the working horse-power of the other two cylinders, giving us as the net horse-power for the forward stroke $11.31 - 3.13 = 8.18$ H.P. For the back stroke of the low-pressure piston the horse-power resistance equals 4.17 H.P., which is, of course, greater than for the forward stroke, because of the increased piston area. The resistance for the working stroke of the high-pressure cylinder equals 8.93 H.P., giving a total for both the low- and high-pressure cylinders of $4.17 + 8.93 = 13.10$ H.P. From this it is necessary to deduct the power due to the intake pressure against the intermediate piston, which is found to be 3.13 H.P. The net power for the back stroke then will be $13.10 - 3.13 + 9.97$ H.P.

While the work of the two strokes is so nearly equal, that of the back stroke is the larger, which is at it should be, as this occurs on the thrust of the connecting-rod instead of on the pull. A sufficient reduction of the terminal delivery pressure would equalize the work for the alternate strokes.

As before stated, adiabatic compression is assumed in each cylinder, with efficient intercooling between the stages. The cylinders are all very completely water jacketed, so that the temperatures of the working surfaces are kept down, and satisfactory lubrication is maintained, but there is little cooling effect upon the body of air in the cylinders during the operation of compression. The circulation of the cooling water is accomplished by a single continuous flow through both intercoolers and all the water-jackets, there being no places where the water can remain without change. The efficiency of the intercooling is sufficiently indicated by the fact that the temperature of the air leaving the second intercooler and entering the last compressing cylinder was found upon a prolonged test to be the same as that of the initial intake or 70 degrees, and the temperature of the air as finally delivered, there being no after cooler, was 188 degrees. The final temperature for perfect adiabatic, single stage compression to 1,000 pounds would be above 1,250 degrees, which would be prohibitive in practice.

In a test which was made of one of these machines, in which the number of strokes of the compressor required to fill a receiver of known capacity was ascertained, the volumetric efficiency of the compressor, or the ratio of the volume actually delivered to the total piston displacement of the low pressure cylinder, was determined to be 0.927.

This compressor considered in detail will be found to be an extremely simple one when the complication of function is allowed for. The main frame combines in itself all the particulars upon which perfect and maintained alignment depends. The first cylinder has a true seat against the frame and the other cylinders successively locate themselves by their seating, all the joints being scraped and the faces going together without packing. Every valve is independently accessible by the removal of its cap. Taking off the high-pressure cylinder (which is no more work than the removal of a cylinder head) makes all the pistons easily removable, and gives complete access to all the cylinder interiors.

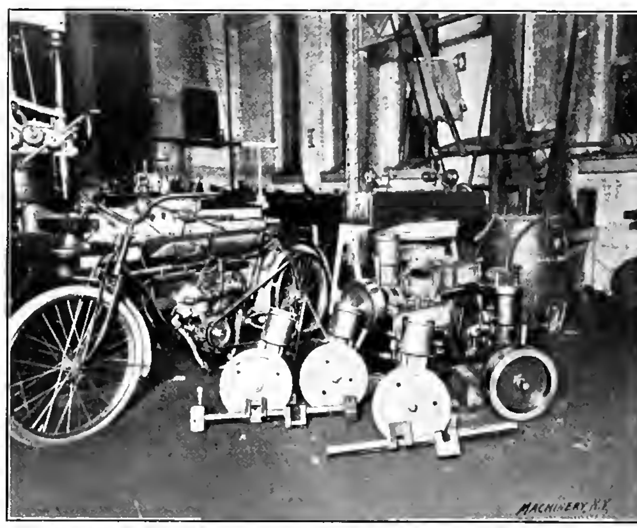
SHOP WORK AT THE UNIVERSITY OF WISCONSIN

As a rule, students graduate from engineering colleges with but a faint idea of modern machine-shop practice. They are often hastened through their required shop work by incapable instructors, who are only too willing to get them off their hands. To offer the students an interesting and instructive class of work, Mr. Paul Sladky, instructor in mechanical practice at the University of Wisconsin, designed last year a small, two-cycle gasoline launch motor. The accompanying engraving shows several of these engines. One of them is mounted on a testing rack, which consists of a propeller working in a barrel of water, enabling the engine to be tried out under almost actual working conditions. Fifteen of these engines were built the last school year by students who had no shop experience, except the work required by their respective courses. Three single and two double engines are now in almost daily service on Lake Mendota, Madison, Wis., giving excellent satisfaction. The cylinder is $3\frac{1}{2}$ inches in diameter with a 4-inch stroke. The cylinder and head are integral, the crank case and side plates separate. The crank-shafts are forged at the university shop from machine steel billets and are machined with a special lathe fixture. By means of a distance piece, two cylinders may be connected to make a double engine.



Gasoline Engines built by the Students at the University of Wisconsin

To give the students instruction in the use, value and manufacture of interchangeable parts, jigs and fixtures are used wherever possible. In designing this engine, Mr. Sladky endeavored to make it as simple and durable as possible, and yet require neat and accurate work on all the different machine tools. So much interest has been taken in this class of work that Mr. Sladky is now designing a four-cycle engine to offer the students a choice of a number of sizes and types. The student buys the castings at cost and owns the engine when it is finished. He is obliged to test his engine himself, thus gaining by actual experience a knowledge of some of the gas engine troubles he is likely to meet in his future work.

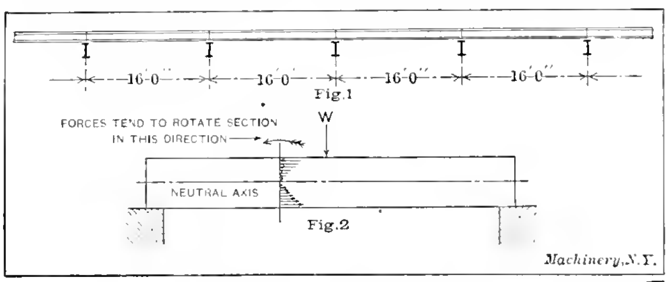
The engraving also shows a motor cycle, the engine of which was made by a junior mechanical engineer.

SPLICES FOR I-BEAMS AND CHANNELS*†

A. L. CAMPBELL‡

It often happens, in the use of rolled shapes for structural purposes, that the material could be spliced together conveniently and with economy, provided an efficient and reliable form of splice were available.

For example, Fig. 1 shows a side elevation of a long row of floor beams, supported every sixteen feet. In such a case the row of beams is usually made up of sixteen-foot lengths, supported on the cross beams, and with little or no connection between their ends. If the floor load is uniformly distributed, the maximum bending moment in the floor beams will be $\frac{WL}{8}$ at mid-span, where W is the total load on the beam per panel, and L is the panel length. Now, assume that the row of floor beams is shifted bodily eight feet to the left or the right, so that the beams will be continuous over the supports, with the ends butting together at mid-span; then, if the ends were efficiently spliced together, we would have a continuous floor beam, with maximum bending moments of $\frac{WL}{12}$ at the supports, and $\frac{WL}{24}$ at the splices. Thus, the bending moment in the floor beams is a maximum where their gross section is available to resist it, while the bending efficiency of the splice at mid-span need be only 50 per cent of the maximum.



Figs. 1 and 2. Diagrams for Calculations of Splices for I-beams

With the second arrangement the floor will safely carry a load 50 per cent greater than it would with the first, or for the same load only two-thirds as much material need be used in the floor beams. Long ties, etc., might also be made up of two or more pieces, with splices, thus saving double freight charges for shipping long pieces.

Splices for I-beams and channels have been calculated in the following, and the splices for the I-beams are also shown in the accompanying Supplement. The sections are taken from Carnegie's Hand-book, and a medium section of each size has been chosen. The calculations may, however, be readily applied to any desired section. In every case the splices for I-beams and channels consist of a top and bottom plate, or plates, riveted to the flanges, and two side plates riveted to the web.

The reason why medium-sized sections have been selected for the calculations, rather than the so-called standard sections, is that the medium-sized section more nearly fulfills the average requirements in design, and as the steel mills constantly roll other than the standard sections, they can be obtained without difficulty. An inspection of a table of steel shapes reveals the fact that the standard section is usually the lightest section rolled of any one size, and has a very thin web. If a short standard section be used as a beam, the load, which will produce a fiber stress of 16,000 pounds per square inch in a beam, will greatly overload the web of the beam over the supports, when it acts as a compression member. If one or more of these light sections be used as columns or struts their strength is limited to the crippling strength of their webs. For these reasons the engineering department of the firm where the writer is employed has adopted the medium weights of I-beams and channels as standard sections for average designs.

* See also article entitled "Beam Formulas," MACHINERY, September, 1905, engineering edition, and MACHINERY'S Data Sheet No. 48, Stresses and Deflections in Beams, Shafts, etc.

† With Data Sheet Supplement.

‡ Assistant Construction Engineer, The Solvay Process Co., Detroit, Mich.

Having assumed a section to be spliced, it is first necessary to find what proportion of the total area of the section exists in the flanges, and what is contained in the web. Then the splice is so proportioned that the strength of the beam will be, at that point, as nearly as possible equal to what it would be if no splice existed in it. The method of procedure when designing the splice will be illustrated in the following computations, in which the working stresses are assumed as follows:

Tension and compression, 16,000 pounds per square inch.
Shear, 10,000 pounds per square inch.
Bearing, 20,000 pounds per square inch.
Double shear is equivalent to 1.8 single shear.

Splice for 24-inch 90-pound I-beam (See Supplement)

Area of section, 26.47 square inches.
Thickness of web, 0.631 inch.
Width of flange, 7.131 inches.
Tangent of web, 20.75 inches (depth of flat portion of web).
Grip of rivet, 27/32 inch (depth of rivet holes in flanges measured on center line of holes).
Sectional modulus of section, 186.6 (neutral axis perpendicular to web).

As shown in the Supplement, the rows of rivets in the web are 2½ inches apart; thus each row may be regarded as carrying a load equal to the stress in a strip of the web extending 1¼ inch above and below its center line. Since the distance from the top row to the bottom row of rivets is 18¼ inches, the portion of the web upon which the web rivets of the splice will be effective is 18¼ + 1¼ + 1¼, or 20¾ inches, and the sectional area of this portion is 20¾ × 0.631, or 13.09 square inches. The area of the section to be cared for by the rivets in each flange, or the sectional flange area, is then $\frac{26.47 - 13.09}{2}$ or 6.69 square inches.

Having now found the flange and web areas of the above section, it is only necessary to so proportion the rivets in the splice that the existing fiber stresses in the beam may be transferred into the splice plates, and to provide ample metal in these plates to prevent excessive fiber stresses in them.

The net section of a strip of the web 2½ inches wide (one 15/16-inch hole deducted) is (2½ — 15/16) × 0.631 = 0.99 square inch, and the allowable tension on this strip will be 0.99 × 16,000 = 15,840 pounds. Allowable double shear of a ⅞-inch rivet = 1.8 × 6,010 = 10,818 pounds, while its bearing value in the web is ⅞ × 0.631 × 20,000 = 11,060 pounds. The number of rivets required in the web plates for each strip is therefore 2.

The net section of the flanges will be 6.69 — 2 × 27/32 × 15/16 = 5.11 square inches, and the allowable stress on this area will be 5.11 × 16,000 = 81,760 pounds. The number of ⅞-inch rivets in single shear required to transmit this stress to the flange plates is 14. The web plates should have a combined thickness greater than the thickness of the web, so two ⅜-inch plates are used. In like manner two ½ × 7⅛-inch plates will have a combined net area of 5.25 square inches, and may be used on both flanges.

The sectional modulus being 186.6, the maximum allowable bending moment in a beam of this section is 186.6 × 16,000 = 2,985,600 inch-pounds. At first, 14 rivets only are calculated for on each side of the center of the splice, in the flanges. Taking moments about the neutral axis of the beam and splice, for the rivets above or below this axis, we obtain the resisting moment for this portion of the rivets as follows:

$$14 \times 6{,}010 \times 12 = 1{,}009{,}680 \text{ inch-pounds.}$$

$$2 \times \frac{73}{96} \times 10{,}818 \times 9\tfrac{1}{8} = 150{,}128 \text{ inch-pounds.}$$

$$2 \times \frac{53}{96} \times 10{,}818 \times 6\tfrac{5}{8} = 79{,}130 \text{ inch-pounds.}$$

$$2 \times \frac{33}{96} \times 10{,}818 \times 4\tfrac{1}{8} = 30{,}679 \text{ inch-pounds.}$$

$$2 \times \frac{13}{96} \times 10{,}818 \times 1\tfrac{5}{8} = 4{,}758 \text{ inch-pounds.}$$

Total resisting moment 1,274,375 inch-pounds.

The fractions whose denominators are 96 represent the ratios of the distances from the neutral axis, of the different rows of web rivets, and the product of this fraction multiplied by 10,818 is the actual working load of any one web rivet, when the flange rivets have assumed their maximum allowable load.

Since the forces producing tension and compression in the beam below and above the neutral axis tend to cause rotation in the same direction (see Fig. 2), the resisting moment of all the rivets on one side of the splice is twice the above amount, or 2,548,750 inch-pounds. The resisting moment being always equal to the bending moment, the bending efficiency of the above splice with respect to the rivets is

$$\frac{2,548,750}{2,985,600} = 85.4 \text{ per cent.}$$

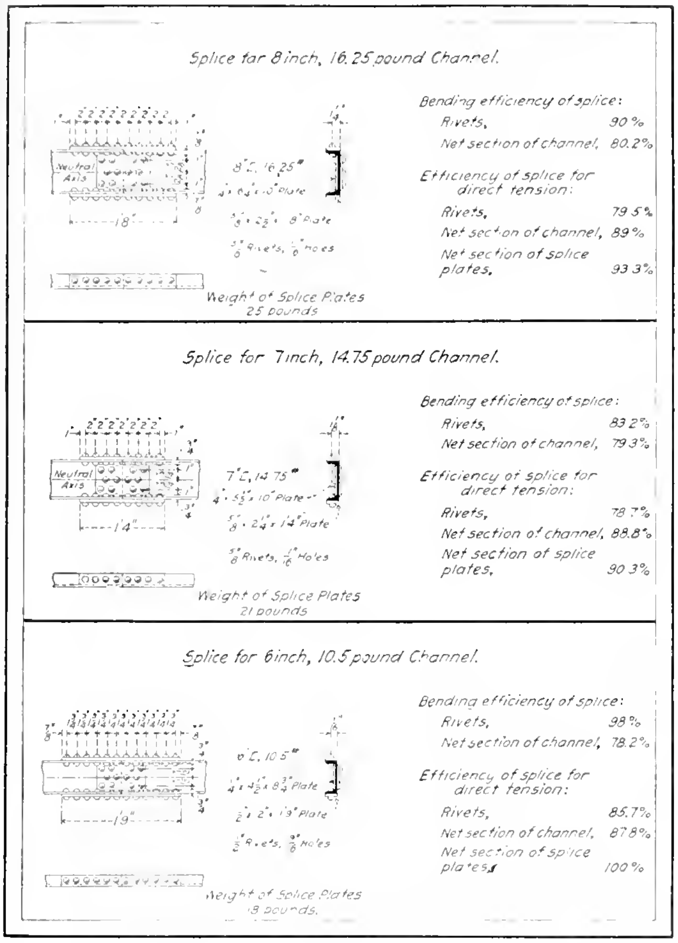


Fig. 3. Splices for 6-, 7- and 8-inch Channels

The point of minimum bending efficiency of the beam at the splice will be found at section AA, two rivet holes being here deducted from each flange. The transverse sectional area of these two rivet holes is 1.58 square inch, and the distance from the center of gravity of this area to the neutral axis of the beam is about $11\frac{5}{8}$ inches. The bending efficiency of the beam at section AA is therefore

$$\frac{2,985,600 - 2 \times 1.58 \times 16,000 \times 11\frac{5}{8}}{2,985,600} = 80.4 \text{ per cent.}$$

Since the minimum efficiency of the splice is the effective one, it is desirable to increase the strength of the beam by a rearrangement of the flange rivets. If one rivet is omitted from each flange at section AA, the bending efficiency of the beam will be increased, but that of the rivets in the splice will be reduced to 80.6 per cent. It therefore becomes necessary to leave two rivets in each flange at this point and add one extra rivet, as shown. Fifteen rivets are now effective in each flange, and the rivet efficiency for bending is 90 per cent. The least bending efficiency of the beam will still be found at section AA, and amounts to

$$\frac{2,985,600 - 2 \times 1.58 \times 16,000 \times 11\frac{5}{8} + 2 \times 6,010 \times 12}{2,985,600} = 85.2$$

per cent.

If the above spliced beam is placed upon supports at the ends in such a manner that the splice does not come exactly in the center between the supports, but so that the section AA comes between the center of the splice and the middle of the beam and yet is not more than 85.2 per cent of half the span from one of the supports, then, if loaded in the middle, this beam will be able to carry the same load as it would carry if the beam were in one piece. It is easily seen that for most, if not all, conditions of loading the above beam, the splice may be so located that the beam will be as strong as though no splice existed in it.

This splice is excellent for direct tension also. The point of minimum efficiency for a net section of the beam will be found at section AA, and will be

$$\frac{26.47 \times 16,000 - 2 \times 1.58 \times 16,000 + 2 \times 6,010}{26.47 \times 16,000} = 91.2 \text{ per cent.}$$

The efficiency of the rivets will be, with fifteen $\frac{7}{8}$-inch rivets in single shear in each flange, and sixteen $\frac{7}{8}$-inch rivets in double shear in the web,

$$\frac{30 \times 6,010 + 16 \times 10,818}{26.47 \times 16,000}, \text{ or } 83.7 \text{ per cent.}$$

The net section of the splice plates will have an efficiency, along the innermost row of rivets, equal to

$$\frac{2 \times \frac{3}{8}\,[6(2\,13/16 - 15/16) + (3\frac{1}{4} - 15/16) + (2 \times 1\frac{1}{4} - 15/16)] + 2[7\frac{1}{4} - 2 \times 15/16]}{26.47} = 82.4 \text{ per cent.}$$

In the design of this splice it has been assumed that the ends of the spliced beam do not butt tightly together. If these ends were fitted together perfectly no splice plates would be needed on the compression half of the beam. Since a perfect bearing is impossible, at least the two web plates should extend to the top of the beam. The top flange plates may, however, be safely omitted when the ends are well butted together and a floor plate is riveted to the top flange.

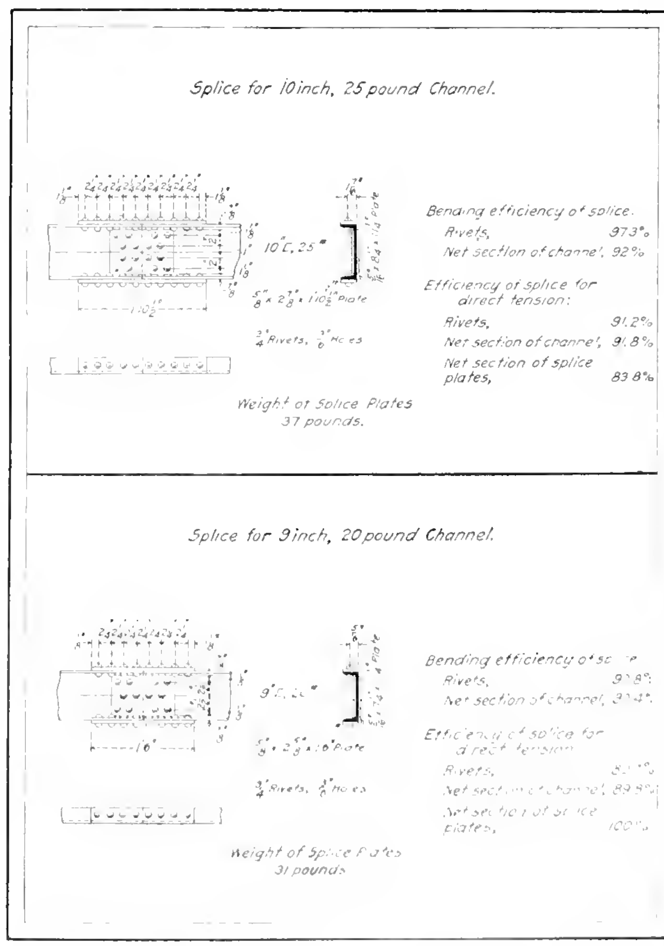

Fig. 4. Splices for 9- and 10-inch Channels

Splice for a 20-inch 80-pound I-beam (See Supplement)

Area of section, 23.73 square inches,
Thickness of web, 0.6 inch,
Width of flange, 7.0 inches,
Tangent of web, 16.5 inches,
Grip of rivets, 29/32 inch,
Sectional modulus of section, 146.7.
Gross web area $= 16.5 \times 0.6 = 9.9$ square inches.

$$\text{Gross flange area} = \frac{23.73 - 9.9}{2} = 6.92 \text{ square inches.}$$

The net flange area $= 6.92 - 2 \times 15/16 \times 29/32 = 5.22$ square inches, and the allowable tension on this area is $5.22 \times 16{,}000 = 83{,}520$ pounds. The number of rivets required is fourteen, but from the computations already made for the 24-inch I-beam it is seen that this number actually ought to be fifteen. Use one $\frac{5}{8} \times 7$-inch plate, and one $\frac{1}{2} \times 7$-inch plate, for each flange, and two $\frac{3}{8}$-inch web plates. As in the preceding case, each row of web rivets should contain two rivets.

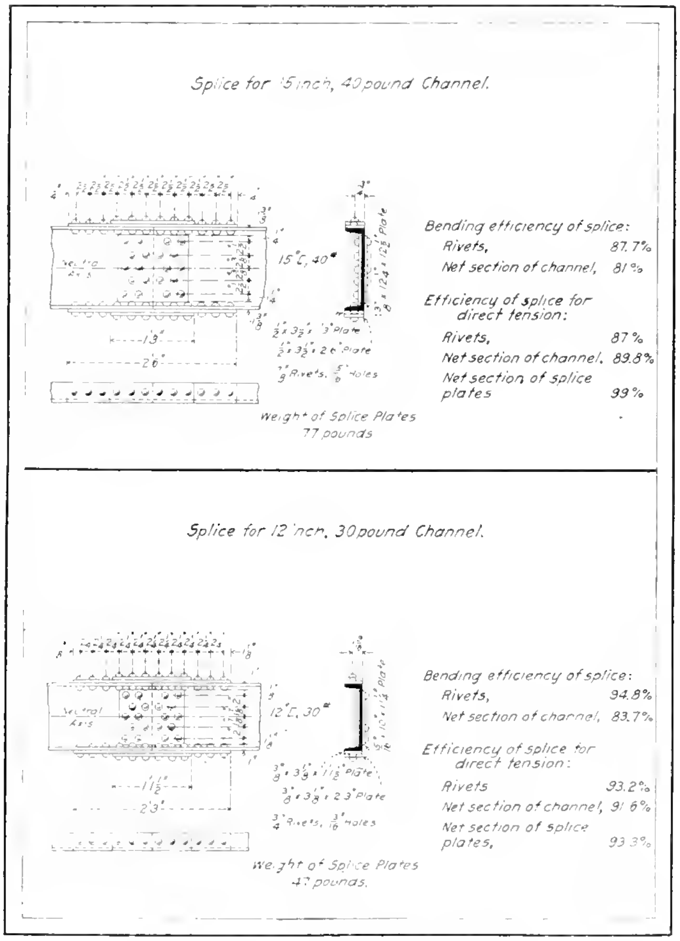

Fig. 5. Splices for 12- and 15-inch Channels

The total resisting moment (twice the moment of the rivets above or below the neutral axis) of the rivets on one side of the splice is

$$\begin{aligned}
2 \times 15 \times 6{,}010 \times 10 &= 1{,}803{,}000 \text{ inch-pounds,}\\
2 \times 2 \times 7/10 \times 10{,}500 \times 7 &= 205{,}800 \text{ inch-pounds,}\\
2 \times 2 \times 9/20 \times 10{,}500 \times 4\tfrac{1}{2} &= 85{,}050 \text{ inch-pounds,}\\
2 \times 2 \times 1/5 \times 10{,}500 \times 2 &= 16{,}800 \text{ inch-pounds,}\\
\text{Total resisting moment.} &\ \ 2{,}110{,}650 \text{ inch-pounds.}
\end{aligned}$$

Note.—10,500 pounds is the bearing value of a $\frac{3}{4}$-inch rivet in the web. This amount is less than that of double shear.

$$\text{The bending efficiency of the rivets is } \frac{2{,}110{,}650}{146.7 \times 16{,}000} = 90$$
per cent.

The minimum bending efficiency of the net section of the beam will be found at section *BB*, two rivet holes being here deducted from each flange. The efficiency will be

$$\frac{2{,}347{,}200 - 2 \times 1.7 \times 9\tfrac{1}{2} \times 16{,}000 + 2 \times 10 \times 6{,}010}{2{,}347{,}200} = 82.8 \text{ per cent.}$$

When this splice is used in a tension member, the weakest part of the beam is at section *BB*, and the efficiency is

$$\frac{23.73 \times 16{,}000 - 2 \times 1.7 \times 16{,}000 + 2 \times 6{,}010}{23.73 \times 16{,}000} = 88.8 \text{ per cent.}$$

The rivet efficiency will be

$$\frac{30 \times 6{,}010 + 12 \times 10{,}500}{23.73 \times 16{,}000} = 80.7 \text{ per cent.}$$

The efficiency of the net section of the splice plates will be

$$\frac{2 \times \frac{3}{8}[4(2\,13/16 - 15/16) + (4 - 15/16) + (2 \times 1\tfrac{1}{4} - 15/16)] + 2\,[(7 - 2 \times 15/16) \times 1\tfrac{1}{8}]}{23.73} = 86.7 \text{ per cent.}$$

Splices for channels are designed in exactly the same manner as those for I-beams, so an explanation of details is unnecessary. It will be noticed, however, in the accompanying engravings, that the flange rivets are not located on the regular gage lines of the channel flanges, but as nearly as possible in the middle of the flange plates. This was done to avoid eccentric loads in these plates.

In the accompanying Data Sheet Supplement are shown splices for I-beams of various sizes, and in the accompanying illustrations are shown the splices for channels. The efficiency of the riveting, net section of the beam, etc., are also given in percentages.

Splices are not shown for I-beams and channels smaller than the 6-inch sections, because it is not often necessary to splice such small pieces; also, the efficiency of the splice would probably be low. The efficiencies of the above splices may be increased by modifying their details. For instance, it will be noticed that usually the least efficiencies are for the net section of the beam for bending, and for direct tension; and the rivet efficiency for direct tension. These values may be increased by using smaller flange rivets, and more of them. In general it may be said that the minimum efficiency of any of the above splices may be made as high as 85 per cent. Only one size of rivet is here used, however, since it is desired to make the details of these splices conform to standard practice as much as possible.

The writer has been unable to find any published data concerning the splicing of structural shapes; he has devised the above method of analysis and furnished designs of splices, with the hope that it may be of some use to others.

In conclusion, it is regretted that none of the above splices have ever been tested to destruction, so that no experimental data are available to confirm or disprove the correctness of the above analyses. However, a set of splices very similar to these was designed by the writer, for a large manufacturing firm in the middle West. These splices have been used continuously for the past two years on all classes of work. In no case have they given trouble, or showed signs of weakness, though often loaded to the full capacity of the pieces in which they occur. One of the most prominent examples is a 15-inch 60-pound I-beam, of 27-foot span, supported at the ends and uniformly loaded with about 500 pounds per lineal foot. This beam is spliced in the middle, and has deflected about one-fourth of an inch under the above load. The beam has deflected in a long smooth curve, showing that the bending efficiency of the splice is really high. If the splice were weak in proportion to the rest of the beam, the tension and compression on the bottom and top of the beam would localize at the splice; and the two halves of the beam would deflect as chords intersecting at the splice, instead of as an arc. Another good illustration is a tension member 116 feet long, composed of two 15-inch, 55-pound channels, and a 1 x 12-inch plate, carrying a load of 544,000 pounds at the middle. It contains six splices, all designed by the above methods, and has borne this load for about fifteen months, with no signs of weakness.

THE BENEFICENT TARIFF

Every family using iron ore, pig iron, scrap iron, steel rails, cash registers, linotypes, typewriters, steam engines, and wood pulp will now be able to buy them for less, and the cost of living will be reduced.—*New York Times.*

CHAPTERS IN THE EARLY HISTORY OF MACHINE TOOLS—3

JOSEPH G. HORNER*

In continuing the discussion of early types of machine tools, we shall take up in the present article the development of drilling and boring machines, the steam hammer, screw-cutting machinery and the primitive forms of gear-cutting and milling machines.

Slot Drilling Machines

Richard Roberts of Manchester is said to have invented the slot drilling machine as well as the slotting machine, but in 1847 Nasmyth designed a slot drilling machine to avoid the labor of cutting grooves by drilling, chipping and filing. The drill was, as now, flat ended with a notch at the center. The machine was provided with a work table having self-acting traverse, the length of which was adjusted by a crank and rod, and a down-feed put on automatically at the end of the stroke. The gain was stated to be ten to one, and a boy or laborer was given the task of attending to it. Nasmyth did not patent it, but "always had an abundance of orders, as it was its own best advertisement."

A Whitworth slot drilling machine of date 1867 is shown in Fig. 18, driven by a cone pulley and shaft at the back of the bed, through miter gears, and sliding horizontal and vertical shafts to the spur gear seen on the top of the spindle. This spindle runs in hardened conical bushings in a sliding octagonal ram. The spindle head is adjustable along the bed by hand to suit the position of the slot or cotter hole in the work. The reciprocating movement of the drill spindle is operated from the small three-speed cone pulleys seen on the bottom slide of the head. The front pulley is keyed to a worm shaft, rotating a worm wheel with a slotted disk, to which is attached a connecting rod, adjustable for length of stroke, the other end of which is fixed to the middle slide. The octagonal ram slide has a cross adjustment by hand, and the octagonal ram itself has a variable automatic and down feed at both ends of the stroke.

Drilling Machines

The drilling machine was early developed into essentially present designs, both fixed and radial. Back geared cone spindles, self-acting and counterbalanced drilling spindles, rack elevated tables and compound movements to tables, may

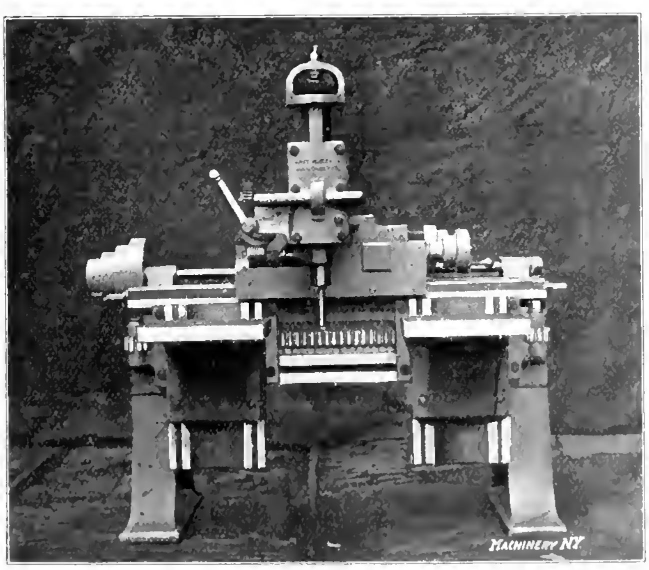

Fig 18. Slot Drilling Machine, Joseph Whitworth & Co. (1867)

be noted in examples dating from 60 to 70 years back. The framings have a strangely skeleton like appearance, for the box framing had not then come into use.

There were radial drilling machines at Soho, the radial arm being capable of vertical adjustment on a round pillar, by means of a screw. The brackets which carried the pillar were bolted to the wall.

A boring and drilling machine at Soho was double back geared and provided with power and hand feed. It stood 25 feet high, its brackets being bolted to the wall, and the floor plate being movable along a bed 36 feet in length on the floor. It was used largely for boring the beams of the early engines.

In drilling machines made by Whitworth 60 or 70 years ago (Fig. 19) the worm-wheel feed was applied to the drilling spindles. The portion of the spindle above the splined driving bevel wheel and between it and the top bearing was threaded. Two worm wheels located on opposite sides engaged with the screw threads. The worm wheel journals worked in bearings, and the ends were prolonged to be embraced by divided friction clips, Fig. 20, tightened or slackened by a vertical screw. When the clips were tightened so that the worm wheels could not revolve, the spindle screw was fed positively. If the clips were slackened to permit the wheels to slip moderately, the amount of feed was lessened. Probably this graduated feed was too uncertain in its action, but it seems to have been used frequently on radial as well as on fixed machines made by Whitworth.

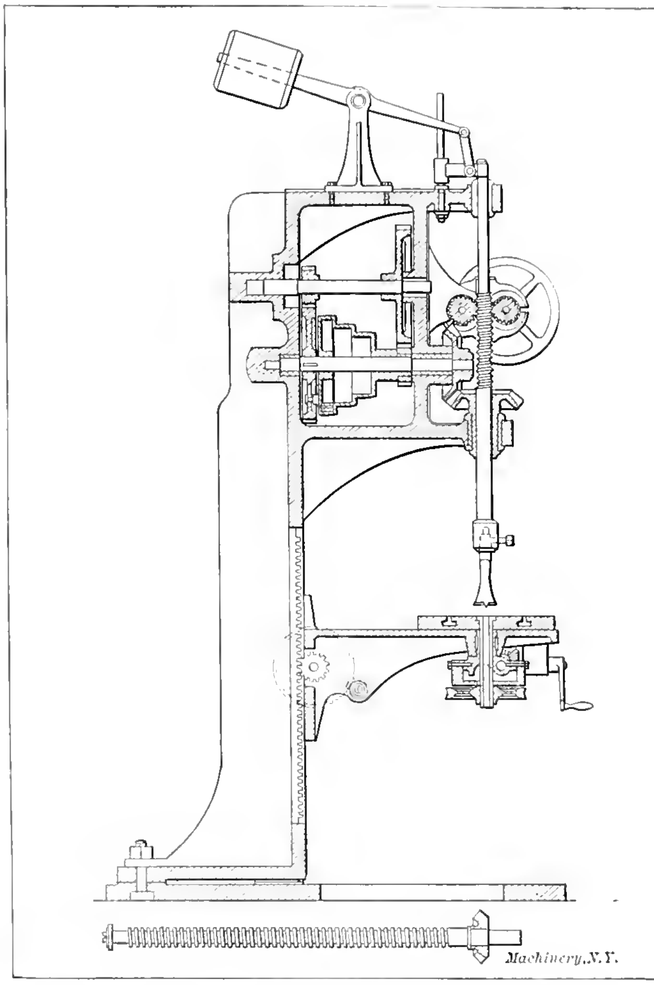

Fig. 19. Vertical Drilling Machine with Screw Feed and Worms Joseph Whitworth & Co. (About 1846)

In the forties we find drilling machines in which the spindle feed is imparted by a treadle and a lever at the top, counterbalanced, pressing the spindle downward by the movement of a bracket sliding on the face of the framing, in which bracket the end thrust was taken.

In the same period the self-acting feed motion through spur gears had been applied by a Mr. Lewis of Manchester to a wall drill. On the spindle above the lower bearing a spur pinion was keyed engaging with a wheel on a feed shaft parallel with the spindle, the driven wheel being engaged or disengaged by a sliding clutch. At the top of the feed shaft a spur pinion engaged with a wheel having its boss threaded to fit a square threaded screw cut on the upper part of the spindle, thus feeding the latter. Hand feed could be substituted for that of power by means of a handwheel on the feed spindle.

Boring Machines

The vertical lathe dates back to the early part of the nineteenth century. It was in use before Bodmer improved it, crystallizing it practically into its present form. The foundation or base carried the spindle on which the circular table

* Address: 15 Sidney Building, Bath, England.

or faceplate was keyed. The tool-box with down-feed motion was carried on a horizontal cross-slide with vertical adjustments on uprights flanking the table. The advantages claimed for it were precisely those claimed to-day.

There were many boring machines both vertical and horizontal in the forties to meet the requirements of the marine engine builders. There were big cylinders in those days, necessary because of the very low pressures adopted, and they were generally bored in vertical machines.

In one of Maudslay's early lathes may be traced the beginnings of the milling and boring machines. The headstock was

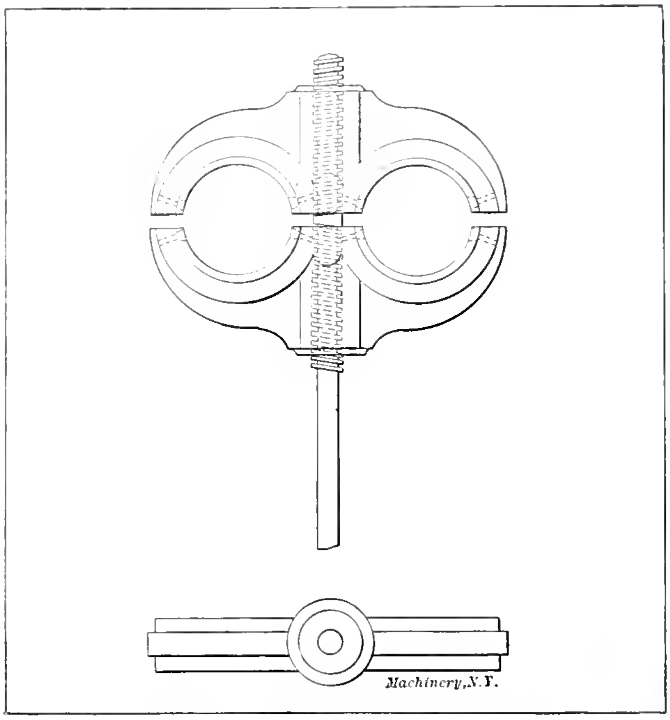

Fig. 20. Friction Collars of Screw Feed Wheel, Whitworth Drilling Machine

provided with a side or lateral traverse by hand or power on a rather long base which would qualify it for milling. Work to be bored was clamped on a table on a bed slide or carriage of large area, the table being raised or lowered on the slide by means of four screws.

A boring machine by Maudslay was already differentiated from the lathe used for boring. The table possessed transverse motion by a screw for boring holes in parallel. The boring bar was capable of vertical adjustment by that movement of its bearings in guides actuated by screws, both driven simultaneously through bevel wheels from a horizontal shaft at the top, just as the cross slide of a planing machine is elevated. The bar was rotated by a five-stepped pulley, grooved for gut band, thence through spur gear to the bar. A screw at the left provided for the horizontal feed of the bar. The feed was put on by power by means of cord-driven pulleys from the bar itself.

Horizontal and vertical boring bars were in existence at Soho. The first was 12 inches diameter, hollow, and having space enough to bore a length of 14 feet 4 inches, and diameter of 4 feet 6 inches. The traversing screw was hand-cut. It was worm-driven, the gear on the end of the bar being a mortise worm-wheel. Differential gears were fitted for feeding the boring head. This machine was made in the period when Murdoch was there, of coal gas fame. There were several boring bars dismantled a few years ago. As Murdoch died in 1839 they must have been built a good while prior to that.

A vertical boring bar 14 inches diameter was the one which bored the cylinders for the screw engines of the *Great Eastern*. This was worm-driven, the gears being below the floor and protected by a plate. The traversing or feed gear was carried on a beam above, built into the wall. These tools were built into the walls and floors as integral portions of the works, and were the precursors of modern tools. Among these ancient machines the dates of which are unrecorded, but which must lie about the period of Waterloo, were lathes, boring machines, wall planers, and others.

After the opening of the Liverpool and Manchester Railway in 1830 there came a great boom in machine tool making. Railways were being constructed all over England between 1830 and 1840, and locomotives and trucks could not be built fast enough. Anything that saved labor was in great demand. The makers of self-acting tools were full of orders. During this period very many great improvements were effected, and the machine tools assumed in several instances nearly their present forms.

Ocean steam navigation was also a potent cause of development, for the marine engines of that time were of massive proportions requiring big boring and planing tools.

Nasmyth Steam Hammer

To this cause the invention of the steam hammer was due. A wrought iron paddle shaft 30 inches diameter was required for the *Great Eastern*, and no firm in England or Scotland would undertake to forge it. Nasmyth was appealed to, and designed his hammer on the essential lines which have survived to the present, except that it fell by gravity only. This was in 1839. The crankshaft was never made, a screw being substituted, and the hammer was allowed to be shelved. In 1842 Nasmyth when on a visit to Creusot saw his hammer at work froging a crank, and learned that the idea had been taken away by a visitor to Patricroft. Then he patented it, and orders came in quickly. Fig. 21 illustrates the first hammer, from a model now in South Kensington Museum.

An offspring of the steam hammer was the steam pile driver, the first two of which were used for the construction of the Keyham Docks, an extension of the Devonport Royal Naval Docks. They were termed steam hammer pile drivers, and were a grand success. A four ton falling weight making eighty blows a minute drove in piles 18 inches square and 70 feet long in $4\frac{1}{2}$ minutes. Previously the same work done by a hand machine had occupied 12 hours.

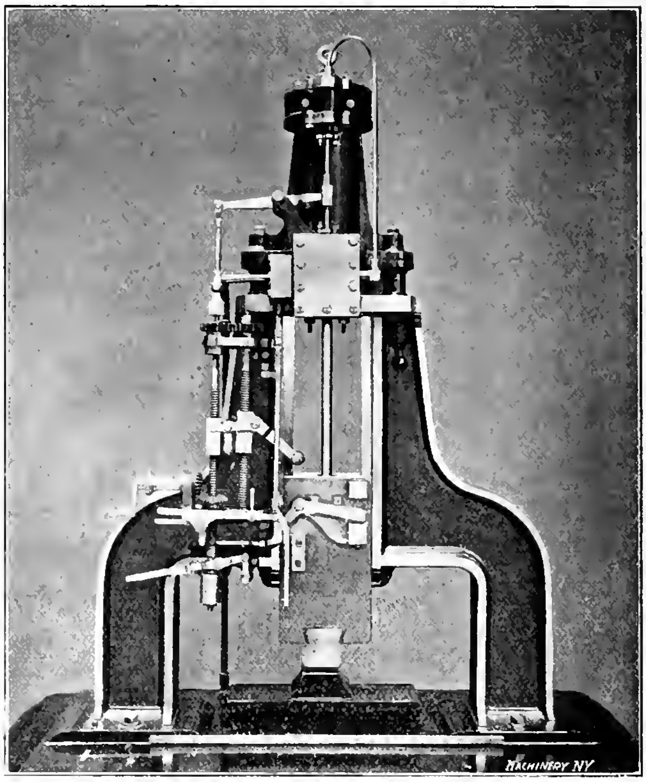

Fig. 21. Model of Nasmyth First Steam Hammer, in South Kensington Museum

When Maudslay began his labors there were no standard screws. Each bolt had its own nut, the two being marked to match. The subsequent work of Whitworth has somewhat eclipsed that of his old master, but he carried on and completed the labors which had engaged the attention of Maudslay from about 1800 to 1835, the time of his death.

Screw-cutting Machinery

One of Maudslay's early devices for originating screws, Fig. 22 (about 1800), and now preserved in South Kensington Mu-

seum, embodied an endless screw and tangent wheel as the essential element. The wheel was mounted with its axis vertical on a table to be slid along a lathe bed. Through a hole in the table frame the bar to be threaded was passed. A tool-holder was secured to the top of the disk, through which a concave chisel edge was projected downwards to come in contact with the bar to be threaded, being set by the tangent screw to the inclination of rake which corresponded with the pitch of the screw to be cut. A chasing tool for the same pitch was carried in a slide rest with screw adjustment, and

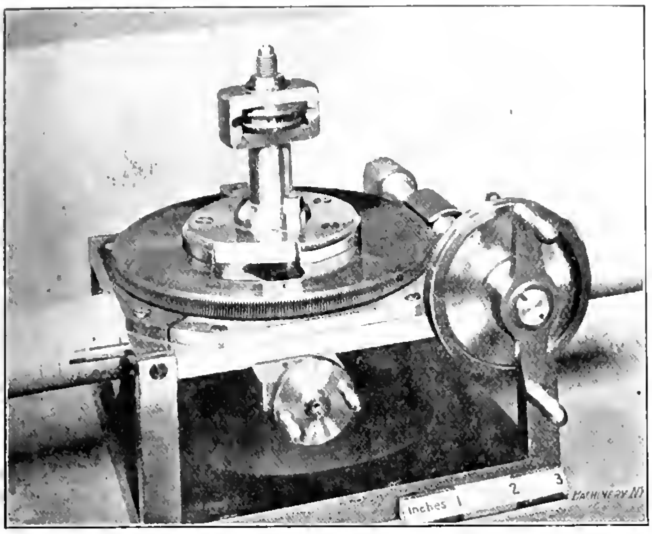

Fig. 22. Maudslay's Machine for Originating Screws (About 1800)

entered a hole at the side. On the bar being rotated, the chisel edge compelled the device to travel longitudinally, while the chaser following, cut the thread. The bar was of soft metal or of hard wood, and from this bar copies were made in steel. In the screw generating machine the essential was the setting of the generating instrument to the precise angle of a given screw. Everything depended on the accuracy of this setting. Maudslay produced a guide screw in the generating machine which he used afterwards in the screw-cutting lathe. In the latter he produced a screw 5 feet in length by 2 inches diameter with fifty threads to the inch. Its nut was 12 inches long with 600 threads.

The screwing machines for threading and tapping were made between 60 and 70 years ago in nearly the same designs as many are at present. They were of horizontal type with

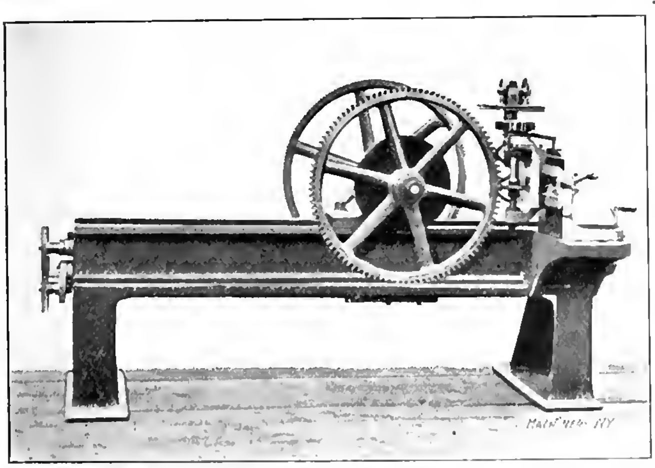

Fig. 23. Gear-cutting Machine, Joseph Whitworth & Co. (1868)

either one or two spindles revolving the bolts, and a cross bar carrying the dies. After cutting, the reversal of the spindles ran the nuts off. A dark fish oil was used for lubrication. Apart from the slowness of their operation they gave practically as good results as those of to-day.

There was a nut tapping machine in the Maudslay shops, and also a bolt screwing machine with a long lead screw in front of the bed having a buttress thread of coarse pitch, and a swing plate with change gears. The clasp nut was a half nut occupying the front portion of the screw, with which it was held in contact by a massive pear weight, much as the pawls of some hand cranes are now. On lifting this at the completion of a traverse, a suspended weight at the right-hand end of the bed pulled the carriage back ready for another cut.

Gear Cutters and Milling Machines

Maudslay made form bevel gear cutters of a peculiar kind, supported on flat topped lathe type of beds. The headstock, comprising two bearings and a mandrel, carried a dividing wheel at the rear end of the mandrel, and the wheel blank at the front end. On a small shaper arm standing out from the bed the tool holder was reciprocated by a crank motion. The inner end of the bar was pivoted on a point in the axis of the mandrel, while the other was fitted with a finger which was retained in contact with the form; a hollow templet larger than the tooth shape held in an adjustable bracket.

Fig. 23 illustrates a Whitworth spur gear cutting machine of date 1868, having a capacity up to 4 feet 6 inches. It is of a design that was very popular a few years ago. The dividing wheel is seen on the farther side of the bed. Its large diameter is noticeable. The cutter spindle is cord-driven, power being gained through spur gears. The change-gears for pitching are seen at the left-hand end of the long bed, and the index handle for operating it at the right-hand end. The cutter slide has a self-acting feed across the tooth faces, and is arranged to swivel in the horizontal and vertical planes for dealing with bevel and worm gears.

A small cutter forming machine by Whitworth & Co., date 1868, is seen in Fig. 24. It is based on the principle of some gear cutters of the period, using a dividing head with circles of holes and an index peg. Its cutter spindle was cord-driven, the cord running over small guide pulleys, and the cutter

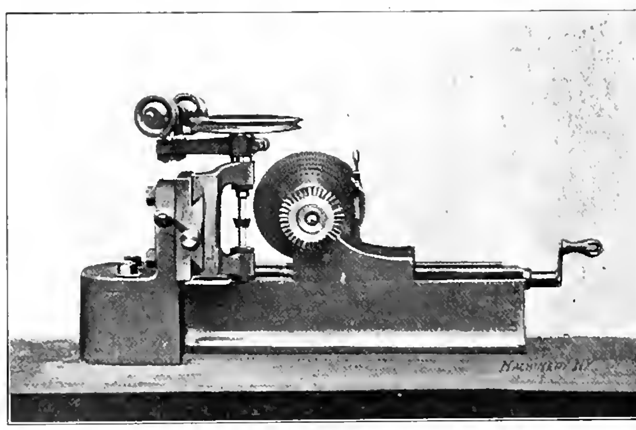

Fig. 24. Cutter Forming Machine, Joseph Whitworth & Co. (1868)

slide was traversed by hand. The cutter was mounted on the spindle of the dividing head, and the slide which carries the latter was adjustable along the bed by hand to suit cutters of different diameters. The cutter head is arranged to swivel in horizontal and vertical planes to suit angular and other cutters. Formed cutters are produced by hand profiling by means of the two handles shown.

The employment of rotary cutters in place of single-edged tools was an epoch the full development of which has been reserved for quite recent years. The first note of this was sounded more than a century ago when one Vaucasson, a Frenchman, invented the milling cutter. It was a very imperfect milling tool, with the teeth of much finer pitch than modern practice allows. The cutter was inefficient in its first form, and nothing but the lathe was available for its operation, and thus the single tools continued to hold their own until the demands made by governments for interchangeability in the parts of small arms brought the opportunity to the circular cutter. Eli Whitney was the man who first recognized, or at least actually developed, its capabilities, and he invented and developed the earlier type of machine for its operation.

There was a nut milling machine in Maudslay's shop in 1829, having been devised as an attachment to the lathe by Nasmyth, who had recently commenced working there. Maudslay wanted a model of a 200 H. P. marine engine made, and entrusted the work to Nasmyth. There were about 300 cast steel nuts to be made, and Nasmyth rigged up a dividing

plate and nut spindle on the slide rest of a lathe and shaped the faces with a milling cutter or "circular file" held in the headstock spindle. Subsequently a special machine was built for nut cutting for use in the factory, and when Nasmyth went into business for himself he built numbers of them for engineers.

Nuts were commonly shaped with a milling cutter in England more than 60 years ago. There was a machine by Archibald Milne of Glasgow in which an end mill shaped the faces. The nuts were mounted on a vertical mandrel projecting from a circular table, having 6 equidistant notches, locked with a spring catch and lever. A self-acting feed was provided for moving the nut up to the cutter. It was cord-driven from four-speed pulleys through a worm and wheel, pinion and rack on the under side of the table. The cutter spindle was driven slowly through spur gears from fast and loose belt pulleys.

A nut milling machine of 1866 by Whitworth is seen in Fig. 25. The nut mandrel was rotated by a worm gear and locked with a pin passing through holes in a division plate. The mandrel head was traversed along the bed past the cutter by a screw, and knocked out by a self-acting clutch arrangement. The cutter drive was by belt and worm gear enclosed. The nut mandrel is firmly held by a self-centering

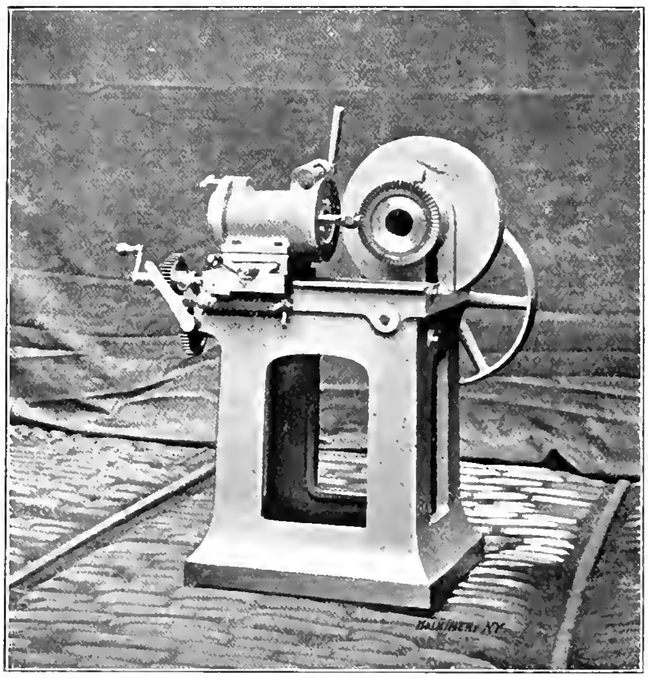

Fig. 25. Nut Milling Machine, Joseph Whitworth & Co. (1866)

three-jaw chuck, actuated by the worm and worm wheel. The chuck is formed with a sleeve which takes its bearing in the head and has keyed to it at the left-hand end a division plate. The chuck and nut mandrel are rotated by hand, and the position defined by a taper pin passing through holes in the division plate. The mandrel head is fed automatically along the bed past the cutter and tripped at any desired point. The cutter drive is by belt and spur gear enclosed.

Mr. Bodmer of Manchester had made a milling machine about 1824. But that was not strictly the first, which was one the late Mr. Parkhurst had seen, and was informed that it was at work in 1818 at a gun factory at Mill Hollow, Middletown, Conn. It was a hand machine. The cutter was driven by a belted headstock, with a three-stepped wooden cone removed from a lathe. The work was traversed under the cutter by a hand crank turning a pinion which slid a rack under the work table. If a second cut was required it was packed up. The idea was there but few improvements occurred until about 1850 when the Howe machine was introduced resembling in several respects the Lincoln miller designed by Mr. Pratt in 1854, in which for the first time a screw feed was substituted for that of the rack. The period of the American Civil War was prolific in milling machines used in the manufacture of small arms. All were of horizontal spindle design, and all were modeled essentially on the Lincoln type. The first universal machine was built about 1865 after the design of Joseph R. Brown, one of the founders of Brown & Sharpe Mfg. Co. The machine, Fig. 26, is still in existence in the works. Essentially it comprises the features of present-day machines, but the latter embody many features which add to their convenience and fulfill the requirements now demanded of a machine.

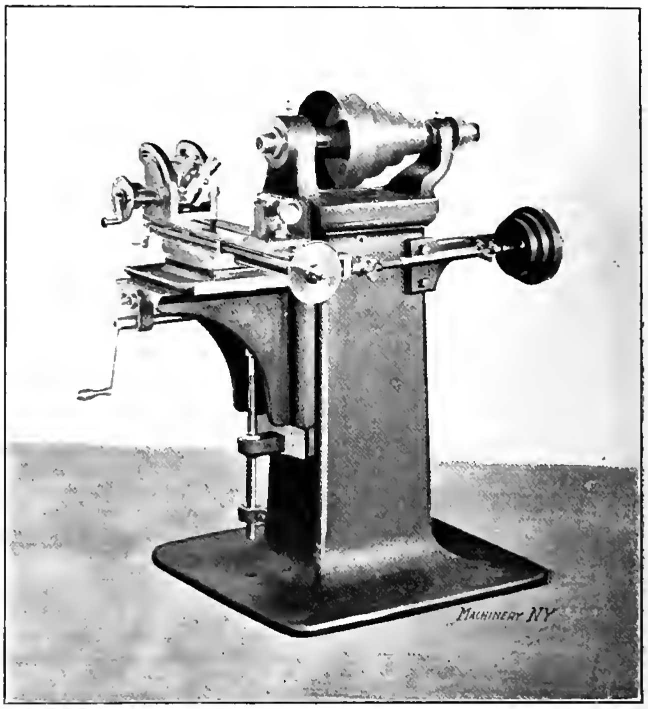

Fig. 26. First Universal Milling Machine. Built about 1865 by Joseph R. Brown, of Brown & Sharpe Mfg. Co.

Fig. 27 illustrates a very massive milling machine with inserted tooth cutters by Whitworth & Co. in 1867. It was designed for tooling the flat faces of marine cylinders and work of similar character. It was driven by a steam engine through worm gear. The work was attached to the table in front, which slides on a bed in front of the main upright, and is provided with cross adjustment by hand. The automatic feed of the table along the bed is operated from the

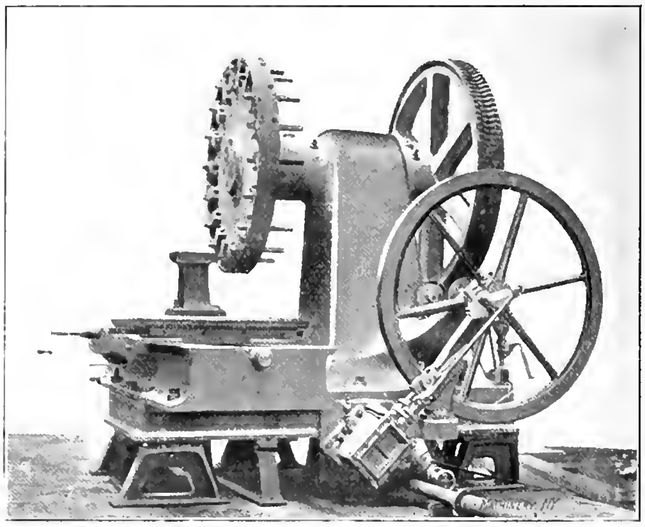

Fig. 27. Very Large Type of Milling Machine, driven by Steam Engine. Joseph Whitworth & Co. (About 1867)

worm shaft through change gears, and worm wheel on the screw, disconnected by hand-operated clutch at the left-hand end of the bed. The cutters are ordinary tools, each fixed by a clamp plate and two bolts, and may be placed with their cutting edges either on the edge or on the face of the disk as desired.

Nasmyth was the first to build the independent machine tool driven by its own small engine, abandoning the shafting, pulleys, belting, and laying down steam pipes instead. This arrangement has met with great favor in boiler making and plating shops where the machines are mostly heavy and scattered. Such machines are still made and used, though the electric motor drive is rapidly displacing them.

THE MAKING OF TOOL STEEL

ERIK OBERG*

Few mechanical processes have, during the general progress of engineering, undergone so little change as the methods and processes employed in the making of tool steel. With the exception of a more direct method for introducing the carbon into the steel, it may be said that, in general, the same methods are still used as were employed centuries ago. Improved methods for heating the furnaces and for handling and working the steel at various stages of the manufacture have, of course, been introduced but there has been no new principle applied in the actual production of the steel.

Before describing in detail the various processes and operations involved in the making of tool steel, the general procedure may be briefly reviewed as follows: Tool steel is made by using low phosphorus and sulphur wrought iron and adding carbon to it. Two methods have been in use, the older one being the so-called cementation process, in which the wrought-iron bars are packed in air-tight retorts with powdered charcoal placed between the bars. When the retorts are thus filled, they are put into a furnace, called the cementation furnace, where they are heated to a red heat and permitted to remain at that temperature for several days. During this time the iron will absorb carbon from the charcoal up to about 1½ per cent of its own weight. The process, in fact, is similar to the ordinary case-hardening process for giving parts made of low-carbon machine steel a hard high-carbon surface. The carbonized bars, called "blister" steel, are then cut up into small pieces and are re-melted in a crucible, and from that poured into molds. The billets thus formed are afterwards hammered or rolled into the desired shapes.

The newer method, largely employed at the present time, consists of putting small pieces of wrought iron directly into a crucible together with the proper amount of powdered charcoal. This charge is then melted and permitted to remain in the molten state for some time before being poured into molds. While in the molten state the iron will absorb the carbon much quicker than when only red hot, as in the cementation process. When the carbon is added directly in the crucible it is also possible to more accurately determine the carbon content of the final product and for this reason the newer method is far superior to the cementation process, which, however, is still considerably in use in the old steel manufacturing districts in Europe. The newer method is more commonly in use in America, and is the method employed in the steel-making plant of the Heller Brothers Co. of Newark, N. J. It is the object of the present article to briefly describe the making of tool steel as this process is carried on in the works of this firm.

* Associate Editor of MACHINERY.

History of the Heller Brothers Company

The original business of which the present plant of the Heller Brothers Co. is an outgrowth was established in 1836 by Mr. Elias Heller, the grandfather of the present officers in charge of the company's business. Mr. Heller at that time engaged in the making of files and horse rasps in a small shop in what is now the central part of Newark, N. J. Up to that time English files had been used exclusively in the United States and Mr. Heller was one of the first, if not the very first man, to make files in this country. The business gradually grew until the first buildings of the present factory were erected in 1873 at Forest Hill, a suburb of Newark, ten miles out of New York City on the Erie Railroad.

Fig. 1. Tool Steel Furnace and Charging Floor at the Heller Brothers Company's Plant, Newark, N. J.

It was found that a relatively low-carbon steel of a uniform composition, such as is required in the manufacture of horse rasps was impossible to obtain at that time in the United States at a reasonable price, and, for this reason, in 1881, the firm built a small plant for the manufacture of high-grade tool steel primarily for its own use. Since then, however, this department of the plant has been considerably increased so that at the present time the firm manufactures a considerable quantity of steel for the market, specializing particularly in high grade brands of carbon tool steel and high-speed alloy steels. The plant now includes a melting furnace having a capacity of thirty crucibles at a time, a number of steam hammers and a small rolling mill, besides the required heating and annealing furnaces. In 1899 the firm was incorporated under the name of Heller Brothers Company.

Material Used for Making Tool Steel

The raw material used by the Heller Brothers Co. for the making of tool steel is Swedish (Dannemora) wrought iron having a carbon content of from 0.10 to 0.20 per cent. This

Fig. 2. The Charge of Swedish Iron, Bag of Charcoal, and the Clay Crucible in which the Charge is melted

iron comes in flat bars, $1\frac{1}{2}$ by 2 inches, and is cut up into small pieces about one inch wide. The reason why Swedish iron is used in preference to other kinds is that it has proved itself superior in the making of high-grade tool steels. It is possible to obtain American iron having by chemical analysis practically the same composition as the Dannemora iron, and being as free from phosphorus, but nevertheless, when transformed into tool steel, the final product will not be of the same quality as that made from the Swedish iron. Metallurgists are at a loss to explain the reason for this. Steel makers say that the Swedish iron has more "body"; but, of course,

Fig. 3 Pouring the Molten Steel. The Photographic Plate shows the Intense Light and Heat and Fireworks Effect

this in itself does not mean anything except that it produces better results. One cause may be that the Swedish iron ore originally contains less impurities, and that for this reason wrought iron of a given quality can be produced without having passed through, in the same degree, the processes necessary for removing the impurities from the iron ore. These processes possibly change somewhat the crystalline structure of the iron, although its chemical composition remains exactly the same. This is mere theory, however, and should not be accepted as the demonstrated cause of the superiority of the Swedish wrought iron for the making of tool steel.

The Melting Furnace

The furnace in which the crucibles containing the metal are heated, which, as already mentioned, has a capacity of thirty crucibles at a time, is gas heated, the gas being obtained from a gas producer in the company's plant. The furnace is of the Siemens type, the gas entering it alternately from either side through checker plates. The action of the furnace is as follows: When the gas enters on one side, the exhaust gases pass out through the checker plates on the other side; these exhaust gases, being of a very high temperature, heat the checker plates rapidly to a red heat; at this time the entering gas is automatically shut off, and gas is admitted from the opposite side. This gas, then, passing through the heated checker plates, is thoroughly preheated, and when combustion takes place a much higher degree of total heat is obtained. The combustion gases from this side now heat the checker plates on the other side, and the process of pre-heating the gas as it enters alternately from the two sides of the furnace is thus automatically taken care of.

The charging floor, or the floor on which the men work who insert the crucibles in and remove them from the furnace, is level with the top of the furnace and iron-braced fire-brick covers, as shown in Fig. 1, are provided, which are kept over the openings of the furnace at all times except when a crucible is put in place or removed. The furnace, of course, is built up of fire brick, and is covered on top with steel plates. It is kept running continuously day and night, as it would

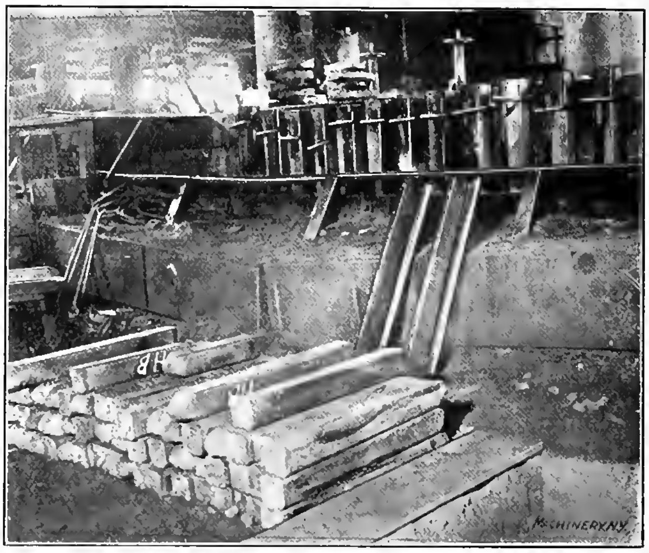

Fig 4 A Row of Molds ready for the Metal to be poured, an Open Mold, and a Pile of Ingots

crack and be destroyed by the severe internal stresses due to sudden cooling if the fire were permitted to go out. The life of the furnace is from six months to a year, after which time it must be rebuilt.

Crucibles

One of the crucibles used for the melting of the iron is shown in Fig. 2. The height of the crucible is about 20 inches and it is one foot in diameter at the central part.

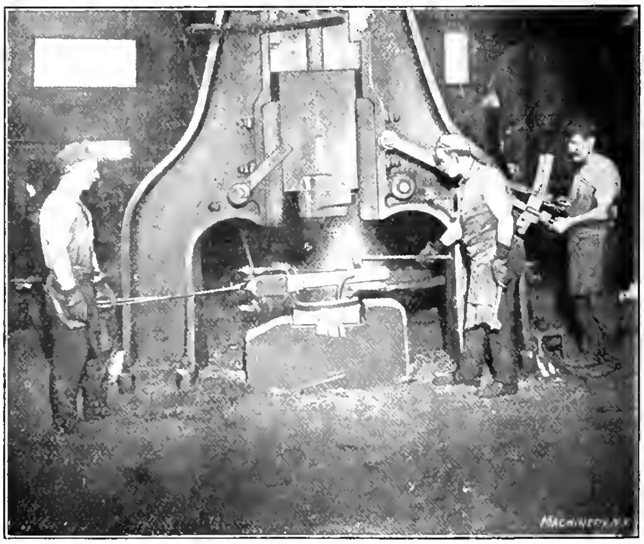

Fig. 5. First Stage in Hammering the Ingot to Size under a 2500-pound Bement Hammer

When placed in the furnace it is provided with a fire-clay cover not shown in the illustration. The crucible has a capacity of seventy-five to eighty pounds of iron. It is made from a mixture consisting of several foreign and domestic clays of

proper proportions. The crucibles are manufactured in the plant of the company, and are made in a manner similar to that used for making clay pots. A form is used to give the outside shape, and a revolving former is employed to shape the inside. When the crucible has been thus formed it is permitted to dry at ordinary room temperature, a storage room being provided where the crucibles are lined up on shelves for the purpose of drying. When properly dried, they

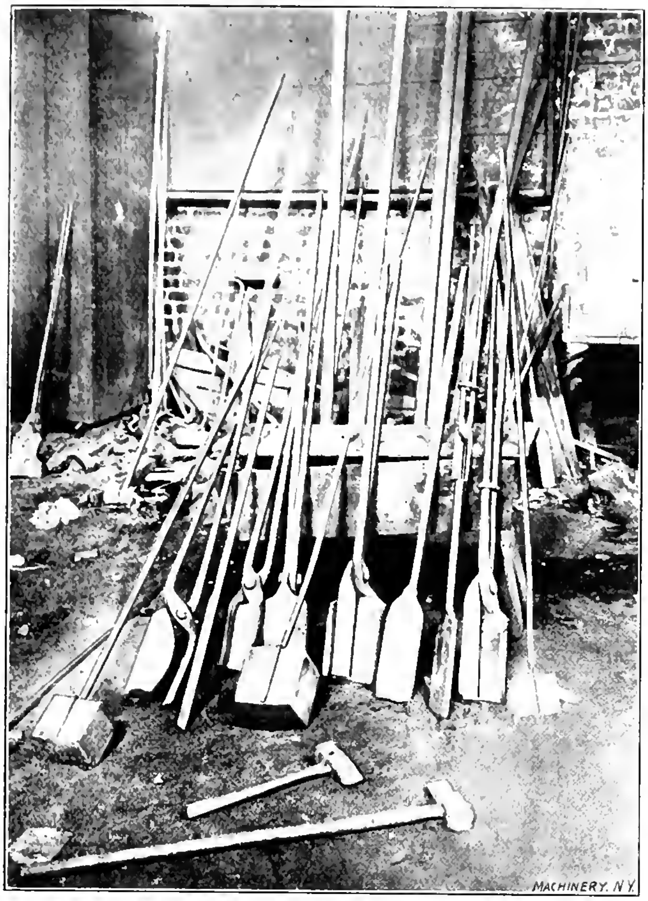

Fig. 6. A Collection of Tools used when handling the Ingots and hammering them to Size

are put into an annealing furnace where they are slowly heated to a high temperature. They must then be taken directly from the annealing furnace while hot, charged with the iron and charcoal, and put into the melting furnace. After this the clay crucible is not permitted to cool off until its usefulness is past. The heat of the crucible and the charge while in the furnace is from 2,500 to 2,800 degrees F.

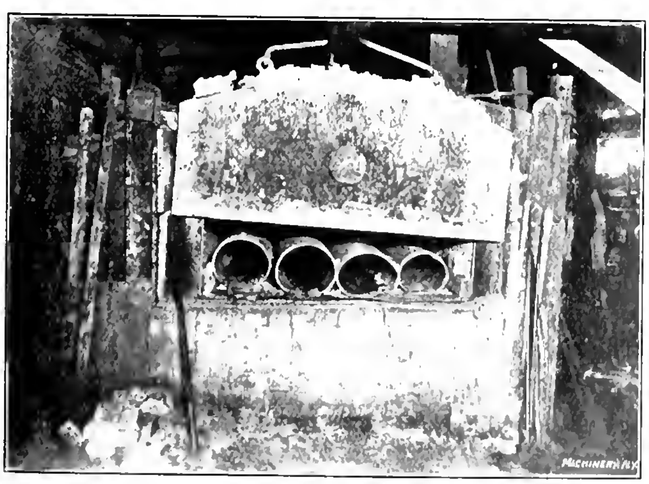

Fig. 8. One of the Annealing Furnaces, showing the Pipes into which the Tool-steel Bars are placed while being heated for annealing

Comparison between Clay and Graphite Crucibles

The use of clay crucibles in preference to crucibles of graphite is important in the making of high-grade tool steel, and is in accordance with the practice employed by the best English steel makers at Sheffield, where the clay crucible has been used for this purpose for centuries past. When the clay crucible is used, there is absolutely no possibility of any extraneous matter mixing with the charge, and the carbon content can be very closely predetermined. When a graphite crucible is used, small particles of graphite will flake off from the inside of the crucible and these particles will mix with the charge. They will, however, not enter into chemical composition with the steel, but will merely mix with it mechanically, so that, in the steel, there will be small particles of graphite imbedded, thus producing small holes and flaws in

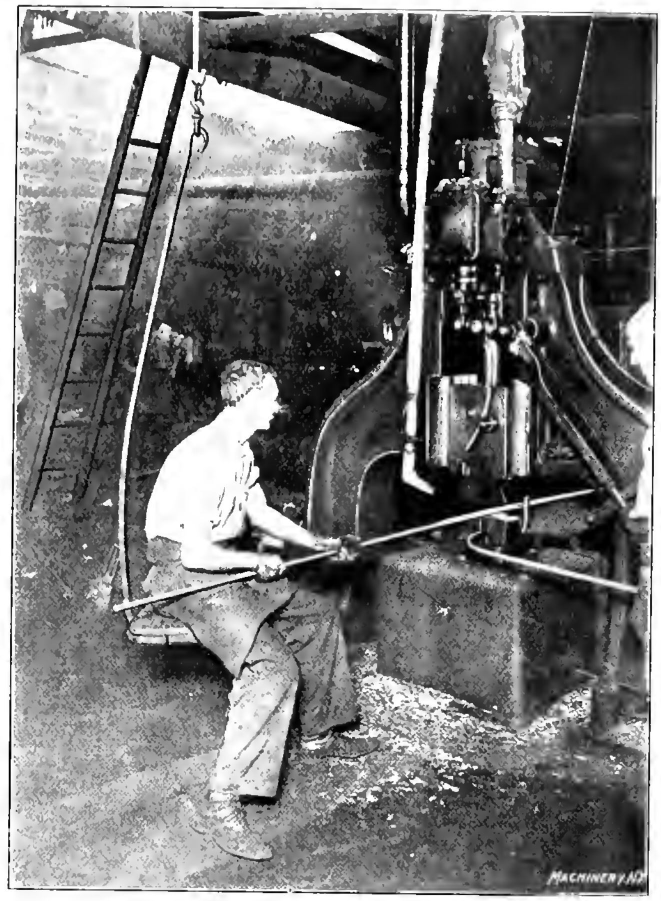

Fig. 7. Hammering a Round Bar to size under a Small Bement Hammer

the finished material. The graphite crucible, however, will last longer, and is therefore cheaper to use, but when a high-grade tool steel is to be produced the clay crucible is the only one which will give entirely satisfactory results.

Melting and Pouring the Steel

The work of charging or filling the crucibles and pouring the molten metal into the molds is carried out on the charg-

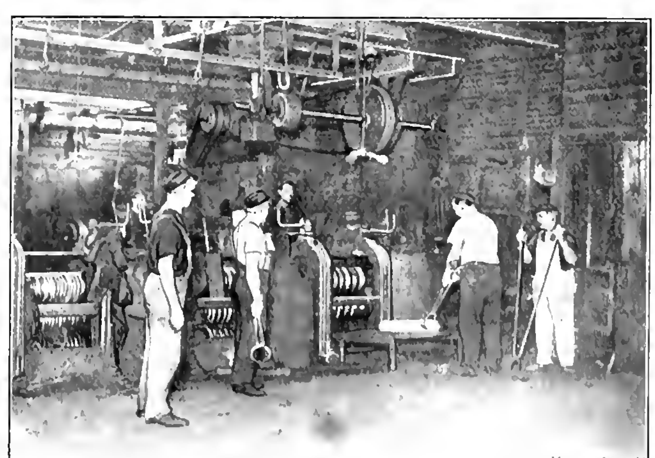

Fig. 9. The Rolling Mill, showing the Ingot just before it passes between the First Set of Rolls

ing floor, shown in Fig. 1. The crucibles are charged with about seventy-five pounds of wrought iron cut up into pieces, as has already been mentioned, a pile of wrought iron ready for the crucible being shown in Fig. 2. About half of the iron is first put into the crucible, then a bag containing the powdered hardwood charcoal, shown on the top of the pile of iron pieces in Fig. 2, is put in, and finally the remainder of

the iron charge is placed on top of this. When high-speed steel is made, other ingredients, such as chromium, tungsten, molybdenum, etc., are placed in the crucible together with the charcoal and iron.

The carbon content in the tool steel is determined by the amount of charcoal in the charge; some carbon, of course, is contained in the wrought iron, so that it is not possible to calculate directly the proportions of charcoal necessary for a certain weight of iron to produce a given percentage. Some of the charcoal is also lost in the slag. The common method of determining the amount of charcoal required, however, is to consider that each ounce of charcoal will give about 0.07 per cent carbon to the steel, or, as the steel maker would express it, one ounce charcoal gives seven "points" carbon. This proportion is approximately correct for ordinary carbon contents, but when steel of a high carbon content is required it is necessary to add charcoal in a greater proportion, partly on account of the fact that the original amount of carbon in the wrought iron is then of relatively less importance, and partly because more of the carbon is lost or wasted. The charge for high-speed steel of standard quality is proportioned so as to give 5 to 6 per cent chromium, 19 to 20 per cent tungsten, and 0.55 to 0.75 per cent carbon.

The crucibles are placed into and lifted up out of the furnace by means of large tongs, the men doing the work standing partly over the furnace while removing the crucible. In Fig. 1 a crucible had just been removed from the furnace from where it was immediately moved across the floor to the molds, which stand vertically, and into which the molten metal is poured to form the ingot. Before pouring, however, but after the crucible has been removed from the furnace, the slag collecting on the surface of the metal is first removed by a long iron bar, and then a small amount of manganese is put into the crucible. This prevents the oxidizing of the metal while being poured, and tends to insure freedom from blow holes or flaws in the ingots. A number of molds ready to have the metal poured into them are shown in Fig. 4, the photograph being taken from the level of the floor of the shop, which is several feet below the level of the charging floor. One of the molds which are made in halves, is shown opened up in this illustration. The molds are made of cast iron and the standard inside dimensions of the molds, and, of course, also the dimensions of the ingots, are four inches square, by about three feet long, the ingots containing about 150 pounds of iron, or the contents of two crucibles with a capacity of seventy-five pounds each. In Fig. 1, one crucible has just been poured into the mold and is now being recharged, while the other crucible stands on the side of the mold ready to be poured. Fig. 3 is a photograph taken at the moment of pouring the molten metal into the mold. The intense heat and the fire-works effect produced is well exhibited in the illustration.

As soon as the metal has been poured, the crucible, which is not permitted to cool off on account of the fact that in such a case it would be destroyed by cracking, is put back into the furnace to be heated up again before recharging. In some cases, when it has not cooled off too much during the pouring, it will be immediately re-charged without re-heating. When re-heated, however, it is removed from the furnace after a few minutes, and the charge put into it as already described. It is then immediately put back into the furnace where it is permitted to remain from four to six hours when it is again removed, and the metal poured, and the same process repeated. As the furnace is in operation day and night, about five heats are obtained in the course of twenty-four hours. A crucible will only last for about four to six heats.

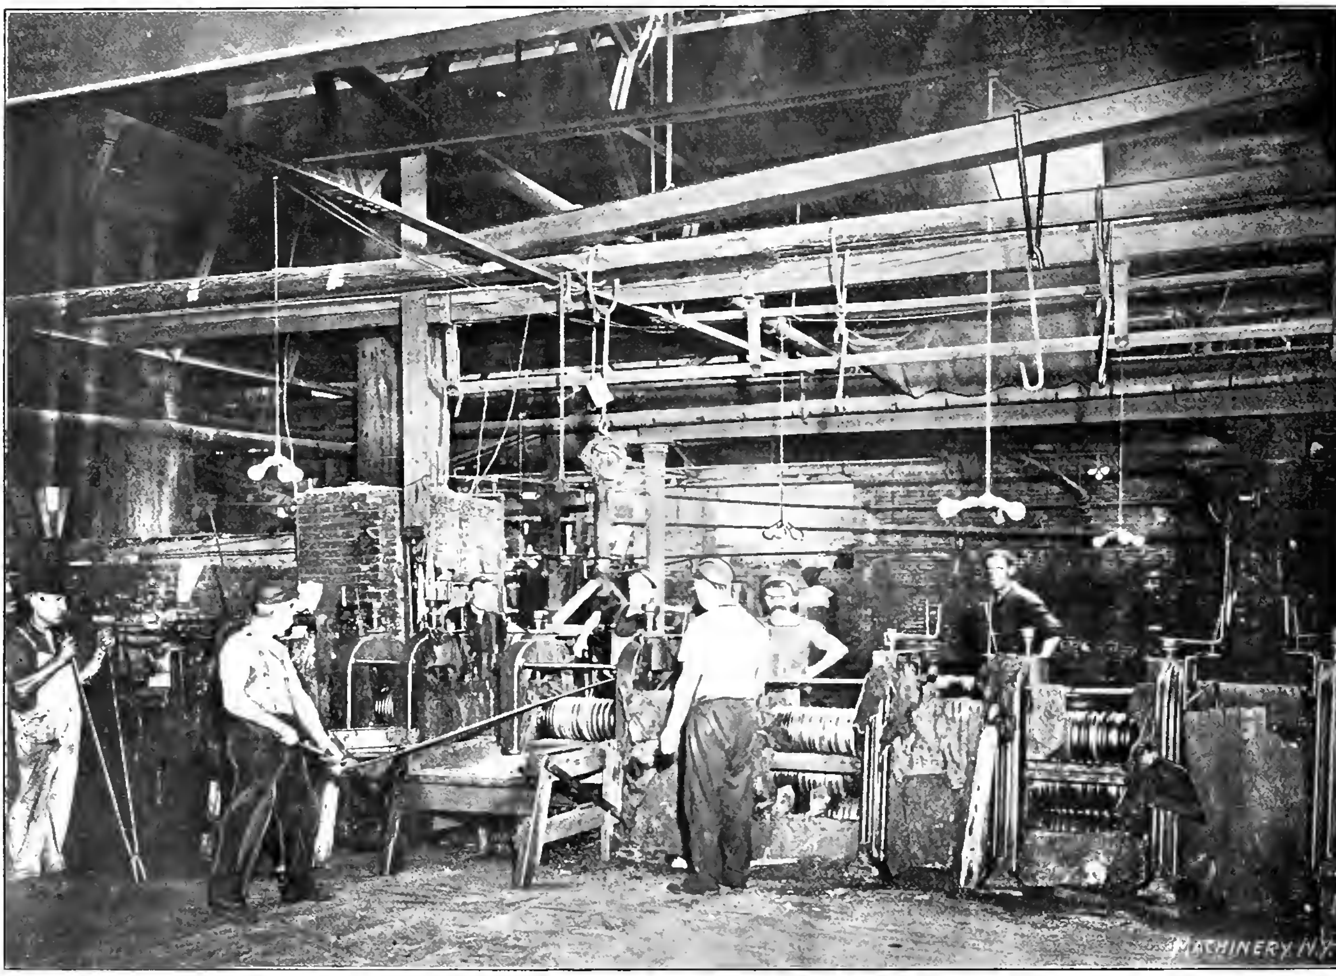

Fig. 10 The Rolling Mill, showing the Ingot after it has been rolled down into a Long Bar of Small Diameter

In order to prevent the steel from sticking to the molds, these latter are "smoked" by burning rosin underneath them which leaves a thick black coat of smoke or soot on the face of the mold. The ingots are permitted to cool off in the molds and are then removed and stored in piles on the floor, as shown in Fig. 4.

The Welding Process

The next operation performed is the heating of the ingots in a heating furnace to a welding or white heat, after which

they are put through what is termed the welding process. This consists in placing the white hot ingot under the steam hammer and lightly tapping it with gentle blows on the surface, so as to close up or weld all minute cracks or flaws that may be present on the outside of the ingot. This insures a homogeneous structure and freedom from flaws and cracks in the finished material.

Hammering to Size

After having been welded, the ingot is either again permitted to cool down and it is then re-heated to a red heat, or it may be immediately taken and placed under the steam hammer and hammered down to the required size. In Fig. 5 an ingot is shown where the hammering to size has just com-

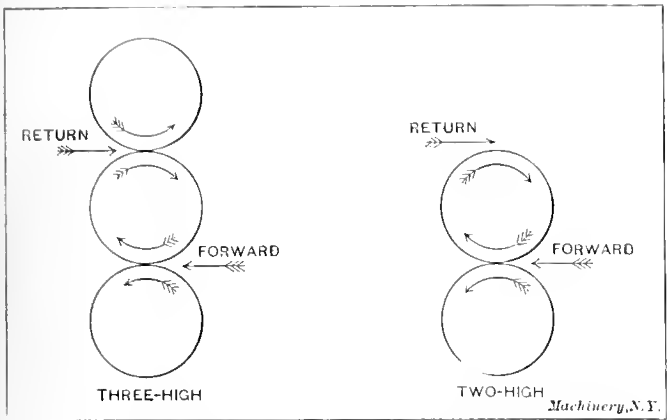

Fig. 11. A Diagrammatical Sketch showing the Difference between the Action of Two- and Three-high Rolling Mills

menced. The hammering adds to the firmness and quality of the steel and insures homogeneity of the material. In order to insure the correct size being obtained, tools similar to those employed by regular blacksmiths are used as stops or gages. A square block provided with a long shank, called a peg, of which a number are shown among the tools in Fig. 6, is placed on the anvil of the hammer and acts as a stop. This block is of the required thickness of the bar. When the steam hammer has hammered down the bar to this size, it will strike this block and is thus prevented from making the bar undersize. Two thin or flat blocks are also shown in Fig. 6, these being used to give the right thickness to the smaller sizes of flat bar stock. After the bar has been thus hammered down to a given size by using the pegs as stops, it is gaged by sheet iron snap gages at various places, in order to ascertain if it has the correct size uniformly along its whole length.

Round bars are made in a similar manner, swages similar to those used by the ordinary blacksmith being employed to obtain a round and smooth surface. In Fig. 7 is shown a smaller steam hammer under which the bars are hammered down to their exact dimensions, this being in a sense a continuation of the operation of hammering down the ingot, shown in Fig. 5.

When the bars have been thus hammered down to the correct size, it is necessary to anneal them in order that they may be soft enough for working. The bars are therefore placed in an annealing furnace. This furnace contains a number of long large pipes, the ends of some of which are shown in Fig. 8. They are regular cast iron water or gas pipes. The bars are placed in these pipes and the ends of the pipes are carefully sealed with fire clay. After this the front of the furnace is closed by the door or cover shown in the illustration, and the furnace is heated for about twenty-four hours; then the fire is deadened and the bars are permitted to slowly cool down for about two days. When the bars are taken out of the annealing furnace they are ready for shipment.

The Rolling Mill

All the ingots, however, are not hammered into shape; smaller sizes of square and round stock are rolled to the required size. Two illustrations of the rolling mill are given in Figs. 9 and 10. The ingot is first heated to a high heat and is then placed between the first set of rolls illustrated in Fig. 9, where the ingot is shown ready to pass for the first time between the rolls. It is here passed between the rolls from one side to the other, becoming smaller in cross section and of greater length at each successive pass. It is of interest to note how the mechanical operation of rolling keeps the heat in the bar, so that a great number of "passes" can be made without losing any of the original heat; as a matter of fact, the bar shows even a higher degree of heat at successive stages, the work performed on the iron in the rolling process being partly transformed into heat.

In Fig. 10 the ingot is shown rolled down into a long bar of small size. This illustration also shows to the left the heating furnace, and the general arrangement of the rolls and the rolling mill. When the ingots are to be rolled down to very small sizes it is necessary to divide the rolling operation into two stages, owing to the great length of the bar when it has been rolled down to a comparatively small size. In such cases the bar, after having first been rolled down to a certain size, is cut up under shears into shorter pieces of equal length, immediately after coming from the rolls. These pieces are re-heated in the furnace and are again passed between the rolls to produce the smaller sizes.

The rolling mill shown in Figs. 9 and 10 is what is called "three-high," that is, it consists of three rolls over each other, of which the bottom and top rolls run in the same direction, while the middle or center roll runs in a direction opposite to both. From the diagrammatical sketch, Fig. 11, it will be seen that by this arrangement it is possible to pass the bar first through the two lower rolls over to one side and then back again through the two upper rolls to the first side. In this way the bar is reduced in size a certain amount each time it passes back and forth. When rolling mills are provided with one set of two rolls only ("two-high") and are not made reversing, as is the case with the set of rolls shown in use in Fig. 10, it is evident that it is possible to pass the bar between the rolls only in one direction, and the bar must be passed back over the top roll to the front side "idle," as

Fig. 12. A Corner of the Stock Room

is plainly shown in the engraving. When the bar has been rolled down to the required size it is annealed in the same manner as described for the hammered bars, and is then ready for shipment.

In Fig. 12 is shown an illustration of a part of the stockroom, showing the finished bars in the racks.

* * *

The freedom from corrosion of tantalum, says the *Scientific American*, has suggested the employment of this metal as a material for writing pens, but tantalum pens have failed to pass a test for durability that is applied in France to steel pens. This test consists in loading the pen with a weight of 180 grammes (6 1/3 ounces) and moving a band of paper beneath and in contact with the pen at the ordinary speed of writing until 10 kilometers (6¼ miles) of paper have passed. The loss in weight of the pen should not exceed 0.7 milligram (0.0108 grain). The tantalum pens were found to lose more than twice this amount, but the loss has been reduced to 0.8 milligram (0.0123 grain) by slightly oxidizing the tantalum.

POWER TESTS OF A STOCKBRIDGE SHAPER

H. P. FAIRFIELD*

The following tests were made on an 18-inch shaper built by the Stockbridge Machine Co., Worcester, Mass., to obtain data relative to the size motor best adapted for driving the machine under normal conditions of roughing cast-iron. No attempt was made to learn what it was possible to accomplish by heavy feeding or abnormal depths of cut, but simply to go somewhat beyond the common shop usage in cuts and feeds. The few data shown in Table IV, for example, were taken merely as a check on those shown in the previous tables, as it was considered improbable that a shaper of this size would ever be used for roughing a cut so deep as one-half inch. I may say, at this point, that each table represents the average results of a series of runs made to conform as closely as possible to uniform conditions, and were made after the machine had been tuned up by careful observation and attention to adjustments, lubrication, etc., and with the cutting tool ground to a gage and kept sharpened to the original gage throughout the runs. A high-speed steel cutting tool was used on account of retaining its keenness for a longer interval of time than a carbon tool would do. The cutting speed selected (25 feet) for runs I to IV, inclusive, was decided on as that which would allow the use of either a carbon or high-speed steel cutting tool, and could be said to fairly represent average shop practice. The material cut was an average grade of cast iron such as is used in ordinary machine tool parts, and the block was cast into such a form as to preclude all springing of the work itself.

TABLE I

Depth of Cut, Inch	Length of Cut, Inches	Feed per Cut, Inch	Cutting Speed, Feet per Minute	Horse-power
1/8	17	0.0147	25	1.20
1/8	17	0.0294	25	1.68
1/8	17	0.0441	25	2.14
1/8	17	0.0588	25	2.68
1/8	17	0.0735	25	3.49
1/8	17	0.0882	25	4.02

TABLE II

Depth of Cut, Inch	Length of Cut, Inches	Feed per Cut, Inch	Cutting Speed, Feet per Minute	Horse-power
1/4	17	0.0147	25	1.73
1/4	17	0.0294	25	2.68
1/4	17	0.0441	25	3.22
1/4	17	0.0588	25	3.90
1/4	17	0.0735	25	4.40

TABLE III

Depth of Cut, Inch	Length of Cut, Inches	Feed per Cut, Inch	Cutting Speed, Feet per Minute	Horse-power
3/8	17	0.0147	25	2.55
3/8	17	0.0294	25	4.29
3/8	17	0.0441	25	6.00
3/8	17	0.0588	25	7.67

Tables I to IV give the average of repeated runs where all conditions of length of cut, depth of cut, and cutting speed were made as uniform as possible for each series, the feed only being varied. The runs were made cutting the full stroke of the machine, a rather unusual condition; but, as it was desirable to know what, if any, additional power might be necessary, if full stroke was to be used, the tests were run as shown.

The additional runs tabulated in Tables V and VI were made to show the effect in power consumption of a change in cutting speed, also as a means of comparing the Stockbridge two-piece crank mechanisms with the ordinary type of crank-shaper. Table V is the average of a series of runs made with the machine in its normal condition as a two-piece crank-shaper, and Table VI is compiled from the same number of runs, but made with the mechanism blocked in such a manner as to convert the machine into an ordinary crank-shaper of the usual type. In making the tests V and VI, the length of the cut was shortened to 12 inches, which conforms very well to the average length of work likely to be done on a machine of this size.

While the cost of power consumed in the average machine shop is not a large percentage of the manufacturing cost, the up-to-date manager is giving this item consideration when he purchases machinery, and when a machine is shown to consume less power and at the same time is adapted to produce the maximum output, he considers it worth while. A glance at Tables V and VI shows that the two-piece crank is a considerable power saver as compared with the regular type of crank-shaper, and while the saving in an hour's time may not appeal to the casual reader, it most certainly will if he uses his pencil and considers the savings effected in a year's time.

These tables are also quite interesting as showing how speeding up in a shop increases the power consumed. While it is a common enough saying among machine users: "It takes power to do work," some cases that have come under the writer's notice lead him to conclude that not all machine men fully realize its full significance. At a recent exposition of manufacturers, a machine tool firm exhibited a line of machines designed to work the modern high-speed cutting tools to their limit. When asked by the exposition management what power it was likely to use, the company's figures were for less than one-half what it actually used. There was no restriction on the power and the company could have been supplied with ample power by merely asking for it, as it was only a question of the wiring and fusing which the management desired to settle. As it transpired, it was necessary for this firm to shut off all but a single machine, changing from one to the other as the show was on.

TABLE IV

Depth of Cut, Inch	Length of Cut, Inches	Feed per Cut, Inch	Cutting Speed, Feet per Minute	Horse-power
1/2	17	0.0147	25	3.20
1/2	17	0.0294	25	5.43

TABLE V

Depth of Cut, Inch	Length of Cut, Inches	Feed per Cut, Inch	Cutting Speed, Feet per Minute	Horse-power
3/8	12	0.0294	15	2.10
3/8	12	0.0294	17	2.68
3/8	12	0.0294	25	3.22
3/8	12	0.0294	30	4.02

TABLE VI

Depth of Cut, Inch	Length of Cut, Inches	Feed per Cut, Inch	Cutting Speed, Feet per Minute	Horse-power
3/8	12	0.0294	15	3.08
3/8	12	0.0294	17	3.35
3/8	12	0.0294	25	3.62
3/8	12	0.0294	30	4.16

In conclusion, the writer desires to again emphasize the fact that the tests were made primarily to establish the size or power of motor to be used as a driver on the above shaper.

* Address: Worcester Polytechnic Institute, Worcester, Mass.

* * *

In the report of the committee on fuel economies, at the American Railway Master Mechanics' Association convention at Atlantic City in June, W. C. Hayes, chairman, made the statement that the investigation of the committee has shown that less than three per cent of all the locomotives on all of the North American continent use anthracite, liquid and other than bituminous fuel. Hence, the problem of locomotive boiler design as regards fuel is mainly concerned with bituminous fuel.

INTERESTING TOOLS AND METHODS OF CINCINNATI SHOPS

THE R. K. LE BLOND MACHINE TOOL CO

ETHAN VIALL*

Many interesting things are to be seen in the machine tool building shops of Cincinnati; some possibly that are not new, others undoubtedly old but nevertheless of the nature of "shop kinks" to many mechanics who have not been fortunate enough to run across anything like them, and in the line of interesting tools and methods the R. K. LeBlond Machine Tool Co., certainly holds its own.

In Fig. 1 is shown the way nine grooves are milled at once, on the outside of the cylinders used on the LeBlond lathes to cover the quick change gears. These grooves are not very long, so the feeding is done by means of the large hand-wheel shown, which operates a worm and gear set into the head of the fixture.

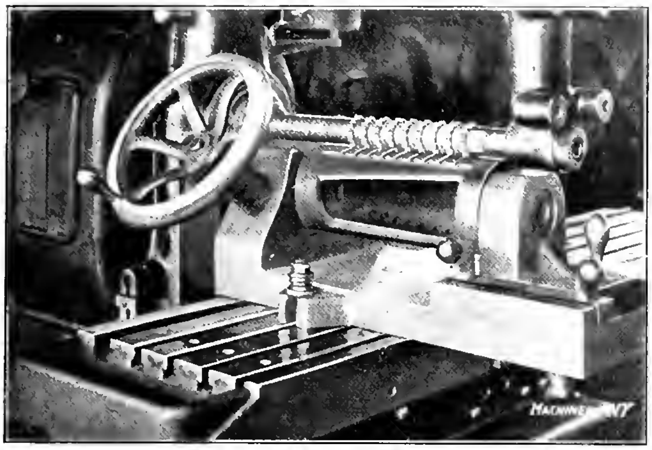

Fig. 1. Milling Nine Grooves simultaneously in a Quick-change Gear Cover

A jig for holding apron half-nuts while milling the dovetail bevel is shown in Fig. 2. Two of the half-nuts are placed in the jig and the bevel on one side is milled; the jig-head is then indexed half a turn and the job finished. Four different sizes of half-nuts are milled in this jig, which accounts for the four grooves to be seen in the head on each side of the dove-tail.

The slots in the bottom of milling machine vises are milled while the vises are clamped onto a cast-iron block, Fig. 3, the base of which is so made as to be bolted to the milling machine table with the block either parallel or at right angles to the line of feed, so that slots may be milled at right angles to each other, with the same jig.

Short shafts are milled for Woodruff keys, while held in the upright V-vise shown in Fig. 4. This vise is also very

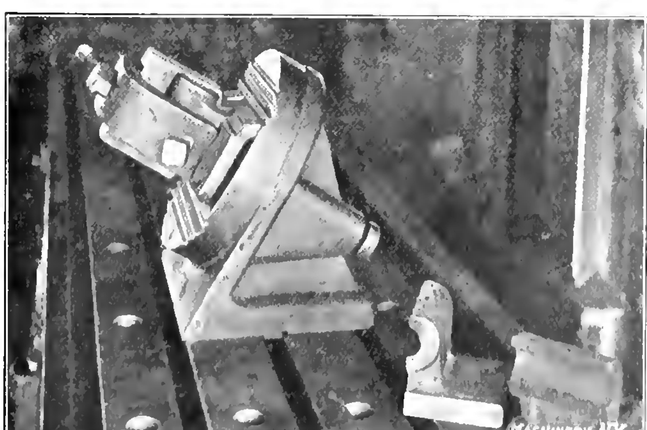

Fig. 2. Fixture for Milling Dove-tail Bevel on Apron Half nuts

handy for many other jobs where it is necessary to hold round stock.

All sizes of plain cast-iron pulleys are faced and crowned in the special milling machine shown in Fig. 5, and a quicker or neater job could hardly be imagined, as with two mills working on opposite sides, simultaneously, only a half revolution of the pulley is necessary to finish the rim. By referring to the engraving, it will be seen that the pulley arbor and chuck, is driven from underneath by a worm and gear, and the big cutter heads are equipped with both cross and

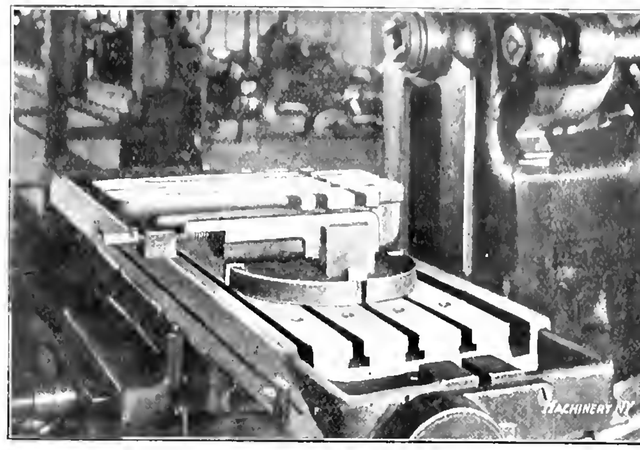

Fig. 3. Fixture for Holding Milling Machine Vises while slotting them

parallel hand feed, making it easy to set the machine for any size pulley within its capacity or to vary the amount of crown wanted on the face. The spindles carrying the milling cutters are back geared and the whole machine is made heavy and powerful in order to do good work.

A neat little jig used for holding the graduated sleeves used on the feed-screws of both lathes and milling machines, while drilling the set-screw hole, is shown in Fig. 6. In order to always have the set-screw hole in the same position relative to the numbers of the graduations, a little pointer for the zero mark on the sleeve is set into the face of the jig. Spacing collars are also used to bring the short sleeves properly under the drill bushing.

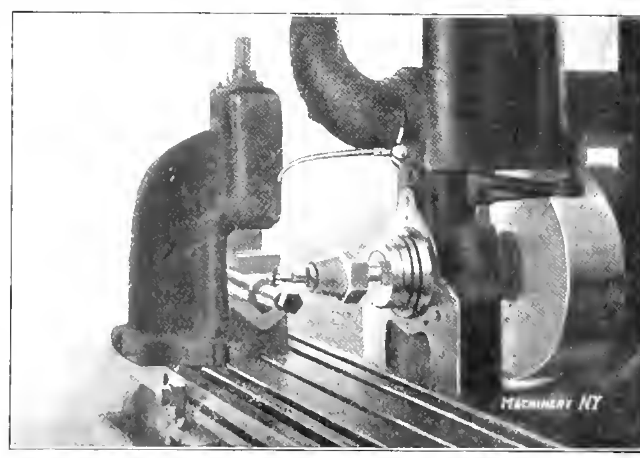

Fig. 4 Upright V-vise for Holding Shafts which are being milled for Woodruff Keys

At *A*, Fig. 7, is a special mandrel on which the large front box nut, for the No. 4 milling machine, is placed and turned after the threads have been cut in it. This mandrel is made to screw directly onto the lathe spindle, the square hole in the center being used for a wrench hold.

After the nut is screwed onto the mandrel, it is locked in place by a slight turn of the handled locking-collar *B*, which has a stop pin *C* set into the back and intended as a guide for setting the locking collar in the same position for each nut, by backing it up against the stop-screw *D*. The width of the nut is gaged by setting the point of the cutting tool against the hardened screw *E*. Another type of mandrel, known in most shops as a friction nose-chuck, is shown at *F* in this engraving. This mandrel screws onto the lathe spindle the same as the one just described, and it is used to hold large bored-out rings or collars, while turning the outside. A ring *G* is shown in place on the mandrel and the way it is locked by the pin *H* rolling and wedging in the beveled notch, is plainly apparent.

Fig. 8 illustrates a little tapping kink which is sometimes very useful when doing special work in the lathe. When

* Associate Editor of MACHINERY.

tapping by this method, the tail-stock spindle is disconnected so as to be free to move out or in; the chuck holding the tap is connected to the lathe carriage by a short piece of rod as shown, the lathe is geared to cut the same thread as that on the tap and with the tap close to the work the feed is thrown in. If in backing out the tap, it is not desirable to use the feed on account of the backlash, the rod is easily backed out of the hole in the chuck, the key in the tail-stock of course keeping the spindle from turning with the chuck and tap, when the lathe spindle motion is reversed. Lead-

finished. Many shops leave a center hole on each end, that on the pointed end being all but cut off; the center is then hardened on this end, which often distorts the end which has been left on for the center hole. Next the piece is placed between centers and the body ground, and finally the center is placed in a split chuck and pointed.

Fig. 12 shows a magnetic chuck which was made by the foreman of the grinding room for special work.

In Figs. 13 and 14 are shown two views of a box jig for holding lathe aprons while machining the holes, and in Fig.

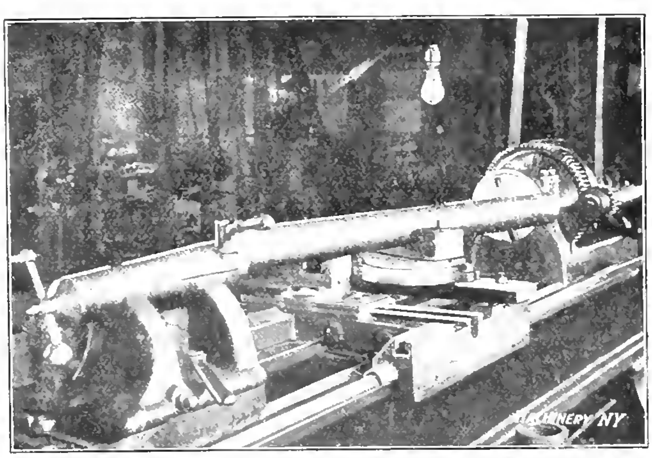

Fig 9. Turntable for Reversing Heavy Work in the Lathe

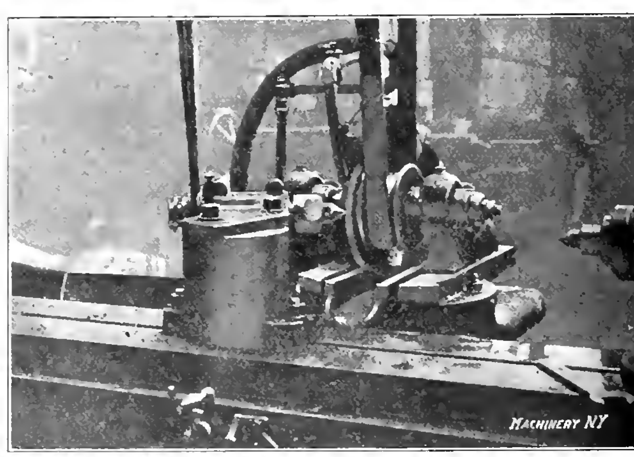

Fig 10. Grinding the Point of a Foot-stock Center—First Operation

ing the tap in in this way, is not always possible or desirable, but as was said before, it is sometimes an exceedingly useful kink.

Where heavy work has to be turned end for end in a lathe, a turntable similar to the one shown in Fig. 9 is sometimes used. This kind of turntable is quite common in railroad shops, but it is seldom seen in other shops, even where it could be used to advantage.

The method of grinding the hardened foot-stock centers may be of interest, as it is done differently in some shops. Here the center is held as in Fig. 10, and the point ground; then using a male and female center, as in Fig. 11, the body is

16 is shown the complete set of tools used. By closely examining these engravings, several interesting things may be noted. In the first place, all tools are driven from the drill-press spindle by the universal-jointed shank and socket shown. Then it will be seen that each tool whether drill, cutter or reamer, has its individual bushing which is kept from turning in the permanent jig-bushing, by a pin set in below the shoulder which fits into a notch in the latter; then, too, the long boring-bars *B*, *C*, *D* and *E*, have keyways running the full length of the pilots for the purpose of engaging keys set into the pilot guide bushings in the jig. These bushings are flanged, and set into another bushing in the jig, in such

a way as to be free to revolve with the boring-bar, instead of having the pilot revolve in it which prevents chips or dirt getting in and scoring the pilot, as usual. The flanges on the inner or guide-bushing keep all dirt from between it and the outer or bearing-bushing, and give long life to both bushings and boring-bars.

in Fig. 15. This jig is made to slide back and forth, in order to bring the work in the proper position under the tool, by means of the hand lever A. This lever is made long so as to project through an opening in a sheet iron drum that is placed on the drill press table, around the jig, to keep the soap water that is used from spattering all over the shop.

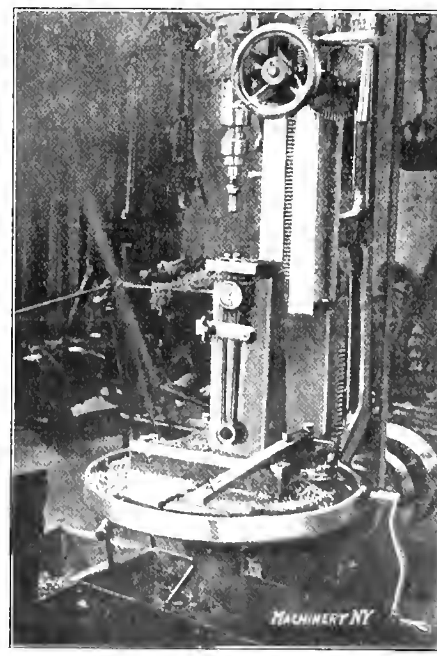

Fig. 15. Jig for Holding Connecting-rods

Fig. 16 Tools used for Machining Lathe Aprons

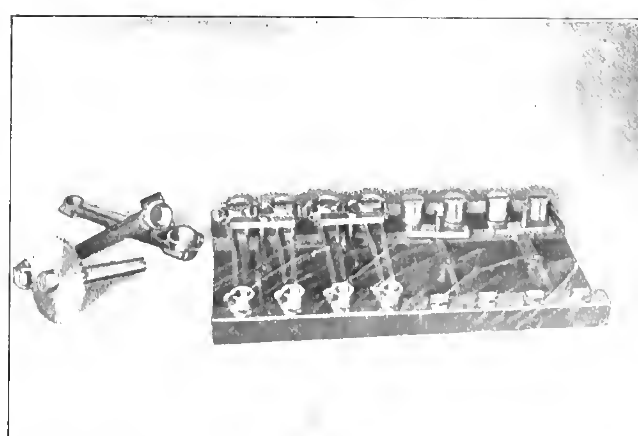

Fig. 17 Fixture in which Connecting-rod Bearings are cut off

During the recent dull season, in order to keep their regular force at work, a contract was taken for the machining of a large number of automobile engine parts, and two of the jigs used for some of the work on connecting-rods are worth describing. These rods and bearing-boxes are cast in one piece, and after the bearings are bored out, the work is put in a jig and the holes in the large end for the oil hole and cap screws, are drilled, counterbored, and tapped as shown

After the holes are finished, the connecting-rods are placed eight at a time in the jig shown in Fig. 17, and the bearing caps sawed off in a milling machine, using the saw shown

In Fig. 18 is a front view of a small hand-operated graduating machine, with the part A of a compound rest in place, and the tool B just finishing a cut, and in Fig. 19 is a rear view, showing the way the machine is geared and operated. The indexing or dividing ratchet wheel and dog is shown

at C, and a cam-wheel with four even and one high rise at D. This cam-wheel gives the tool its four short strokes and one long one, which is the usual motion.

In the planing department, there are a number of "clapper-box" tools such as shown in Fig. 20, used for side cutting on the planer. The two large ones, made right and left, have a little plunger and spring with a crosspiece A, which may be turned lengthwise of the clapper to allow the tool to be drawn back out of the way if necessary, but it is turned crosswise when the tool is in use, in order to draw the clapper and tool back into position at the end of the reverse stroke. Several other forms of tool holders, which need no explanation, are shown in Fig. 21.

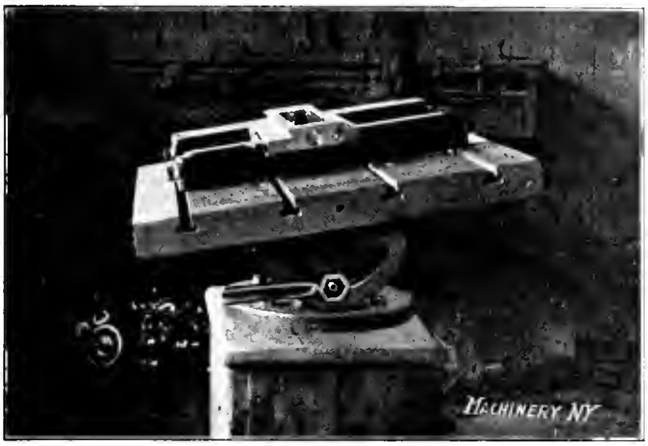

Fig. 26. Adjustable Table for Holding Lathe Carriages or Other Parts while Scraping and Fitting

A jig for holding ten top-slides for lathe compound rests, while planing the bottoms, is shown in Fig. 22, and in Fig. 23, is a combination-jig for holding grinder knees. The illustration shows two in position, but this is only done to show how they are held for the two planing operations, only one, of course, being planed at a time. Fig. 24 shows how gibs are planed, seven at a time, being held by pins inserted in holes drilled in the ends. Lathe carriages are lined up for the planing of the cross-ways, by being laid on the pieces A shown in Fig. 25. In order to get these pieces absolutely at right-angles to the travel of the planer table, the device B is used. This is simply laid on one of the pieces A as shown, and then tested by a dial indicator placed in the tool-holder. When the indicator reads the same for the entire length of B, the cross-piece A is tightened down, and the next one tested. A very handy iron table used to hold carriages or other parts while scraping and fitting is shown in Fig. 26.

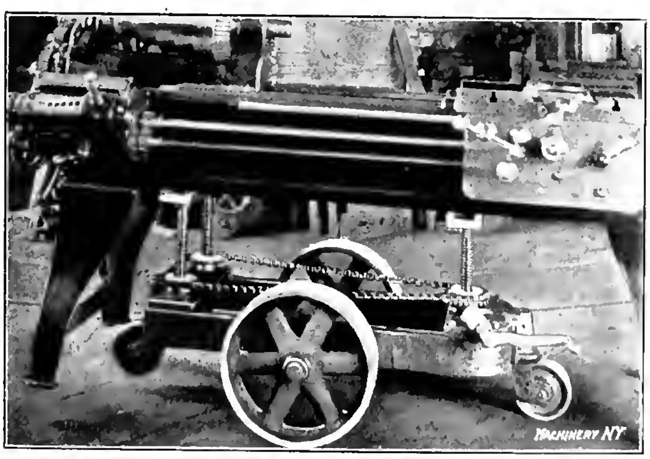

Fig. 27. An Elevating Truck for Raising and Moving Lathes

Every shop foreman knows what a nuisance the starting and stopping of an emery wheel is and how apt a man is to leave it running when he is through with it. The LeBlond shop had the usual trouble and so the arrangement shown in Fig. 28 was put on. As the man steps on platform A, the belt is shifted over and the wheel starts, and as soon as he steps off, the weight B pulls the belt over onto the loose pulley and stops the wheel.

Fig. 27 shows the ingenious truck used to move lathes around, the construction of which can be seen at a glance.

BIG GUN MAKING IN A NUT SHELL

This is how big guns are built at Elswick according to a clipping from *Pearson's Weekly*, a popular British journal, sent to us by a valued contributor. The account is graphic, but, though somewhat lacking in detail, it probably passes muster as the "real thing" with the class of readers to whom such "fluffy" literature appeals:

"Red hot steel ingots are forced into a rough cylindrical shape, either by the pounding of steam-hammers (some of them can give a blow of 700 tons), or by hydraulic presses. The largest of the latter gives a pressure of nearly 6,000 tons.

"Now that the rough forging has been made it has to be tested, and this is a critical part of the process: A few pieces are cut off from the main forging, heated in oil at a temperature of about 1,500 degrees F. and fixed firmly in iron jaws. Hydraulic pressure now tries to tear each lump in two, the strain sometimes rising to 46 tons on each square inch. If all the sample pieces stand the test, the forging is held good enough to make a gun. If not, another forging is made.

"If the test is satisfactory the rough pillar of steel is now 'rough-bored' inside and 'turned' on the outside. Then it is hardened by being dipped into a bath of hot oil; then bored and turned again till smooth; then annealed, or allowed to cool slowly from a high temperature; then it is 'fine bored' and 'fine-turned.' The next process is that of testing the surface. It is tested both chemically and by mirrors.

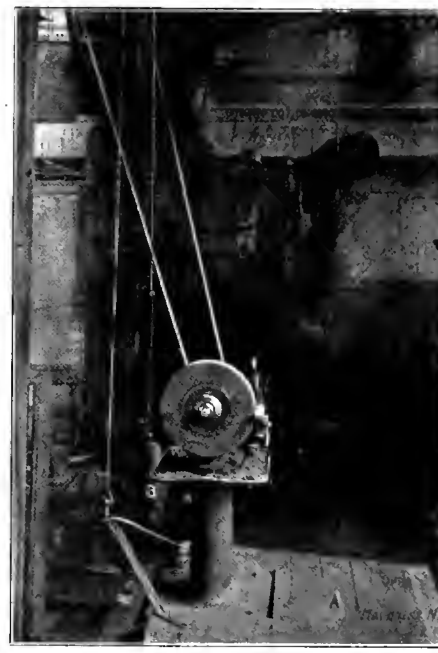

Fig. 28. Automatic Emery Wheel Belt-shifter

"The gun is now well into shape, but it needs strengthening. A deep pit is dug, and the gun set upright in it. Red-hot hoops of steel are dropped on from on top. As they cool they tighten. After each layer of hoops the gun is planed by a lathe to make it smooth for the next layer.

"Now the inside is rifled or grooved like a screw. When the powder chamber has been bored out and the breech-block fitted, the gun is nearly ready for its trials. The Elswick big guns are tested near Silloth, on the flat and lonely shores of the Solway Firth."

* * *

A remarkable high-speed run of regular passenger trains is being made by the Great Western Railway of England, in connection with transporting the passengers of the Cunard liners from Fishguard to London. The total distance from Fishguard to London is 261 miles, a distance which was covered, on August 30, in 268 minutes by the special mail train, and 276 minutes by a passenger train consisting of ten cars, and weighing 274 tons. The first part of the run is a difficult one, owing to heavy grades, including one, over a mile in length, of 1 in 50. The latter part of the run, however, presents more favorable conditions and the run from Carmarthen to London, a distance of 230 miles, was made in 228 minutes, including a stop of four minutes. At one section 75 miles were actually covered in 60 minutes, and 100 miles were covered in 83 minutes 19 seconds, a remarkable performance with so heavy a load behind the tender. The locomotive pulling the train was a four-cylinder, non-compound, six-wheel coupled engine weighing $75\frac{1}{2}$ tons, cylinders $14\frac{1}{4}$ by 26 inches, working pressure 225 pounds, and with driving wheels $80\frac{1}{2}$ inches in diameter.

AN ELECTRIC SURFACE GAGE

GEO. J. MURDOCK*

Geo. J. Murdock†

The purpose of the electric surface gage is to obtain aural as well as visual evidence of the truth of a plane surface. There are places on many classes of work, such as jigs, where it is difficult to see whether or to what extent the surface is out of truth, with the common surface gage. This is notable where there is an overhanging projection so close to the surface plate that it is impossible to look under. In dark weather it is very trying on the eyes to see whether the fine point of the needle touches the work or to what extent it does not. The electric current will communicate an audible signal when the needle comes in contact with the work, when under the most favorable circumstances such contact cannot be seen with the eye. This surface gage can also be used for many purposes for which the usual type is comparatively useless; for instance in truing up work on the face-plate or in a chuck, concentric with the axis of the lathe spindle, or for ascertaining the truth of a shaft between centers in the lathe or an arbor in the same position. When the pointer makes contact with the work, the electric current will speak to the brain through the ear where the eye cannot see.

Fig. 1 shows a side elevation of this gage. Its general design is similar to that of the gages in common use. The

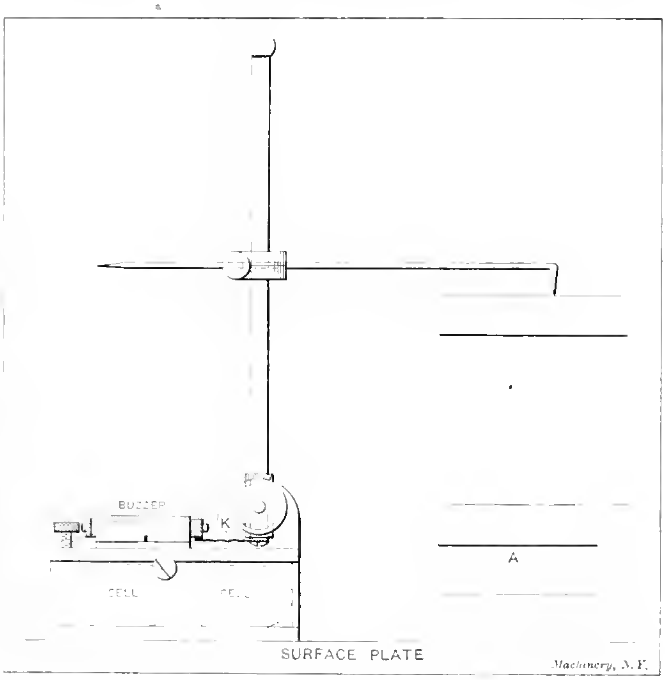

Fig. 1. Surface Gage equipped with Electrical Apparatus for Producing Sound when the Pointer is in Contact

base is cast with a recess in the bottom in which lie on their sides, two small dry cell batteries known as "Ever Ready" No. 650. This cell is 1¼ x ⅝ x 2 inches, and is especially adapted for this work. The ends of the cells are shown in Fig. 1 by dotted lines. On the top of the base is a small buzzer known as a midget, which is noisy enough for the purpose and which occupies but a small space. The positive and negative terminals of the cells are soldered together as shown in Fig. 3. The cells are then inserted in the base so that only the terminal G of the battery comes in contact with the metal of which the base is composed. The other terminal is passed up through a hard rubber bushing H (Fig. 4), and connected by a wire J to one binding post of the buzzer. The other binding post is connected to the insulated needle-bar by the wire K which is rolled up on a small wire so as to give it a coil. After it is coiled it is well to dip it in shellac varnish so that the current cannot short circuit through an accidental contact by the wire with the top of the base. It will now be seen that the circuit has two terminals, one being the base, and the other the needle point; consequently, whenever the point of the needle comes into contact with the work being tested, the current will pass through the work to the surface plate, and thence back through the base of the gage to the terminal G of the battery which is in contact with the inside of the base. Whenever the current passes through this circuit it energizes the magnets in the buzzer and causes it to

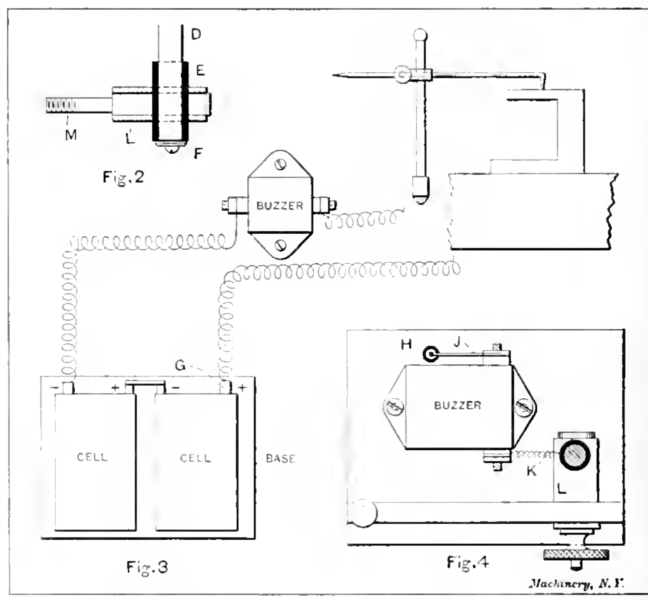

Fig. 2. Diagram showing Electrical Connections and Plan of Gage

give out a clear sound that can be heard several feet away. The moment the needle point passes to a low point on the surface of the work, the contact is electrically broken and the buzzer ceases to sound. At E, Fig. 2, is shown the hard rubber sleeve that insulates the needle-bar D from the base L. The usual form of binding device is used, of which the threaded stem M is a part. It is well to have a small shoulder on E so that the bar cannot slide down and make contact with the base of the tool, in which case it would run the battery down. It will be seen that no switch is required, as the circuit can only be closed through the needle-bar and needle.

The buzzer is secured to the top of the base by two screws, one at each end, and it does not require insulating from the base, as the binding posts are insulated at both terminals from the enclosing case. In trying the truth of a surface, as at A in Fig. 1, the foot of the work would be set up on parallels and the needle inverted with its point up; it can then be placed under this surface and indications taken in a location that would be difficult or perhaps impossible to see. For work in the lathe, the base of the gage can be set on the tool-post foot, and when the point of the gage strikes the work, no matter how lightly, the current will pass through the work in the chuck or on the face-plate to the lathe spindle, shears, and thence back through the tool-post foot and to the base of the gage, ringing the buzzer as the result, and the work can be trued accordingly. The same happens when an arbor is between the lathe centers, and no matter how fast it runs, the buzzer will sound when the point touches, when it is impossible for the eye to see it touch.

After the cells are inserted in the base, a metal bottom should be fitted so that they cannot drop out, and the work should be done so they cannot shake around in the base. It is also advisable not to leave the point of the needle long on the work as it runs the batteries down uselessly; but for all ordinary requirements they will last a very long time if a little care in this respect is taken.

* Address: 33 Wallace Place, Newark, N. J.

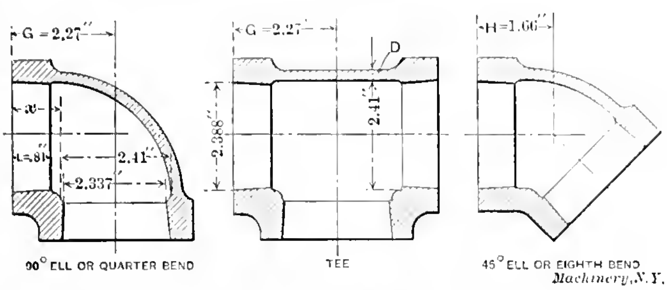
† George J. Murdock was born in New Berlin, New York, 1858, and received an academic and engineering education. He has been employed by the Hall Signal Co., New York; Western Instrument Co., Newark, N. J.; Manhattan Typewriter Co., Newark, N. J.; Sloan & Chase Mfg. Co., Newark, N. J., in the capacity of foreman, tool-maker, draftsman, foreman of instrument finishing work, etc. At present he is practicing engineering on his own account, making a specialty of instrument and precision tool work.

PIPE FITTINGS—THEORY VS. PRACTICE IN THEIR MANUFACTURE

F. W. BARROWS*

If I were asked what determines the thickness of ordinary, screwed pipe fittings, I should reply that the market price is now the final and controlling authority, all other essentials having long been dominated by this price; the weight being the conclusive test of merit. In theory the fitting should be strong enough to resist the internal pressure to which it may be subjected either by the fluid it is to convey or by the piper in "making up"; and the fittings now in the market have been proved, by numerous tests, to be not only strong enough to resist these internal strains, but have also successfully withstood the strains caused by changes of temperature, and by failure to "line up."

Using the formula $p = \frac{St}{r}$, in which p represents pressure; S, ultimate strength; t, thickness; and r, inner radius, and by substituting the values for ¾-inch gray iron fitting found in



Two inch fittings for 100 pounds pressure, proportioned according to MACHINERY's Data Sheet for June, 1905.
E (outside diameter of body) = 2.85 inches and tap diameter (outside at end) = 2.337 inches.
$E - 2D = 2.41$ inches or inside diameter of fitting, and $\frac{2.41 - 2.337}{2} = .0365$ inch clearance for tap.
$G - \frac{2.41}{2} = 1.065$ inch or X, and $X - L = .255$ inch, which is the clearance for the run of the machine or for making up. (Approximately three threads.)

Fig. 1. Sectional Views of Gray Iron Fittings illustrating Clearance for Threading and "Making Up"

the Data Sheet for June, 1905, giving dimensions for fittings to withstand 100 pounds pressure; p (bursting strain) $= \frac{20{,}000 \times 0.15}{0.55} = 5{,}454$. This product divided by 100, the pressure for which such fittings are guaranteed, gives a safety factor of 54.54. Through stress of circumstances, a line of ¾-inch piping, connecting a testing pump with its work, which was to be tested to 1,000 pounds, was made up with ordinary (100-pound pressure) gray iron fittings and brass check valves; and so well did it stand this extreme (water) pressure, that it was continued in use for some years. The pump used was a lever hand pump and the efforts to keep the pressure above 1,000 for the time considered necessary for inspection, caused the gage to show at times as high as 1,500 pounds.

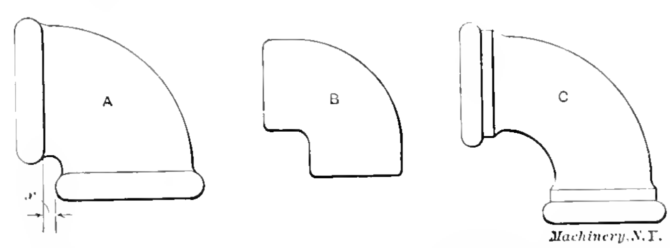
Taking t and r from the same list for 2-inch fitting, $p = \frac{20{,}000 \times 0.22}{1.205} =$ bursting strain of 3,731 (nearly), which would give, for this fitting, a safety factor of 37.34. This is without doubt a safe thickness.

Bronze (commonly called brass) fittings are usually made of yellow brass, which, strictly speaking, is not a bronze because it contains zinc, and for which the value of S may be safely taken (even for the miserable stuff used in "Rf" brass fittings) at 18,000; and t, as the patterns have an allowance for finishing, may be set down at 0.19. Substituting these values, the formula now reads: $p = \frac{18{,}000 \times 0.19}{1.205}$, which gives the bursting strain at 2,838, and a safety factor of 28.38 for this fitting, which factor, though less than that for the iron fitting, is still great enough for safety.

A line of six-inch piping, supplying steam from a boiler (gage pressure, 100) to an engine, ran along the ceiling and was connected, through a 90 degree elbow and a vertical pipe some eight feet long, to the engine. In the horizontal pipe there was an expansion joint of the ordinary, sliding type, and through somebody's oversight, this piping was used for several days without any stop for the expansion joint other than the rigidity of the elbow connecting the vertical to the horizontal piping. No accident occurred.

For 6-inch fitting, $p = \frac{20{,}000 \times 0.42}{3.41} = 2458$, giving a factor of 24.58 for safety. With the same factor as for 2-inch, this fitting would have been 50 per cent thicker and the 12-inch, with the 2-inch factor, would be nearly twice as thick as shown on the Data Sheet referred to in the foregoing. For a 6-inch bronze fitting, if designed on the theory that a 2-inch fitting is a good standard to base calculations on, the thickness of body would have been from 50 to 100 per cent (as the value of S might be varied to suit different mixtures) more than "good practice" calls for. Some exception may be taken to the stated value of S for the brass fittings, but in my opinion it is placed quite high enough when taking into consideration the large amount of poor scrap that is commonly used, and the shiftless methods of melting and pouring allowed in some foundrys, through either inefficiency or carelessness.

To go back again to the common practice, a little further consideration of what might be called the necessary attributes of a good fitting, will show that the fixing of the weight has also fixed, within very small limits, the thickness; which term as applied to fittings, means the thickness of body between thread bosses. The weight should be properly distributed in the length, and in the diameter of the ends, which must successfully resist the strain of making up. The length



A—Beaded brass ell with long ends, with clearance for tool at "x" to machine beads, and large fillets between bead and body that fitting may be readily finished all over by strapping, as is often required.
B—Malleable iron ell without bands or beads, known as a gas fitting. Because of their uniform thickness these castings are more easily made sound—a very good feature of this fitting.
C—Gray iron longturn or water fitting. This fitting, because of its long, easy curves (a prominent feature in all its different forms), is well adapted for piping intended to convey liquids.

Fig. 2. Types of Common Fittings

must be such as to permit a suitable length of thread and also room for tapping without any danger of the taps striking together at the end of the run, or of the piper's being able to screw the pipes in until they meet. The threaded ends and the tapped holes vary in size, and the piper is usually a strenuous individual who may be relied upon to accomplish this if possible. Then there remains a certain amount of metal which may be divided between the length of end bands and thickness of body, the inner diameter of which, fixed by the pipe size, is usually made slightly larger than the outside of the pipe to prevent any shoulder being formed in tapping.

One may vary the diameter of the ends, but after having become acquainted with the aforesaid piper and his trusty "Stilson," the inclination will be to increase this diameter, even at the expense of body thickness. Again, when one has once learned how easy it is to crack a cast iron tee or ell through the "corners," there will be a still greater inclination to enlarge the ends of new fittings. The beaded fitting is probably the best form for resisting this making-up strain, and most brass fittings are made in this form, but the beaded, gray iron fitting does not seem to suit the trade.

If the foundry is to produce good sound castings, at the minimum cost, the change of thickness where the tapping boss and the band join the body, must not be too abrupt, a requirement which will keep the end size down and thus limit the amount of metal which can profitably be used in strengthening the ends. Another reason for not reducing the end size—for small fittings especially—is found in the practice followed

* Address: 581 Colorado Ave., Bridgeport, Conn.

by nearly all manufacturers, of tapping these smaller sizes with straight taps—thus bringing the strain of making up more exactly at the end of the fitting. Some makers claim that small fittings tapped in this way are just as good as the others. The smaller sizes of pipe show up rather badly; Briggs' standard gives a good length of thread, nicely tapered, which allows for quite a variation in size of the tapped hole, but requires, for a solid die, too much thickness of stock: at least this seems to be the verdict of those who make solid dies, as they are, almost without exception, made too thin. (Can this be another question of cost?) The dies are also often made with greater taper than Briggs' standard in order that the thin die may cover as much variation in size as the standard does, and even if the fittings were tapped taper, the pipe cut with the commercial die wouldn't fit. It may be that the claim "just as good"—for straight taps—should be allowed to stand.

The thickness of the body may be increased by shortening the bands, but if carried to extremes, this would hurt the appearance of the banded fitting. The net weight may be increased by using cheaper material, but this would not *improve* the goods, and the quality, fixed by the ever-present need of keeping down the labor cost, is now about as poor as it can well be. Iron fittings must be soft, and brass fittings must be of a mixture which will cut smoothly, in order that the cost of tapping may not be increased by spoiled work. Labor cost saved by improved facilities, is frequently expended in increasing the weight, and thus causing greater sales. Some customers may demand that the material used show a certain tensile strength; this would, in most cases, mean better material, and the customer expects to, and does, pay a better price. Again he may require that they be tested up to some stated pressure, which would raise the price by causing the rejection of some pieces, not for lack of strength, but because of holes through the castings. If the test is made by water pressure, the fittings unable to stand the test at first will often be found, upon testing again after some hours, to be perfectly tight; the holes, too small to be seen until located by the test, after the first wetting, are soon closed by rust. Natural gas fittings are often tested to 1,000 pounds, and, to prevent leakage through the casting, they are boiled for hours in paraffine.

In brief, the qualities demanded by the trade have placed the ordinary fittings far above any theoretical strength, and the efforts to improve these fittings tend, not to change the weight, but rather to a better distribution of the metal, so that when the new fitting is placed on the market, the first and final question, deciding its success or failure, will be: "What does it weigh?"

* * *

The Patent Office issued 33,514 patents in 1908, and registered 6,029 trade-marks, labels and prints; 22,328 patents expired during the year. The total receipts were $1,896,848 and the expenditures $1,712,303. On January 1, 1909, the Patent Office had a balance to its credit of $6,890,726. The work on that date was current, except in five examining divisions out of 49, and those five have caught up with their work since then. Special attention is being directed to the classification of the 915,000 United States patents, the 2,000,000 foreign patents, and the 85,000 volumes in the library, which is expected to reduce the expense of examining applications by one-third, and to improve the character of the work. Commissioner Moore has requested Congress to use a part of the surplus earned by the Patent Office for the erection of a building suitable for its needs.

* * *

A sensation was created in marine circles by the announcement that the Curtiss steam turbines in the Southern Pacific liner *Creole*, built for the New York and New Orleans service, are to be taken out and reciprocating engines installed in their place. It is claimed that the vessel has not operated satisfactorily; her coal consumption is said to be excessive, 2,000 tons being required for the round trip between New York and New Orleans. The contract with the Fall River Shipbuilding & Engine Co., which built the vessel and turbines, called for a speed of sixteen knots an hour on a fixed maximum coal consumption. The vessel cost about $1,000,000.

MACHINERY'S DATA SHEETS—A WAY TO USE THEM

W. A. WARMAN*

I have preserved and used MACHINERY'S Data Sheets since their inception, and I shall offer a few suggestions from my experience concerning a method of filing them. Binding these sheets is unsatisfactory, as the index is never up-to-date. Again, few if any shops have occasion to refer to all the sheets, and dead material is undesirable, especially if it encumbers live stuff.

The most satisfactory arrangement I have found is that illustrated herewith. This is what is known as a transfer case for the open filing system. It consists of a box 5 by 8 by $10\frac{1}{4}$ inches, with a cover opening part way down each side, making it very easy and convenient to handle the sheets. The folders shown are made of heavy manila paper with a tab on one side. For convenience, these tabs are staggered. The folders can be made with three or five tabs if desired. The guide cards, with white tabs, are of heavy binder board. As shown in the illustration, the tabs are located on the guide

Filing Case for Machinery's Data Sheets

cards so that four extend across the filing case. Those on the folders are wider, being about one-third the width of the case.

The operation of the system is as follows: Divide the box into subjects with the guide cards, and subdivide the subjects with the folders. For instance, when filing the data on gears, mark a guide card *gears*. Then mark a folder *bevel*, one *miter*, one *spiral*, one *spur*, one *worm*, etc. The sub-classifications may be carried to any extent required for convenience. By this method the indexing is done once only, and the index is always up-to-date. The data pertaining to a class of any subject are in a folder convenient to handle, and fresh material is so easily added that special tables and data pertaining to one's own line may be made on standard size sheets, and inserted in the folders. Such sheets greatly increase the value of the outfit as a time saver.

MACHINE SCREW TAP AND BODY DRILL SIZES

Size	Threads per inch	Body Drill	Tap Drill	Size	Threads per inch	Body Drill	Tap Drill
2	56	43	48	8	32	18	28
3	48	38	44	10	32	9	20
4	46	32	41	12	24	I	15
5	40	30	36	14	20	c	10
6	32	28	33	14	24	c	6

I had a set of sheets shellaced for use in the shop. The shellac keeps them quite clean and they can be washed when soiled. After using the shellac, I found that celluloid lacquer was much easier to use. It may be applied directly to the sheets, while to avoid discoloration, they must be sized before shellacing.

As to the Data Sheets, most all that we have used have been very satisfactory. The only one on which I would suggest a change would be the tap drill list for machine screw taps. The list given herewith is very near for average machine shop work. It is certainly healthier for taps than the

* Address: Keller Mechanical Engraving Co., 570 West Broadway, New York.

list given on Data Sheet Number 2. To devise a tap drill list with which an amateur cannot go wrong, would be an almost impossible task; so many factors need to be considered in determining the drill size that will give the best result. I do not see how any table of sizes for small taps can be used without variation, as conditions vary. The best one can do is to compromise.

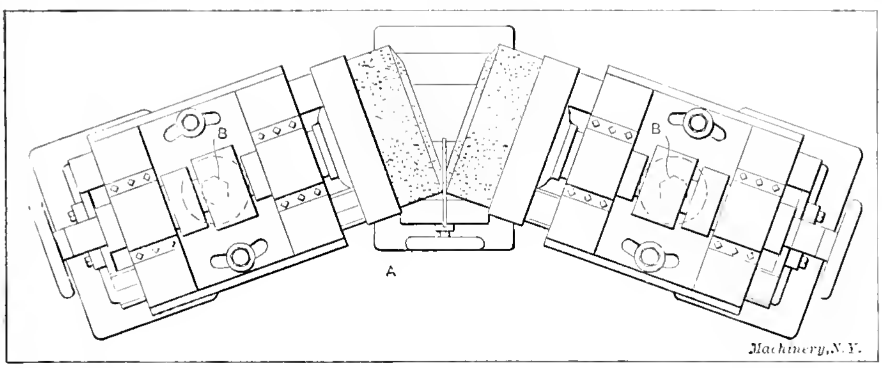
If a screw has little to do, what is the use of taking a chance of breaking a tap by forcing it to cut a full thread? The kind of materials must always cut a large figure in determining drill sizes.

* * *

GRINDING MACHINE FOR SKATES, ETC.

A machine that will grind metal bars on both sides simultaneously has been patented by Chetwood Smith of Worcester, Mass. (U. S. patent No. 930,626, Aug. 10, 1909). His machine is particularly adapted for grinding the blades of skates or in the formation of tools where the sides are to be tapered or ground on a curve.

Mr. Smith found that for successful operation, the axes of the grinding wheels should be at an angle to each other, as shown in the engraving, which is a plan view of his machine. The wheels are cup-shaped and beveled at their working edges to present frusto-conical grinding faces. The axes of the wheels are set at such an angle that the adjacent portions of the grinding faces are substantially parallel when the wheels are employed to grind the blade, the blade being supported on a rest which is made vertically adjustable by the hand-wheel *A*.



Grinding Machine for Skates and Other Parts Finished Simultaneously on Both Sides

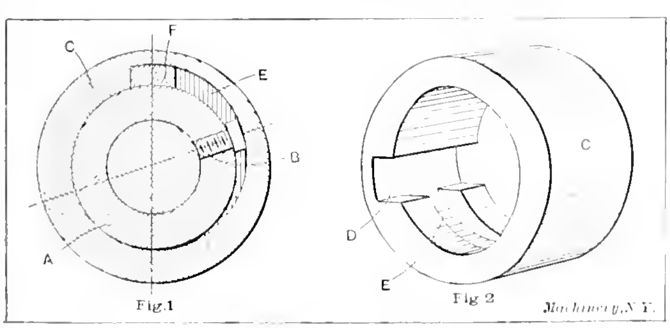
Each carriage has at its under side below the stud *B* a threaded boss and screw with a hand-wheel, which adjusts the carriage longitudinally of the base of the frame, thus adapting the grinding faces of the wheels to the thickness of the work or compensating for the wear of the grinders.

* * *

SET COLLAR FOR SHAFTS

A set collar with an effective retaining means, whereby the danger of its becoming loosened upon the shaft is eliminated, was patented by Israel W. Exley of Colville, Washington. (U. S. patent No. 930,169, Aug. 3, 1909.)

Fig. 1 is a cross-section of the assembled device and Fig. 2 is a perspective view of the locking collar.



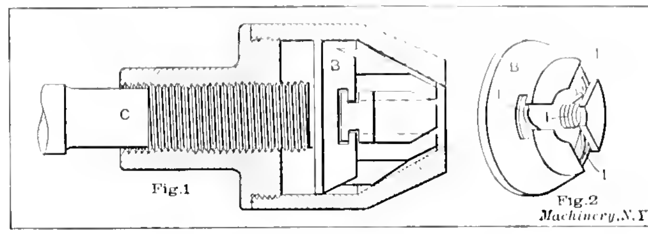
Set Collar for Shafts with Protector for Screw Head

After collar *A* is fastened upon the shaft by the retaining element *B*, collar *C* is slipped over it, the longitudinal opening *D* in the latter coming over the projecting head of *B*. The collar is rotated, bringing the head within the annular passage *E*, which has walls diminishing from its point of connection with the surface of the longitudinal passage. A wedge *F* is then inserted in *D*, and the collars *A* and *C* are thus securely locked upon each other, and the retaining element *B* effectively locked and held in position on the shaft.

* * *

DRILL CHUCK

Thomas J. Fegley and George O. Leopold in U. S. patent No. 932,259 (Aug. 24, 1909), assigned to North Bros. Mfg. Co., Philadelphia, Pa., describe a simple and cheap chuck that will readily and firmly grasp a drill or other tool. A longitudinal section is shown in Fig. 1 and a perspective view of one of the jaws in Fig. 2.



Drill Chuck with Radially-acting Jaws

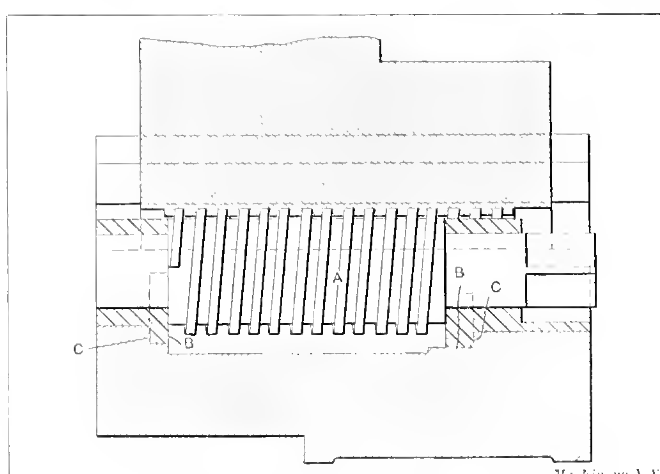
The operation of the chuck is as follows. On screwing the stem *C* into the shell, the disk *B* is forced toward the conical portion of the shell, which, in turn, forces the jaws toward each other against the pressure of the springs *I* (Fig. 2), closing the jaws upon the drill inserted in the chuck. By reversing the movement of the shell the jaws are released from pressure and the springs *I* will force them apart.

By making the disk hollow (Fig. 2) and mounting the springs on studs, the springs are held in position even when the chuck is dismantled.

* * *

CHUCK JAW SCREW MOUNTING

In U. S. patent No. 930,075 (Aug. 3, 1909) Albert P. Kern describes an improved mounting for the radially adjustable jaws of a chuck, which he has assigned to the Cincinnati Chuck Co., Cincinnati, O. The engraving is a section of one of the jaws, showing the operating screw *A*, and the sleeves Mr. Kern uses for bearings. The sleeves are of hardened steel, each having a flange *B* engaging against the shoulder *C* of the body to prevent the sleeve from being radially displaced in its seat. Preferably the outer sleeve has a portion of its periphery cut away for providing clearance for the sliding jaw. The ends of the screws are thus given a hard steel bearing in the radial slot, so the greatest possible efficiency may be derived.



Hardened Chuck Jaw Screw Mounting

Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

NOVEMBER, 1909

PAID CIRCULATION FOR OCTOBER, 1909, 21,196 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

INDEX FOR VOLUME XV

MACHINERY was started September, 1894, the first volume containing only 192 reading pages and about the same amount of advertising. The fifteenth volume contains 1,000 reading pages and more than double that number of advertising pages. While the growth of MACHINERY has been somewhat unusual in the history of trade publications, it measures quite accurately the growth of the machine tool and kindred industries which the publication represents.

The index for Volume XV, engineering edition, comprises over 4,000 references and fills seventeen pages, type size slightly larger than the regular MACHINERY page, set in six-point, four columns to the page. Copies of the index of the engineering, railway or shop edition will be sent to subscribers on request.

* * *

PROGRESS IN SAFEGUARDING MACHINERY

The promoters of the national movement for providing safeguards for the dangerous parts of machinery to prevent the many distressing accidents to life and limb, should be gratified by the material improvement in this detail noticeable in machine design in the past two or three years. Comparatively few builders of engine lathes, for example, now neglect to cover the back gears and other gears with guards. The appearance of the lathe is improved, and a potential danger to the fingers of the operator is removed.

Purchasers of machine tools can materially accelerate the movement by insisting that all danger points be safeguarded. There is scarcely ever a good reason why gears should not be covered. A pair of spur gears is about the wickedest combination for mutilating fingers that can be conceived of; why should they be left uncovered when so dangerous? The proper shielding of all moving parts that can be covered without interfering with the function of the machine is essentially the designer's duty, and it should never be done as an afterthought when avoidable. This costs less in the original design with which it can be made harmonious, and what is most important, the guards integral with the machine cannot be readily removed by the workmen. Many machines have been wrecked or put out of commission for several days by having clothing or tools accidentally drawn between the gears, resulting in bending the shafts and even breaking the frames. By all means provide gearing with suitable covers, harmonious with the general outline of the machine. This remark is addressed to the designer.

* * *

LEARN TO DRAW

Every machinist who aspires to advance himself in his trade should learn mechanical drawing, or its rudiments, at least, so that he can make an accurate, understandable sketch. Drawing is a universal language, and the mechanic who cannot read drawings or blue-prints is not of much account nowadays. Picture writing is the earliest known form of written language, and the easiest understood. It is so comprehensive and simple that the most intricate ideas are made clear even to a child who perhaps cannot read. A sketch tells much that cannot be imparted by word of mouth. We never lose our wonder at the miracle and mystery of the repeated line—the repetition of the straight and curved that is the substance of all delineation.

A machinist would be ashamed to acknowledge that he could not read or write, and he should consider that he is equally at fault in his mechanical training if he cannot draw and read mechanical drawings. Drawing is an exceedingly useful accomplishment to a man who has to direct the activities of his shop mates. He can save time and convey clear ideas by resorting to sketches. The record can be made permanent, and is often a convenient reference long after it was made. The man who can make an accurate sketch of a machine part or a mechanism must have an accurate mental picture of it, and that means clear thinking. One great difference in men that makes some leaders and others followers is the respective capacity for thinking. The mere act of drawing accurately will stimulate mental activity wonderfully. It will usually make the individual study to understand things that in his conceit he believed he fully understood before. Drawing in this respect is akin to writing for the press. A man never realizes how little he actually knows of a process, method, or mechanism until he tries to describe it accurately in written words.

CATALOGUE FILING FOR SMALL CONCERNS

Every concern, large or small, that receives many catalogues listing machinery and other products likely to be useful in its business, should have some systematic method of filing them for ready reference. The average proprietor of a small shop probably will say that it is all right for the big concern to provide a catalogue file but, when you are superintendent, foreman, business manager and office boy all in one, there is mighty little time left for such fol-de-rol. Doubtless there is not much time left for systematic effort in the poorly managed business, but the time wasted in looking through a heap of papers for a catalogue that is dimly remembered and badly wanted will, if rightly directed, more than suffice for properly filing catalogues and price lists so that they can be readily found.

A simple and cheap method of caring for advertising literature is in use in the editorial department of MACHINERY that is recommended to those particularly who cannot afford a more elaborate system. First, a number of ordinary letter files was provided that cost at retail 25 cents each. These files were numbered on the back, beginning with 1 and filled with the catalogues on hand. Each catalogue put in No. 1 file has the number 1 written or pasted on its cover and those put in No. 2 file are marked 2, and so on. The obvious purpose of these numbers is to facilitate replacement in the proper file when removed. The date of receipt of all circulars and other advertising literature is written on them, thus 9/28/09. A card index of 3 x 5 cards is compiled, each concern represented having a card on which is written the number of the file in which its catalogue is stored.

Catalogues are filed as received, filling the new boxes without regard to matter on hand except when new literature from concerns already indexed is received, then the new matter is put in the old box and no change in the cards is made. No attempt is made to file in alphabetical order, but a small concern could preserve the alphabetical order without great trouble, and in that case the card index would not be necessary.

Another means for avoiding the cards is a list of the concerns represented in each file pasted on the back of the files. The common letter files are 10 x 11½ inches inside, and will store the average size catalogues easily, and if a little care is taken each file can be so filled as to leave very little waste space.

* * *

LIGHT AERONAUTIC MOTORS

The aeroplane has been aptly typified as "an engine with wings," meaning that the motor is the heart and substance of the heavier-than-air flying machine. No other vehicle is so dependent on its motive power: A motor boat will still float if its engine is disabled; an automobile may be run off by the side of the road and left until the repair man can be called; a motor-cycle can be propelled by foot power; but the aeroplane must at once leave its element and negotiate the best landing place available when the engine stops. A dependable motor is so necessary to the success of the flying machine that we are forced to conclude that until it has been developed into a perfected state the aeroplane will remain little more than a dangerous toy for a few bold experimenters to risk their lives in.

In the race to develop aeronautic motors that will fly, the effort has been made to excel in lightness of construction, and some of the resulting motors have been marvels of power per unit of weight. It now appears, in the light of experience, that the sacrifice of dependability to mere lightness has defeated the object of making a motor that will certainly fly. It is not sufficient that the engine be made so light and powerful that it can easily raise itself; it is of equal or greater importance that it continue in flight and develop full power so long as the operator desires and the fuel supply holds out. One flying machine experimenter says: "Three different types of light-weight aeronautic motors experimented with have proved more than unsatisfactory. While the machine easily flies and rises with each of these motors, none can be depended on to stand the strain of continued operation. This experience forced me to consider the building of a new motive power, meeting more efficiently the requirements of the new art. The manufacturers of the present-day light motor, in an endeavor to lighten the engine, lose sight entirely of the real function of the motor. In an aeroplane, continued, ever-ready and dependable power is more important than in an automobile for a hundred and one reasons."

The experiments of the Wright brothers indicate that very light or very powerful motors are not absolutely necessary. In the official test at Fort Myer, Orville Wright lifted and carried 1,300 pounds with an engine rated at less than 24 horse-power, at a speed of about 45 miles an hour. Comparing this with the Curtiss record at Rheims, France, in August this year (see October number) the difference in weight per horse-power is marked. The Curtiss aeroplane, loaded, weighed about 700 pounds and developed 63 horse-power, the weight per horse-power being about 11 pounds, while in the Wright aeroplane it was about 55 pounds per horse-power. The greater area of wing surface in the Wright machine undoubtedly means that less power is required for sustaining the load.

The correlation of power of the engine, the size and speed of the propellers, and the area and shape of wing surfaces to secure the highest efficiency will undoubtedly require many more experiments than have been made by the Wright brothers and others, and probably some strange discoveries will be made in the realm of aerodynamics.

CHAIN MAKING WITHOUT SCRAP

Practically all manufacturing operations are accompanied with more or less waste. The turning of logs into merchantable lumber, for example, is enormously wasteful, not 50 per cent of the cubic contents in the logs appearing in the finished lumber when worked up by the machinery in general use twenty years ago. It is true that considerable improvement has been made in eliminating waste since the advent of band saws and thin resaws that convert a much smaller amount of wood into sawdust than the old circular saws of a generation ago, but even with the highly developed modern wood-working machinery the waste still is large, and in the majority of wood-working operations it must so continue except in the case of veneering. So it is in the milling industry, and all along the manufacturing line with a few notable exceptions.

Machine shop operations consist of turning, planing, drilling, boring and milling, all of which remove metal from where it is not wanted, thus making the finished product by wasting material in chips. Cutting, bending and forming is done in presses, however, with little waste, and some press work has been so highly developed as to eliminate practically all scrap. The article on another page of this number (engineering edition) "Chain Making Extraordinary in a Scrapless Press Room" is a notable example in which the elimination of scrap in an automatically formed product has been carried to the limit. While the process is typical of similar processes for the cold conversion of metals in wire or ribbon form into merchantable products, none we believe has equalled this.

To convert a coil of cold steel ribbon into perfect machinery chain, hardened against wear without a particle of scrap except a trifling scallop at each end of the coil, is a triumph of manufacture, and when it is considered that the product is turned out automatically, and the finished chain is 95 per cent of the length of the steel ribbon, we figuratively take off our hat to the man or men who have made this astonishing feat possible. Remember that the product is not the light plumbers' chain made from thin brass stock, but is machinery chain in sizes from ½ inch to 3 inches wide, and in thickness of 0.045 to 0.250 inch. The large sizes are capable of transmitting heavy power.

That man is called a public benefactor "who makes two blades of grass grow where one grew before," and equal justice requires that we acknowledge our debt to the men who have made scrapless chain, screws, nails, and other useful products possible at a labor cost so low as to be almost negligible.

THE MASSACHUSETTS PLAN FOR INDUSTRIAL INSURANCE

In the August, 1907, issue of MACHINERY, an article was published entitled "Industrial Life Insurance and the Workman." In this article the great waste incident to industrial life insurance, as conducted by the large industrial life insurance companies, was pointed out, and in a short item in the September, 1907, issue mention was made of the law enacted in Massachusetts permitting the savings banks to conduct industrial insurance. It appears that the Massachusetts plan during the two years it has been in operation has proved successful, and many firms and industrial corporations employing great numbers of men have taken active interest in the matter by way of facilitating the spread of information relating to the methods employed by the savings banks. One of the latest large Massachusetts manufacturing corporations to introduce into its plant the plan of savings bank life insurance and old age annuities is the B. F. Sturtevant Co. of Hyde Park, Mass. A savings bank agency has been established within the works, in charge of a person furnished by the savings bank insurance committee of the Boston Chamber of Commerce. As industrial insurance is practically a necessity to the majority of industrial workers, this departure is a very important one, and it is to be expected that this form of insurance will be introduced into other states as well.

Under this system of savings bank life insurance, any savings bank is authorized to establish an insurance department for issuing life insurances, limited to $500 and annuities limited to $200 per year, to residents of Massachusetts. While the amount of insurance in any one savings bank is thus limited, the same person may take out life insurance and annuities in more than one bank. The most important feature of this system of insurance is that the cost is much lower than that charged by the large life insurance companies in the past, notably the Metropolitan of New York and the Prudential of New Jersey. The savings bank industrial insurance is conducted at actual cost, and all profits are returned to the policy holders. The causes of the high cost of the industrial insurance in the large companies has been high managing expenses, which for instance, in the industrial department of the Metropolitan Life Insurance Co. in 1904 were 42.08 per cent of all the premium receipts. In the same year the percentage of managing expenses to the deposits made

during the year in the Massachusetts savings banks was 1.47 per cent. These facts were disclosed during an investigation made in Massachusetts, and as a result of this investigation the law relating to savings bank life insurance was enacted.

Although the general public has not responded as readily to the advantages of life insurance as was expected, the response of the various industrial establishments, where the managements have done considerably towards presenting the advantages of the scheme to the employes, has been satisfactory. A large amount of savings bank insurance has been obtained at the leading shoe factories in Brockton and Haverhill, and at the Fore River Ship Building Co., Quincy, and the United States Shoe Machinery Co., Beverly, Mass. The success has been greatest where the employes are well paid and of an intelligent class. To facilitate making this class of life insurance known to the employes the literature on the subject is usually first distributed in the pay envelopes. After that a trained insurance man from the Boston Chamber of Commerce interviews all the men and women who have shown interest in the subject. The success of the plan has caused considerable interest among manufacturers in other states.

An interesting comparison between the savings bank insurance and that offered by the large industrial life insurance companies is given by the Massachusetts State Actuary in a recent publication, wherein he shows that under this system an old age annuity with the life insurance feature added, costs less than what the working man now pays for his industrial life insurance alone. If a man is twenty-five years old and pays to the savings bank $1.30 each month, and his neighbor of the same age pays $1.35 each month to the insurance company, then the savings bank depositor when he reaches the age of sixty-five will have no more insurance to pay, but will begin to receive an annuity of $100; his neighbor, however, will continue to pay $1.35 each month to the insurance company until he is seventy-five years old, and yet nothing will be paid to him as annuity at any time, but his insurance merely amounts to a given sum payable at death.

Some figures relating to the actual cost of insurance under this system may prove interesting. By paying $1 a month, a man twenty-one years old may secure for himself an annuity of $200 a year, commencing at an age of sixty-five, and continuing throughout life. A man twenty-five years old by paying $1.16 monthly for twenty years may obtain a life insurance of $500. By a payment of eighty-two cents a month for life, he can purchase the same amount of insurance, his family receiving $500 at his death whenever it may occur. Including, as this system does, the annuity plan at an age of sixty or sixty-five years, it is an efficient substitute for the old age pension systems adopted in England and Germany, and instead of making the pensioner a *dependent* for life, this plan makes the man who commences to save a small amount early in life, *independent* in his old age. Under our present industrial conditions the importance of this system can hardly be overestimated.

* * *

An extensive plan for a system of airship lines to be established in France is outlined in *Page's Weekly;* where the capital for permanent structures and equipment is to be had is not explained. In view of the fact that service of this kind can hardly be expected to be financially successful, this most important consideration seems to have been given too little attention. Five airships, it is stated, capable of carrying from eight to twenty passengers besides the crew, will be built, and four lines will be immediately operated. Three stations, it is stated, are practically ready (?), and that of Rheims will be ready within two months. One line will extend northeast from Paris, another southeast to Lyons, another southwest to Orleans, Bordeaux and Pau, and a western line to Rouen. A similar company has been formed in Germany. It is stated by the *Practical Engineer* that the capital is 3,000,000 marks and that two ships are being built by the Zeppelin company, each capable of carrying the necessary crew and twenty passengers, the cost per ship being $140,000. No attempt is made, it is stated, to *estimate the profits*; this seems to be the most sensible part of the venture.

BOARD DROP-HAMMER DESIGN

H. TERHUNE*

About two years ago the writer had occasion to redesign an entire line of drop-forge machinery for a large drop-forge plant in the East, using board drops exclusively. In years past the use of these hammers has been severely (and justly) criticised because of the high cost of upkeep. For some reason the builders of these machines have neglected to keep the design up to the demands put upon the machines. Having been designed mostly for straight work, they often fail when forging four- and six-throw crank-shafts, automobile front axles, or any other kind of work requiring a lot of "break-down" (bending into shape) work.

So serious have been the repair bills on this class of work that many drop-forge plants have adopted the system of using two sets of dies, one to break down and another to finish, so that the impressions in the die blocks can be placed more central in the hammer. This not only entails extra cost for dies, but the tying up of an extra hammer as well; whereas, if the hammer had been properly designed to withstand the additional strains put upon it due to the breaking down, as well as wide enough between uprights, the work could have been done in one machine at a much less cost; the break-down being done at one side, and in the same die block as the finishing impression.

It is the side thrust that causes so much trouble with the piston rod and packing gland of the steam hammer.

Economy of Board Drops

For forgings up to say 300 pounds, the writer does not believe that a more economical way can be found to forge them than in a properly designed board drop hammer. The power consumption is extremely low. In one plant using 45 board drops varying from 400 to 3,000 pounds or a total falling weight of 50,700 pounds, even with a bad arrangement of jack-shafts, these hammers together with 23 trimming presses and kindred machinery are driven by two motors of 75 and 100 H.P., respectively, and yet there is power to spare. For convenience let us assume that 40 H.P.—a low estimate—are used on the presses and other machinery; this leaves 1 H.P. for every 375 pounds of falling weight.

Almost every builder of steam drops recommends a boiler plant of at least 0.75 H.P. for every 100 pounds of falling weight. It is true that a steam drop will do more work in a given time for the same number of pounds falling weight than a board drop, but this is not so important when we consider that the best furnace to-day will hardly keep a board drop constantly going. Besides, what would become of the average drop forger if kept constantly before his fire for a full day of nine hours?

General Construction of Board Drop Hammer

To meet the requirements of an up-to-date drop-forge shop, the hammer, of which a front and rear view are shown in Fig. 1, was designed. It is an almost indestructible machine, the capacity of which seems to be limited only by the ingenuity of the die sinker. In the design many new and commendable features have been introduced.

The bases are of cast iron and in one piece, a weight ratio of 15 to 1 between base and hammer being adopted; that is, if the hammer weighs 2,000 pounds, the base would weigh 30,000 pounds. A shoe or "sow" of 0.45 carbon steel is keyed and doweled into the base, and the die openings planed into this. The recess in the base for the uprights is planed straight through, assuring a permanent alignment, as there is a bearing the entire width of the uprights.

Fig. 4 shows the section of upright used by most builders since board drops first came into use. As work became more and more severe, and uprights failed, nothing was done, however, but to increase the cross sectional area till the center became very porous, an even section of metal being impossible. The V's too have failed, and in every case the break was perpendicular to the surfaces in contact (see Fig. 4). These failures, together with a practical and theoretical knowledge of conditions led up to the form of upright shown in Fig. 5, which has nearly an even section of metal distributed so as to

* Address: 114 Brook St., Hartford, Conn.

better withstand the shocks brought to bear upon it. The V is backed up by a beam of the depth A and the thickness B, and any direct thrust that is perpendicular to the apex of the V is taken up by beams of depth C and thickness D.

Adjustments

It often happens in drop forge work that the dies do not match exactly sidewise, and some adjustment is necessary to bring them in line. The top die is generally doweled securely onto the hammer, and some drop forge plants use double keys for holding the bottom die in the shoe. One taper key is driven in from the front, and another taper key is driven in from the rear. In adjusting the location of the lower die relative to the upper one, all that is necessary is to back one key out and drive the other one in. This form of adjustment, however, is rather limited, as the taper of the keys must not be too lower part of the upright thus straddles or forks over the body of the bolt, as shown in Fig. 6. The collar-nut on the end of the bolt is shown at A in Fig. 1, this nut bearing against a boss on the upright. One bolt of this kind is provided for each upright. In adjusting, the hammer with upper die is let down until the faces of the dies come together. Then the base binding bolts are loosened, and also one of the upright adjusting bolt nuts. The other adjusting bolt nut is tightened, thus moving the entire upper structure—uprights, hammer and head—to the right or left, as the case may be, until the dies are properly matched. Then all parts are again locked into place. The moving of the entire structure is quite common in board drop hammer designs and is considered good practice, especially when the base binding bolts are at an angle, as is the case in the present hammer, as this

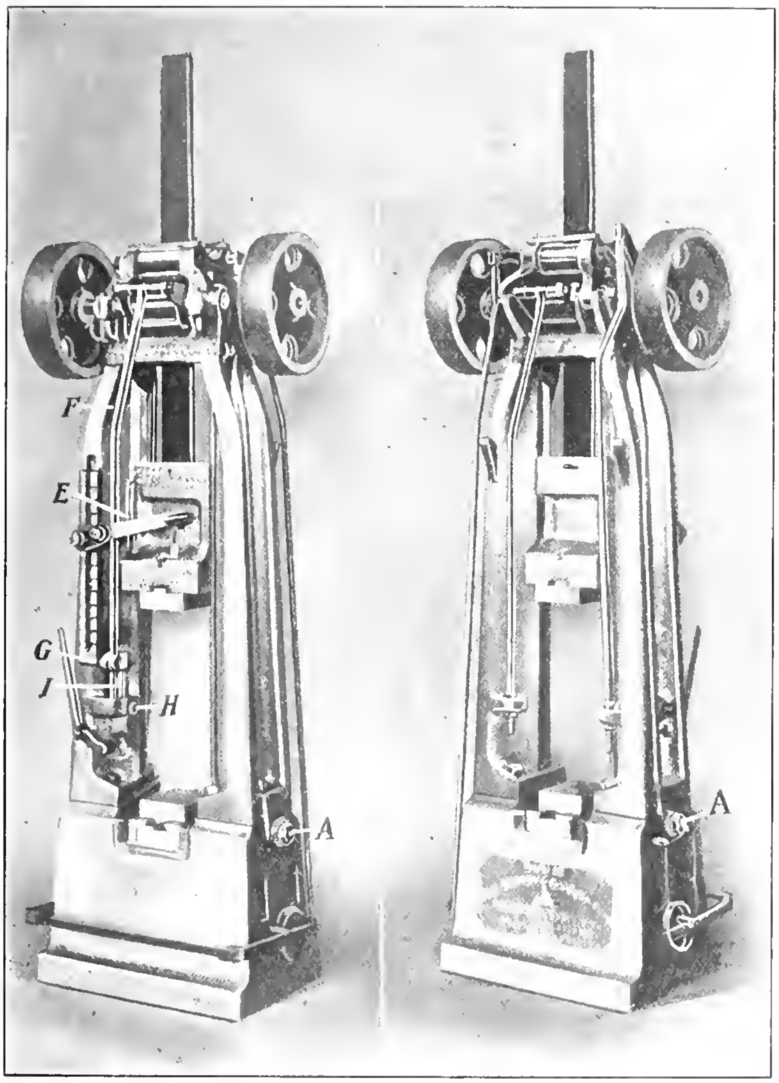

Fig. 1. Front and Rear Views of Board Drop-hammer of Rigid Design

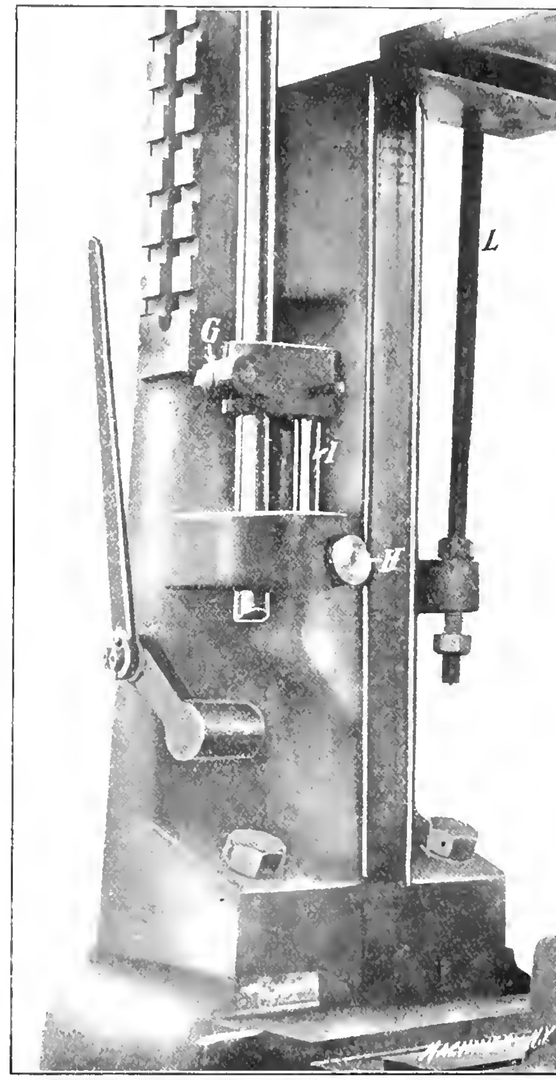

Fig. 2. Automatic Knock-off Arrangement

great, or the keys will not remain in place; it also adds an extra piece to fit and possibly jar loose.

A better method of adjustment is to move the entire upper structure sidewise on the base by means of an adjusting bolt; but this bolt has, possibly, been one of the greatest annoyances of the board drop in years past. For a long period all makers used practically the same construction, consisting of a set-screw passing through a nut inserted in and fastened to the base, the point of the screw bearing against a projection of the upright. The hammering action of the upright, however, is very severe, especially on break-down work, and the point of the adjusting screw soon becomes upset so that it can neither be removed nor used for adjusting the uprights.

In the present construction, therefore, a bolt with a T head has been laid horizontally in the recess for the upright cast in the base. The T-head is let into the base, so that the bolt cannot move relative to the base casting. The round part of the bolt rests on a finished surface in the recess, and a finished groove is provided in the upright to fit over the bolt; the draws the uprights apart and back against the adjusting bolt nuts.

Notches are cut in the collar of the nut, as shown in Fig. 3, and a flat spring is fastened to the base and brought to bear in the notches, this forming a positive lock and an easy means of adjustment. With a special thread on the bolt, an adjustment as fine as 0.0028 inch can be had.

The trouble due to constant vibration causing the uprights to creep together and pinch the hammer at the bottom is overcome by setting the base binder bolts at an angle, thus keeping the upright back against the upright adjusting bolt nut. The adjustment for different heights of fall is made by a bracket clamped to a modified form of rack in any desired position on the left-hand upright. (See Fig. 1.) The roll releasing lever E, better shown in Fig. 7, allows the friction bar F to release on the up stroke without shock or noise. The automatic knock-off H is best shown in Fig. 2.

Adjustment for different thicknesses of dies is made through the adjustable dog G, carrying a stop pin I.

the latter resting on a flattened surface of the knock-off *H*, which has an elongated hole through it. The side of the hammer is beveled to fit the beveled end of the knock-off *H*. As the hammer descends the knock-off is forced back, allowing the stop pin to fall through the elongated hole. For thick dies the stop pin is set forward, and, as shown in the line engraving Fig. 8, consequently falls earlier. In this line engraving, *C* is the elongated hole in the upright allowing adjustment for the stop pin; the pin is shown set for thick dies and it is moved back in the slot for thinner dies. The elongated hole through the knock-off is indicated at *D*. As the hammer descends it is evident that when the knock-off is forced back, the stop pin falls through the slot in the knock-off and allows the friction bar to drop, and thus the eccentrics on the lifting rolls are brought into contact with the lifting board. The hammer then rises until the hammer pin, which is made of wood in order to lessen the impact, comes in contact with the roll releasing lever, which raises the friction bar and thus releases the rolls.

As shown in Fig. 8, the stop pin rests on a surface the width of which equals *y*. Should the stop pin be moved to

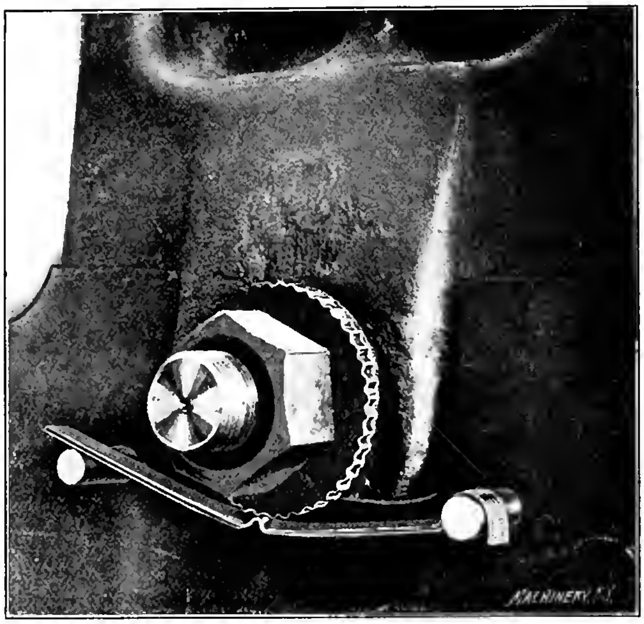

Fig. 3. Locking Arrangement for Upright Adjusting Bolt Nut

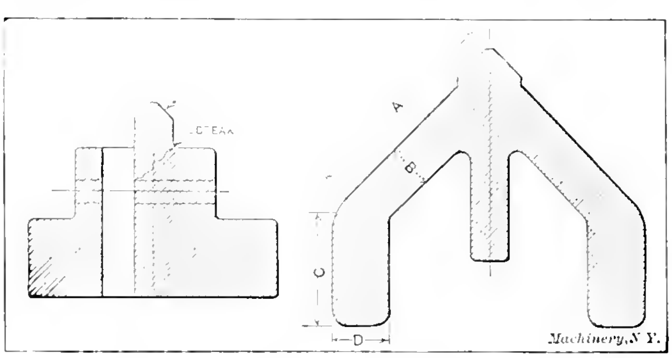
the left to the end of the slot in the upright, the knock-off evidently would have to be forced back a distance equal to *z* before the friction bar could fall. As the side of the hammer and the front of the knock-off are beveled only $5\frac{1}{2}$ degrees, the hammer must travel a considerable distance to force the knock-off back $1\frac{1}{4}$ inch, which is its extreme travel.

Even if the drop forger is not careful in setting the knock-off, little can be lost in having it act too early, unless



Figs. 4 and 5. Section of Uprights of Usual Type and of the Type used in the Hammer shown in Fig. 1

at a very short fall, because the hammer has a velocity of a free falling body, having fallen several feet, while the friction bar starts from rest when the knock-off releases it. The friction bar should be heavy enough to throw the rolls against the lifting board with force enough to lift the hammer readily. The best condition is to catch the hammer when rebounding from the dies.

It will be noticed that there is no provision made for preventing the knock-off from turning around its own axis. Provision to prevent turning was made on the first hammer built, but it was found unnecessary, as the weight of the friction bar resting on the flattened surface always keeps the knock-off

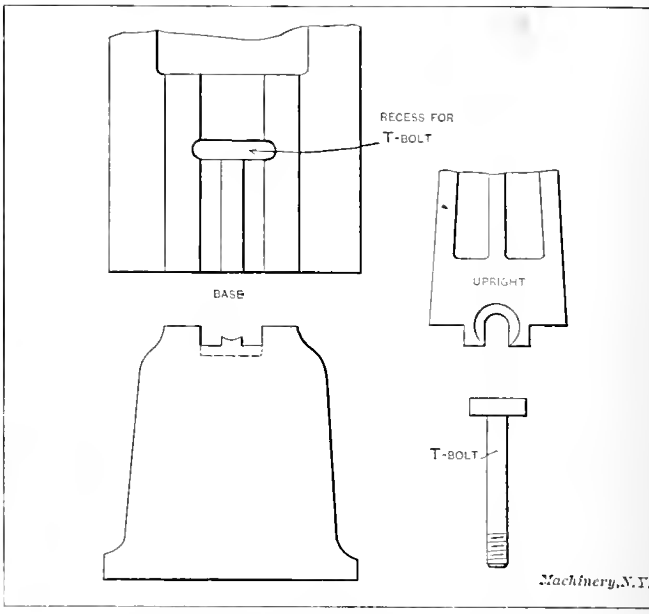


Fig. 6. Details of Sidewise Adjustment of Uprights

from turning when the bar is up, and as soon as released, the pin passes down to the slot in the knock-off, making turning impossible.

The knock-off stop is counterbored instead of being bored clear through. The reason for this is that the impact of the hammer would be likely to shear off the taper pin. With the construction shown, the pin has nothing to do but overcome the impact and pressure of the spring, and even this impact is lessened by fiber washers which act as cushions, as well as by a safety cotter pin which would act in case the taper pin should fail.

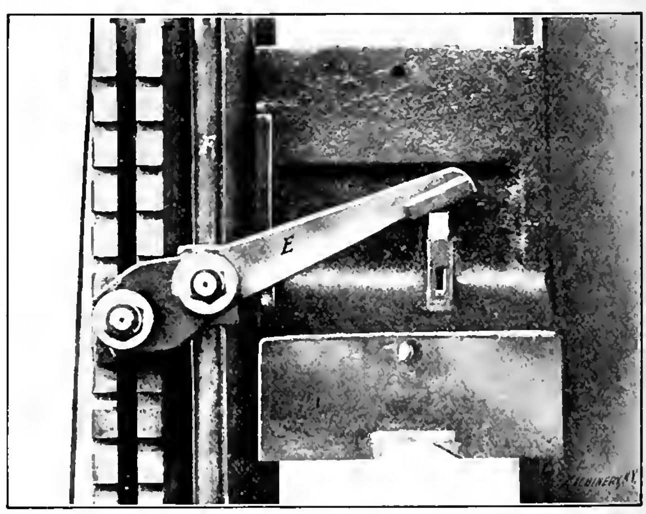

Fig. 7. Arrangement for Adjustment for Different Heights of Fall

When the hammer pin comes in contact with the roll releasing lever, as previously mentioned, thereby raising the friction bar and releasing the rolls, the hammer again falls and will continue to run automatically until the treadle is released. At this time it comes to a rest on the top of its stroke, and is held there by board-clamps *K*, Fig. 9, located above the rolls out of the way of any oil that may work out of the bearings. By a greater or less depression of the treadle, any blow may be struck regardless of the set fall. The hammer can also be stopped at any point when falling, without injury to the machine.

Head Construction

Fig. 9 gives a good idea of the head construction. Both lifting rolls, as well as the board clamps, are mounted on eccentric sleeves, the front one of each being intended for operating and the rear one for the adjustment necessary, due

to the rolling down or wear of the board. This feature is one of the most important in the whole construction as a perfect alignment of the rolls is always assured, regardless of how careless the operator may be. The adjusting bars *L* are carried down in the back of the uprights through lugs cast on them, and locked within easy reach of a person standing on the floor. (See Fig. 2.) Adjustment for the wear of the board can thus be made in a few seconds, whereas usually on all drops offered to the trade a ladder is necessary for reaching the set-screws located behind each end of the rear roll bearing. It is then a mechanical impossibility to ever get the rolls and clamps parallel, with the proper amount of friction, while the drop is running.

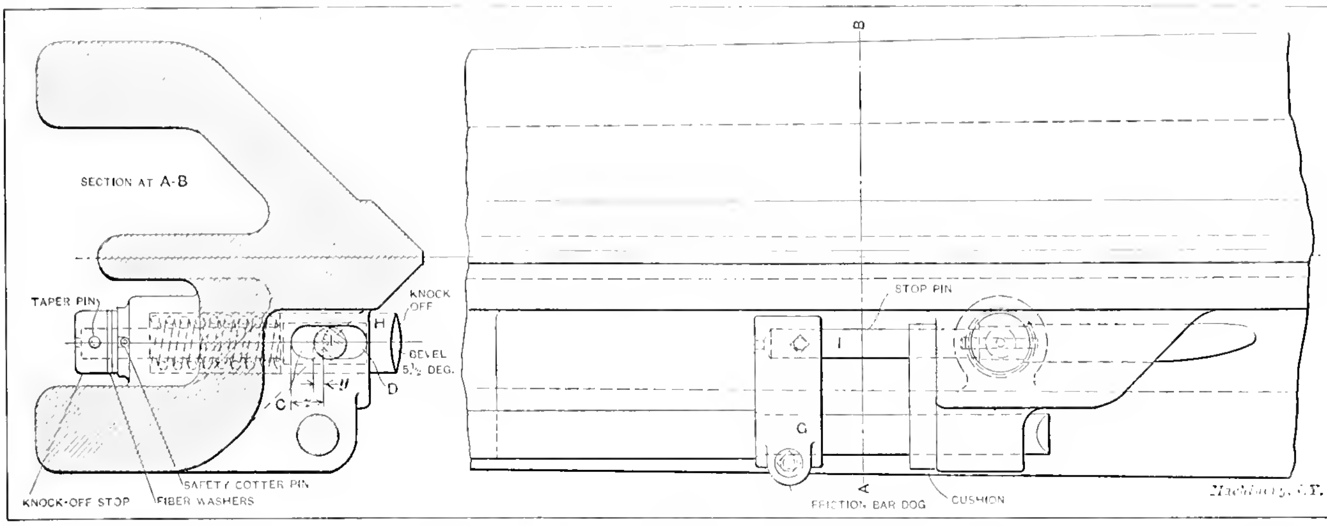

Fig. 8. Details of the Automatic Knock-off Arrangement

An even pressure must be brought to bear across the entire face of the board, or a rapid wearing away will result, and many times this causes it to split. A double pressure on one side also has a bad effect on the bearings.

Seasoned maple boards have been found to stand better than any other kind of wood or metal. Paper fiber has been tried with fairly good results—but as yet the cost of this material is prohibitive. All running bearings of the hammer illustrated are exceptionally long, bronze bushed and provided with large oil reservoirs.

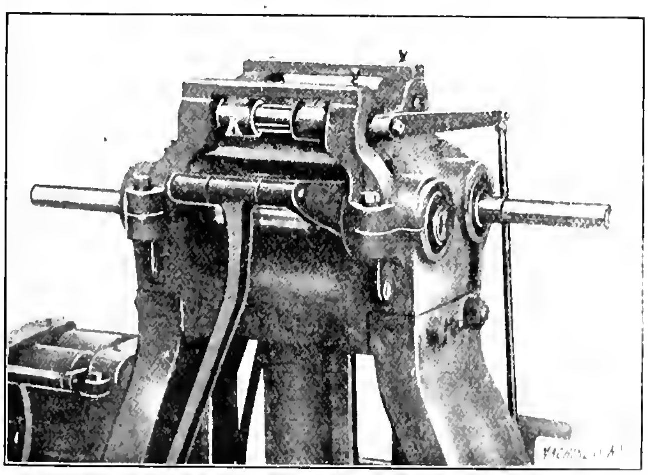

Fig. 9. Head Construction of Board Drop-hammer

Fig. 10 shows the foundation construction, which, like the ratio of 15 to 1 between base and hammer, was adopted after a long and varied series of experiments. The concrete mixture is made up of three barrels of stone, two barrels of coarse sand, and one barrel of cement. To meet the various classes of work that comes into the average drop-forge shop, these hammers were built very wide between uprights, *viz.*, 400-pound hammer, 12 inches; 800-pound, 14 inches; 1,200-pound, 17 inches; 2,000-pound, 20 inches; 3,000-pound, 24 inches. It does not seem practical to build board drops larger than 3,000 pounds falling weight. The field in which heavier blows than this are required is best covered by the steam drop and the hydraulic press.

THE MAKING OF AN ACCURATE LEAD-SCREW

In a paper read before the Institution of Mechanical Engineers, of Great Britain, by Mr. H. F. Donaldson, an incident is related showing the pains which are sometimes taken by mechanical men to accomplish their ends. The author of the paper states that some years ago he visited certain British works where it was claimed that micrometer screws were produced with exceptional accuracy. He there had a conversation with one of the members of the firm who claimed to have produced, by his own efforts, an accurate master screw upon which the accuracy of all the firm's subsequent work of this character depended. This man first cut a screw as accurately as possible by the common methods, and he then shut himself in a room, the temperature of which was constantly kept nearly at the heat of the human body, so as to in this way by artificial means minimize the effect of the heat of his body on the work in which he was engaged. His screw had a square thread and was about twelve inches long;

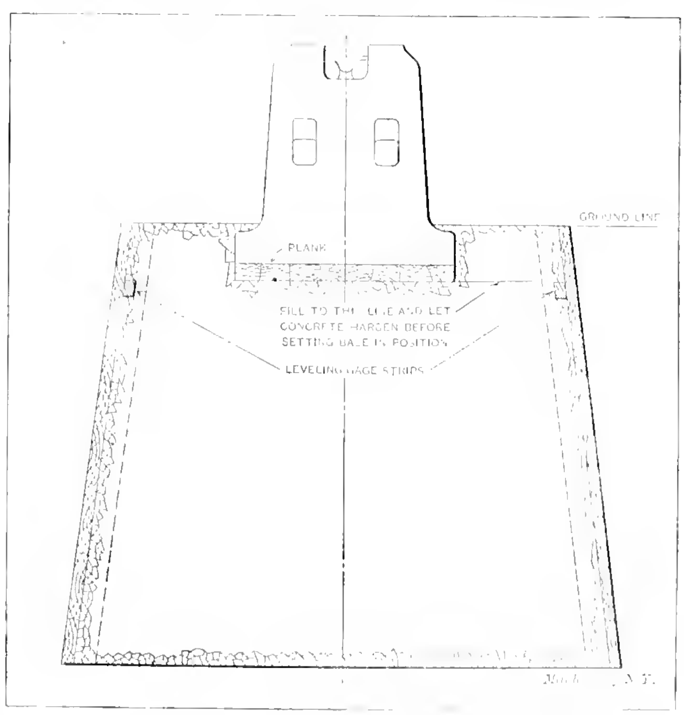

Fig. 10. Foundation of Drop Hammer

when the temperature of the room had been brought to a level as high as he considered he could stand, he shut himself in the room and proceeded to measure short lengths of the whole of the screw and lap the inaccuracies on both sides of the thread until he secured, as near as could be obtained, absolute accuracy in the screw. He remained in the room until he had gone over the whole length of both sides of the thread which required about twenty-four hours, when he came out of the room with the screw in its finished state.

SOME CAUSES OF BELT FAILURES*

G. S. BAKER†

Nearly every large manufacturing plant is constantly making changes and improvements in its machinery for the sake of effecting greater economy in its output. Strangely enough, many of our largest manufacturing plants, though equipped with most modern machinery, have most inefficient methods of installing belting equipment. There seems to be a general feeling that belting a machine is something that everybody understands and something which needs no particular study or attention. The result of this indifferent attitude toward belting and its proper installation, has been constant extravagance in the belting equipment of plants where the greatest possible economy is followed in other directions.

The causes of belt failures are many. In some instances the cause may be traced direct to the manufacturer of the belt, who has not furnished in the goods delivered the qualities which he should. But, let us assume, that only the best belting is bought and delivered, and then analyze why the best belting, wrongly installed, will have need for frequent replacement. Under such conditions the causes are two-fold: First, belt failures are often due to a defective working out of the underlying principles of practical belt transmission; and second, belt failures are often the result of the selection of an improper type of belting for the particular kind of work to which it is to be put.

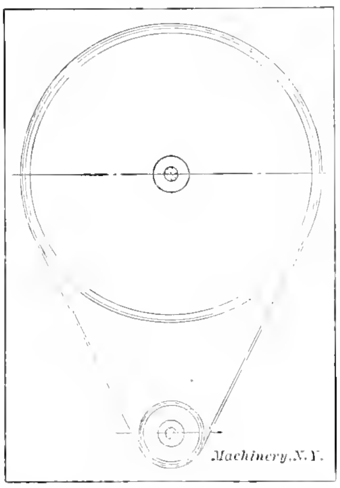

Fig. 1. Drive from Large to Small Pulley, showing Decreased Arc of Contact

We shall, in this article, attempt to show how a large percentage of the unnecessary costs of belting could be eliminated by following out three suggestions: First, by foreseeing and modifying the mechanical and architectural plans in the building of plants, so that they will conform to the most modern principles of practical belt transmission; second, by modifying pulley conditions in a plant already built; and third, by the selection and proper installation of the right type and size of belting for the particular machine and pulley upon which the belt must operate.

Very often slight changes in transmission conditions would save great losses of time on many types of machinery in many of our factories. Here for example are some of the common mistakes in transmission which could easily be rectified, if attention were called to them.

Allowing too short centers between the shafting. This practice works havoc with the belt where the load is heavy. Owing to its limited length, the belt does not sag on the top side, as it would when driving from the bottom of the pulleys, which is the correct way; therefore it becomes necessary to draw the belt very tight to avoid slippage, thus straining it and adding to the frictional resistance in the bearings. When the diameters of the driving and driven pulleys differ to any extent, as shown in Fig. 1, there is a material reduction in the arc of contact on the smaller pulley, as the distance between the centers of shafting is lessened, and as the driving power of the belt, in a measure, depends upon the area of contact between the belt and pulley surfaces, the advantage of increasing the distance between centers is apparent.

Installation of pulleys which are too small. A slow-running belt must be heavy if any strain is put upon it.' It must also be wide to get the proper area of contact to insure it against slippage. Where small pulleys are used, the above condition is doubly true. Were the pulleys at their installation enlarged proportionately, they would still give the same number of revolutions, but the belt speed would be increased, the grippage area increased and a narrower and lighter belt could be used. Such a belt will invariably outlast a shorter, heavier and thicker belt. In determining the minimum diameter of pulleys to be used with single and double belting, it is necessary to take into consideration the width of the belt to be used, belt speed and horse-power transmitted. In a very general way it may be said that it would be well, whenever possible, to have the pulleys on which single belting is to run not less than 8 inches in diameter, and those for double belting not less than 12 inches in diameter.

The avoidance, as far as possible, of quarter-turn drives. Quarter-turn drives (Fig. 2) bring about one of the hardest conditions found in belt transmission. This character of drive can often be avoided in one of three ways: (a) By installing two loose pulleys so that the belt will operate over them, as well as over the regular driving pulleys, as shown in Fig. 3. The loose pulleys must correspond to the tight pulley on the same shaft, and be so placed that the crowns of all four pulleys in plan would form a rectangle. The advantage of this arrangement, generally speaking, may be said to be in the fact that when the belt operates at a quarter-turn with the delivering faces of the driver and driven pulley plumb, the belt does not get the full degree of contact with the pulley which it does with the loose pulley arrangement, which gives for pulleys of the same size a full 180 degrees contact. This condition, of course, makes for greater driving efficiency of the belt than when the area of contact between the pulley surface and belt is lessened by the quarter-turn arrangement.* (b) By the use of a right-angle transmitter. (c) Possibly by installing two idler guide pulleys on the top side of the belt.

An avoidance of the use of small pulleys on extra long center drives. This condition taxes the tractive power of a belt to the utmost. Under such conditions it is necessary that the belt be kept under a certain tension at all times. The result of this is usually either constant taking-up during damp seasons, or lengthening in dry periods.

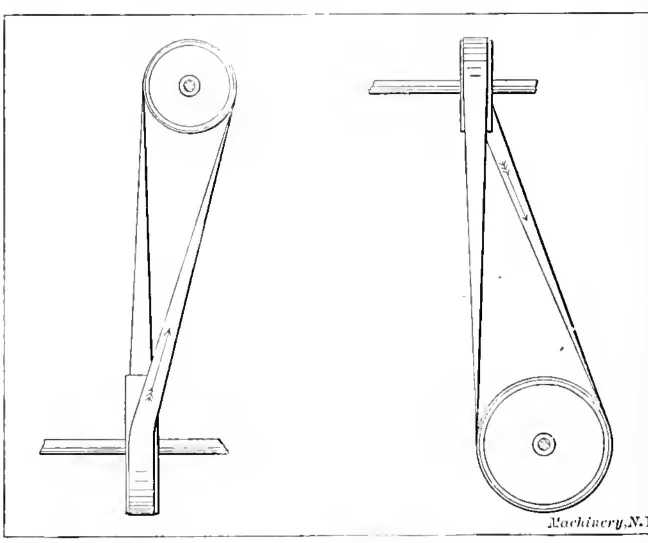

Fig. 2. Quarter-turn Drive showing Distortion of Belt as it leaves Pulley

By so installing the belt that the slack side is above and the driving side on the bottom of the pulleys. If this condition is reversed, the slack side being below, as shown in Fig. 4, the arc of contact of the belt with the pulleys is materially lessened.

Types of Belting for Different Classes of Work

Perhaps the most common cause of wastefulness in belt transmission is the selection of improper types of belting for particu-

* For additional information on this subject, see the following articles previously published in MACHINERY: Apparatus for Measuring the Slip of Belts, May, 1908; Loss of Velocity Ratio Due to Belt Elasticity, January, 1906; The Manufacture of Belting at the Schieren Factory, May, 1906; Tests of Belt Preparations, March, 1906; Horse-power Transmitted by Belts, July, 1906; Belting, June, 1905; Belt Drive for Shafts at Right Angles, June, 1902; Belt Drive for Three Pulleys, March, 1901.

† Address: 51 Beekman St., New York.

* Where the quarter-turn drive cannot be avoided because of lack of room or for other reasons, the straining of the belt can be minimized by lacing the joining ends so that the flesh side of one and the hair side of the other is out. This method was described in the February, 1899, number of MACHINERY. As will be understood, when a belt is placed over the pulleys in this way it is not twisted any more than with the common arrangement, for what was a quarter twist one way becomes a quarter twist in the other direction when the belt end is turned half way around. The advantage of connecting a quarter-turn belt in this way is that there is equal stretching of the belt on both sides, as a given point on one side of the belt is first on one side and then the other of the pulleys for each revolution, whereas with the usual arrangement all the stretching occurs on one side.—EDITOR.

lar classes of work or machinery. We cite in the following a few instances where practical mechanical knowledge of conditions should govern the selection of the belting.

Drives with varying loads should be equipped with belts that have an abundance of elasticity and which are capable of retaining it. The elastic qualities should be such that upon the relaxation of the load, the belt will go back to its original state. Another instance where elasticity has great bearing upon the selection of the proper type of belting is in connection with quarter-turn belts. Here the belt must be able to form a long side and yet be elastic enough to insure of it not becoming permanent.

On drives where there is a long distance between centers, it is necessary that the belt be absolutely uniform and have perfect balance throughout. Unless a belt is procured which contains these qualities, its tractive powers and its driving powers will be materially reduced. Its life will be short and it will be continually running off the pulleys. Nothing but the best woven types of textile belts should be used on this character of drive, or leather belts made from absolute center stock. Often textile belts are selected for use with shifters. This is a mistake and should never be done, unless roller shifters are used. In the event that a belt is wanted which is to carry a heavy load, and where it is necessary that the belt should be kept tight at all times, it is always well to select a belt sufficiently heavy to give it a large factor of safety with regard to tensile strength.

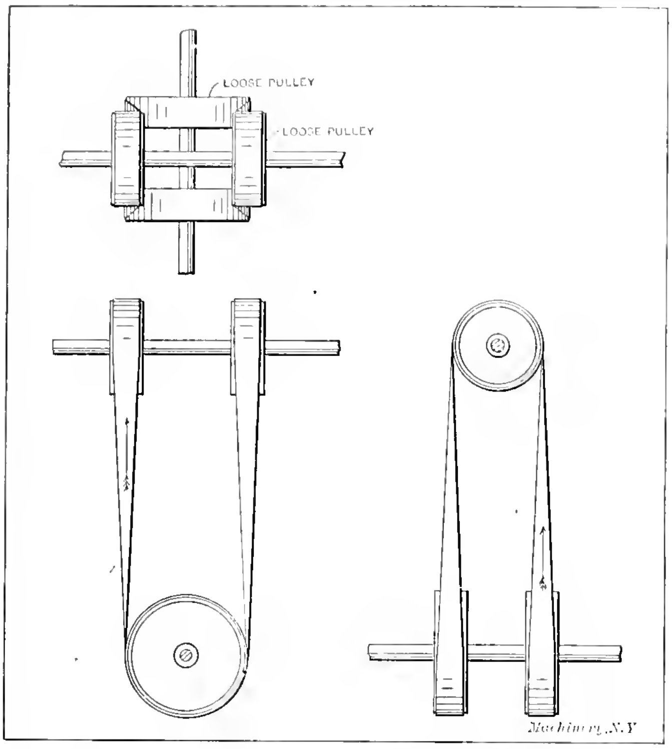

Fig. 3. Four-pulley Drive for Eliminating the Quarter Turn

As to the Arc of Contact

On the drives where the arc of contact that the belt has with the pulley is small, the transmitting efficiency of the belt will depend mostly on its width, since only in this way can an approach be made to the proper area of contact. Tensile strength, under these conditions, has very little to do with the horse-power the belt will transmit. The horse-power depends almost wholly upon the speed at which the belt travels. The area of contact of the belt with the pulley should, however, be large enough to prevent slippage.

Starting Machines with Full Load

One blunder very often made by the engineers of large plants, which plays havoc with the belting, is the starting up of machinery with the full load on. The belting is then required to transmit at a speed of, say, 100 feet per minute, the full amount of horse-power that it was designed to carry when running at a speed of, perhaps 2,500 feet per minute. Unnecessary strains of this sort are among the prime factors which cause belting to go to pieces.

Effect of Water and Dampness

Another condition which is a large factor in belting difficulties, is water and dampness. To meet conditions of this sort, selection of the proper type of belting is of first importance. Dampness is, without doubt, the cause of more belt replacements than any other condition. While water itself may not splash on the belt, or the room in which the belt is operating may be free from water, nevertheless the action of dampness will often work havoc with belting. Dampness, unless the leather is specially treated to withstand its action, will cause the very best of leather belting to stretch, run crooked and in many cases open up the laps and piles. Belting at rest is affected much more by the action of moisture than when driving, as the frictional heat generated by the belt when driving tends to keep the belt dry. The problem of waterproofing and damp-proofing belting is a very important one at the present time, as our largest factories at the present day are being constructed of reinforced concrete and cement blocks. It is a well-known fact that unless special precautions are taken, as is seldom the case, that it is next to impossible to keep a factory constructed in this manner free from dampness, especially in warm seasons when no heating system is in operation. Since so many of our factories are being constructed in this manner, it means practically the dawning of what may be termed "the water-proof belting age." Dampness will penetrate readily through concrete walls. In one instance, which the writer recalls, underground concrete conduits were built in which the driving pulleys were to operate. The object of this idea was to save space by putting these belts under the floor, and also to get solid bearings for their shafting. The superintendent of this factory desired to use untreated, flat leather belting. He claimed that there would be an absence of water and moisture in conduits of this sort. It worked out, however, that the dampness from the ground penetrated the concrete walls and made the place very unsuitable for belting which had not been specially waterproofed.

As to Fasteners

Seldom does the question of belt fasteners receive the attention that it deserves. Almost invariably the complaint registered against the belt because it has torn out where joined, reflects more upon those who had charge of the installation than upon the belt with which fault is found. In determining the type of fastener to use, consideration must first be given to the mechanical conditions under which the belt will operate. If it runs under a tightener or drives from both sides it follows that the joint must be of the hinge or flexible variety, or the belt made endless, and under these conditions we must eliminate from consideration some types of fasteners which are very satisfactory where the belt operates on free open drives. In the selection and application of fasteners, textile belting calls for even more care than does leather. The punching of a hole which is too large or too close to the end frequently results in the fastener tearing out. In punching a hole in leather belting you weaken it only to the extent of the material removed, but a like operation on textile belting goes further in that it severs many of the interwoven strands and weakens the construction. The aim, therefore, should be to make the holes as small as possible and to place them at regular intervals. In preparing the ends of a belt for lacing or fastening, invariably use a square so that the ends will be at right angles with the edges of the belt. It has often been found, where fasteners do not give entire satisfaction, that this condition was due to the fact that the ends had not

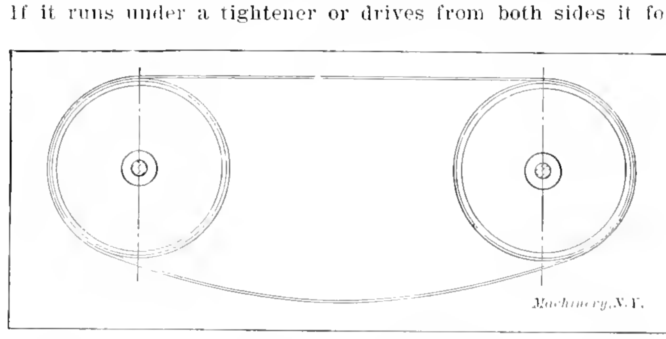

Fig. 4. Belt driving on Top Side, showing Decreased Arc of Contact

been cut true, consequently, when joined together, the strain was not evenly distributed across the width of the belt, falling more on some points than on others and resulting in the tearing out of the fasteners.

As to Belt Dressings

If a belt does not operate properly or does not seem to grip the pulleys as it should, the average shop superintendent gives the belt a generous dose of belt dressing. It is the writer's belief that as a general thing belt dressings do little good and tend to shorten the life of the belting. In most belt dressings a certain amount of resin is used and in almost all dressings some form of graphite. While both of these compositions possess certain adhesive qualities, in time they are bound to ruin the fiber of the leather. If leather belting is properly curried, it seldom becomes hard or dry, unless it is working under conditions where it is impractical to install a leather belt. In practical experience, it has been found advisable, under such conditions, to use as a belt dressing tallow mixed with a certain amount of castor oil. The tallow softens the fibers of the leather and the castor oil restores to a large extent the adhesive qualities in the belt. But even this most harmless type of dressing should be used sparingly, or the result will be a stretching of the leather. Where trouble is experienced through slippage of the belt, a few drops of castor oil on the pulley where the slipping occurs will be found to give good results. The oil will not injure the leather to the extent that most dressings will. Most all the slippage of belts is due to the fact that frictional heat causes the grain or pulley side of the belting to become dry. Castor oil tends to soften the grain and reduce slippage. Belt dressings, if not used very sparingly, in places where there is a certain amount of dust in the air, will invariably clot on the belt and cause it to run unevenly.

General Service Conditions

The problem of selecting a proper type of belting for different classes of work is one that requires careful study and much experimenting on the part of those who operate different classes of machinery. Considerable money could be saved in belt replacements if the type of belting best adapted for the place were used. The writer knows of many instances where for years leather belting had been used on some particularly difficult drive, where it had an average life of only from two to three months. After allowing this condition to continue for years, the factory superintendent would finally instal some other type of belting which would be found to last much longer than the leather belting. This condition works both ways. Most of the largest belt manufacturers have experimented with different types of belting on different classes of machinery and are able to give authoritative recommendations as to which type of belting will prove most economical for each machine. Such recommendations should receive careful attention with a view to economies. The problem of properly belting machinery is a large one. New types of belting, new methods of fastening and new types of belt dressings are being introduced almost every day. While the proposition of belt transmission is an old one, there is still much room for improvement and need for closer attention on the part of those who use belts.

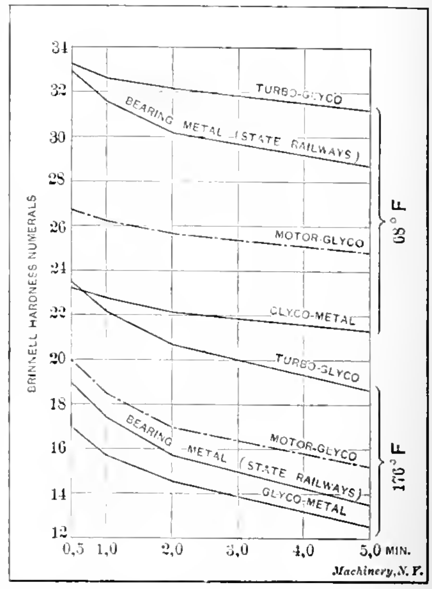
A NEW METHOD OF GALVANIZING

A new method of galvanizing has recently been patented by George L. Paterson, Thomas L. Mornes and Carl H. Zieme of New Castle, Pennsylvania. The iron or steel to be galvanized is first coated with a paste composed of 88 parts of zinc flue dust, 2 parts of lamp black and 10 parts of clay. These ingredients are mixed with water and applied to the cleaned surface. The material is then placed in a furnace and heated to a temperature of from 600 to 1,000 degrees F. The heating is continued from one-half to four hours, when the article is removed from the furnace and allowed to cool in a place free from oxidizing influences. The paste, now dried, is easily removed, but the surface of the iron or steel is coated with zinc. The inventors claim that the coating thus produced is superior to that obtained by "sherardizing," and that much less zinc dust is used. From a sanitary point of view, the process is also commendable, as the operators are not subjected to the influences of the dry zinc dust.

THE TIME ELEMENT IN HARDNESS TESTS BY THE BRINELL SYSTEM*

A diagram indicating the effect of the time element in hardness tests made by the Brinell method is given in the September 25, 1909, issue of the *Zeitschrift des Vereines deutscher Ingenieure*, and is reproduced in the accompanying engraving. The tests were made by the German Glico Metal Co. On the lower scale in the diagram is given the time, in minutes, during which the pressure on the metal was permitted to act, while the scale on the left-hand side gives the hardness numerals according to the Brinell hardness scale. It will be noted that the longer the pressure was permitted to act, the greater was the impression made on the metal, so that a lower hardness numeral resulted. Two sets of curves are shown, one with the metal heated to 176 degrees F., and one with the metal at 68 degrees F. It is interesting to note that the curves in each set are almost parallel, except in one case, thus indicating that for *comparative* purposes the Brinell test is accurate no matter what the length of duration of pressure, provided, of course, that the various samples tested are all subjected to pressure for the same length of time. It is also interesting to note the difference in the hardness of the metal brought about by the change of temperature. It will be seen that at the higher temperature its hardness numeral is not only less than at the lower temperature, as, of course, would be expected, but when the pressure on the metal is permitted to remain for a longer time, the metal apparently gives away much easier to continuous pressure when heated than when at a lower temperature. Tests of this kind should be of great value in determining the relative value of bearing metals which for long periods are to be subjected to heavy pressures under increasing temperatures. A new factor in hardness testing is also introduced, which the Brinell method is particularly adapted to measure, *viz.*, the power of resistance to *continuous* pressure of various metals, a factor which may be found to vary considerably for different materials.



Curves showing the Variation in Results obtained in Hardness Tests of Varying Duration

* * *

An apparatus was exhibited by Mr. S. H. Schneider at the meeting of the British Association for the Advancement of Science at Winnipeg, which seems to claim the distinction of being a new *perpetuum mobile*. The apparatus, which was not satisfactorily described, consists of a collapsible air-tight box which, when closed, sinks in water by its own weight. On reaching the bottom it is expanded by a magnet, when, being lighter than the water displaced, it rises to the surface where it again folds up and sinks. The inventor states that a full-sized generator weighing 600,000 pounds and displacing 10,000 cubic feet of water would generate 50,000 horse-power at practically no cost of operation. Surely the millennium is fast approaching!

* * *

To prevent the formation of rust inside boilers, experiments have been made at the Berlin Technical Institute, Germany, to use water deprived of the air it contains by means of charcoal. Sacks of freshly prepared charcoal have been put into the water from which the boilers were fed, and the decrease of rust in the boilers fed with this water has been about twenty-five per cent.

* See MACHINERY, September, 1908: The Brinell Method of Testing the Hardness of Metals.

ASSEMBLING A 24-INCH ENGINE LATHE*

ALFRED SPANGENBERG†

While the problems encountered in assembling engine lathes are not as difficult of solution as those met with in assembling machine tools of a more complicated nature, thorough and careful consideration of the methods employed is essential in order to minimize the cost. The most important operations involved are the scraping of the bed and carriage and the lining up of the head- and tail-stock. To a large extent the cost of these operations is dependent on the accuracy of the machine work.

It is the object of the present article to discuss the methods employed in machining, and to illustrate and describe the erecting process on the bed, the principles involved in assembling the units having been fully outlined by the author in previous articles in the September and October issues of MACHINERY. For the purpose of giving a concrete example, a 24-inch engine lathe with quick-change gear device is selected, the general features of which are shown in Fig. 1.

Planing the Bed and Carriage

The practice of some makers to rough out the surfaces to be planed on the bed and carriage, and allow them to season before taking the finishing cuts is indicative of the modern tendency toward accurate machine work as a means to avoid unnecessary scraping. The seasoning process simply consists in letting the casting stand in some convenient place in such a way that it will not be subjected to any outside forces, and allowing the stresses in the casting itself to become equalized.

Next in importance to providing accurate planers on which to machine the bed and carriage, is the necessity for gages that will enable interchangeable work to be produced. The gages shown in Fig. 2 are particularly well adapted to this class of work, and are far superior to the common type having a bearing on both sides of each V. Feelers or thickness gages are used in connection with the gages illustrated, in order to measure the amount of error. The advantages this form possesses over the common type are that the V's on the casting being fitted will both be of the same width, and no difficulty is experienced in keeping the gage level, since it always lies in a horizontal plane by resting on the top of each V. At *A* and *B* are shown gages for the bed and carriage respectively; these gages are made of steel ¼ inch thick.

Assuming, for example, that the V-surface on the bed at *C* is tight to the gage, and a 0.002 inch feeler will just pass between the bed and gage at *D*, then 0.002 is the exact amount that must be planed off the surface *C*. When these two surfaces fit the gage so that no error can be detected with a 0.001 feeler, the gage is turned end for end, and the surfaces *E* and *F* are tested in the same manner. It is, of course, necessary to set the gage square with the bed and this is accomplished by trying the feelers on both sides of the gage. The same remarks apply to the carriage gage *B*. At *G* and *H* in the same engraving are shown gages in the form of cast iron blocks about 6 inches long which are used for testing the ways on bed and carriage as indicated; *I* is a sheet steel strip fastened to one end of gage *H* and this is used to test the apron seat *J*. All other measurements are tested with ordinary height blocks or caliper gages, as the case may require.

Referring now to the carriage, the sequence of operations in finish planing it is to plane the bearing for the shoe, and square up the ends, and then turn it over in the position shown in the engraving and plane the V's and other surfaces on this side. It is good practice to plane lathe carriages of this size in lots of six at a time by placing them in a "string" on the planer table. When completing the final operation, that of planing the V's, it is evident, however, that the carriages farthest away from the angle plate by which they are squared up, are particularly liable to error. With careful setting up, this error should not exceed 0.003 inch, which is easily and quickly scraped off by the assemblers.

Machining the Head- and Tail-stock

The methods of machining head- and tail-stocks vary greatly in different shops, and also with different sizes. Some makers first finish all the planing and then perform the boring operations and scrape in the head-stock spindle, while others leave a finishing cut to be taken on the bottom of the head- and tail-stock after the boring and scraping are completed, by setting up the castings on arbors held in V-blocks on the planer table. Both systems, or modifications of both, are frequently used in the same shop. While the first-mentioned system is the most economical in that it saves setting up the work on the planer twice, it is essential that the machining be such that very little scraping is required on the head-stock boxes; otherwise the head-stock will be thrown out of line in fitting the spindle, which necessitates replaning the head-stock and possibly the tail-stock.

In any event, it will always pay to leave 1-16-inch stock to be bored out of the bearing boxes, so that after the boxes are fitted in the head-stock it can be replaced in the boring jig and a finishing cut taken in the boxes, allowing 0.005 inch to be reamed out. Adjustable shell reamers are mounted on the boring-bar for this purpose. When this precaution is taken, and

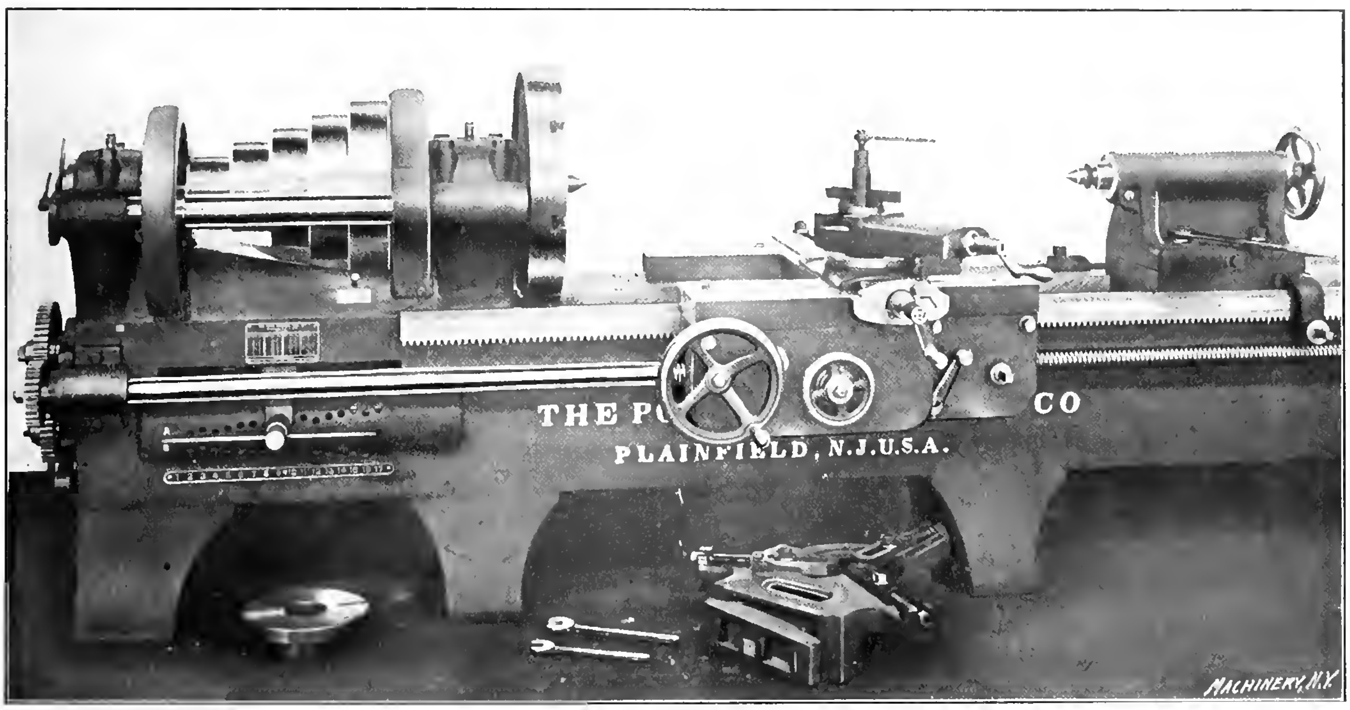


Fig. 1. Twenty-four-inch Engine Lathe with Quick-change Gear Device

* For additional information on this and kindred subjects, see "Assembling Machine Tool Units," in the October, 1909, issue of MACHINERY, and articles there referred to.

† Address: 951 W. 5th St., Plainfield, N. J.

the spindle is accurately ground to size, very little scraping should be necessary to make a good bearing. The object of leaving the 1/16-inch to be bored out with a cutter before reaming, is to insure that the reamer has an even cut and that sufficient stock is left for reaming.

Boring and Drilling the Bed

When all the planing is finished on the bed, it is next sent to the drilling department where the first operation consists in boring the shaft holes for the tumbler mechanism shown in Fig. 3. This operation is performed on a horizontal drilling and boring machine with the aid of a jig which also locates the sweep clamping bolt hole. The shafts *A* and *B* run in long cast-iron bushings that are a light drive fit in the bed, and to provide for standardization and enable the bush-

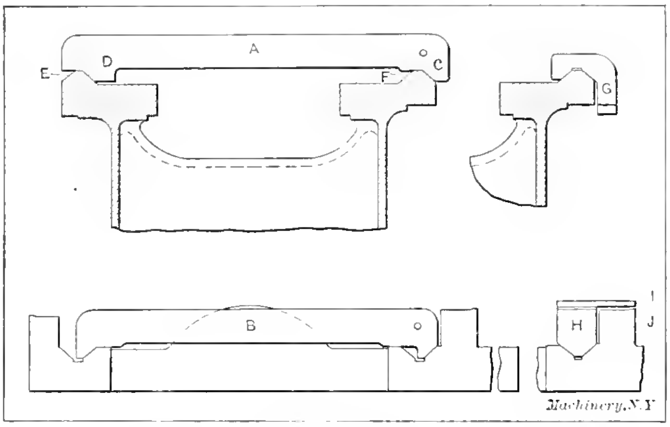

Fig. 2. Gages for Testing the Planing of Lathe Bed and Carriage

ings to be finished in large quantities, the holes in the bed are reamed to gage, adjustable shell reamers being mounted in the boring bar for this purpose. The hole for stud *C* is drilled and then finished with a rose reamer, after which it is hand reamed to gage. This hole and the sweep clamping bolt hole are the only ones that require facing, the method of taking the measurements being apparent from Fig. 4; *A* is a sheet-iron templet having an outline indicated by the heavy line; the opening at *B* locates the surface to which the stud boss is faced, while at *C* is shown whether there is sufficient clearance cored out for a feed gear. The templet is located sideways by the spline *D* which is riveted to the templet and

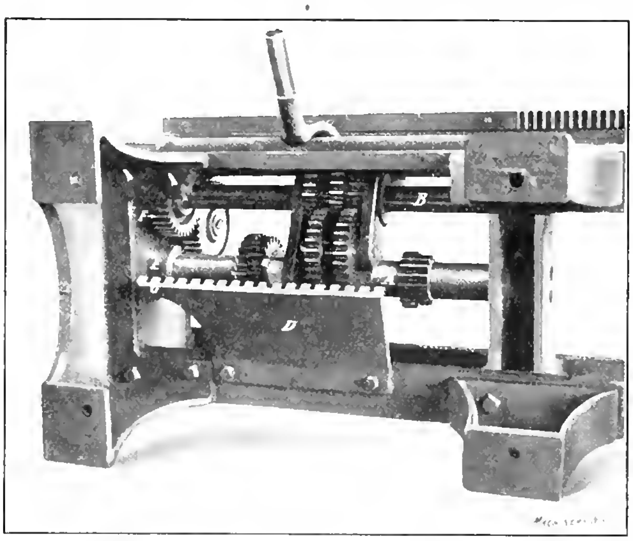

Fig. 3. Quick-change Gear Mechanism of Lathe shown in Fig. 1

fits the keyway in the bed; and endwise by being brought flush with the end of the bed. When in this position lines are scribed at *B* and *C*, after which the templet is removed and the hole counterbored to the line; *C* is chipped out later on if necessary.

To locate the surface *E* for the sweep clamping bolt hole, the gage *F* is used, its construction being clearly shown in Fig. 4. All lateral measurements on the bed are taken from the surface *B*. Facing surface *E* completes the operations for this setting, and the bed is then moved around for drilling and tapping the lead-screw box bolt holes.

In Fig. 5, *A* and *B* are jigs for drilling the front and rear lead-screw box seats, respectively. As will be seen, both jigs are located from the flat surface on top of the bed, the rear jig clearing the front V. Jig *A* is located endwise by seating against the hub *C*; the wooden pole *D* is used to set jig *B*. This pole has lines cut on one side, giving the settings for various lengths of beds up to 16 feet, so that the distance between the boxes, when bolted on, will be correct for the lead-screw. For longer beds, especially those in two sections, jig *B* is set from the rear end of the bed, and after the boxes are bolted on, the measurement is taken for the length to cut the lead-screw; it is not practicable to set the rear box or cut the lead-screw in the same way in this case as in the previous one, due to the error that is likely to occur in the length of the bed. This completes the work at the horizontal drill, and the bed is now moved to a radial drill, where the holes for the rack are next drilled. Special eccentric clamps are used for holding the rack in place, one of which is seen resting on top of the bed in Fig. 7. The advantages of this clamp over the common C-form are that it does not mar the work, no copper packing is needed, the clamping and loosening is quickly accomplished, and there is no danger of shifting the rack when clamping it.

When holes for the rack are all drilled, including the pin holes, the drill-hand taps and enters one screw in each rack section, so as to keep the rack in place after the clamps are removed, and until the bed reaches the assemblers. This avoids tying up the radial drill while the rack is being fastened on the bed, which is the practice in some shops.

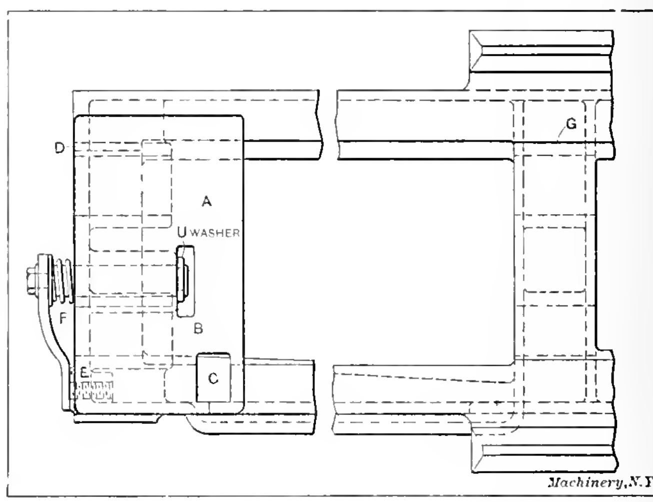

Fig. 4. Templet and Gage used when boring the Bed, shown in Position

On top of the bed in Fig. 7 are shown two fixtures *A* and *B*, respectively, which are used to locate the tumbler locking bar *D*, Fig. 3. Fixture *A* is also used to set the bushings *E* and *F*, Fig. 3, by inserting the stud in the fixture in place of the stud *C*, and bringing the bushings (which are straight) up against the hubs shown on the fixture. Now, with fixture *B* in position in the tumbler shaft hole, the locking bar is set so that its first notch *G*, Fig. 3, fits over the projection *C* of fixture *A*, Fig. 7. The plates *D* and *E* on fixture *B* are then moved so as to enter slots near the ends of the locking bar, after which the locking bar is set so that its slots bottom in the fixture plates. In this position the bar is marked off, and after drilling the two bolt holes, which have 1/16-inch clearance, it is again placed in position and clamped by its bolts. It is then shifted so as to bring it in the correct relation to the fixtures, and then the pin holes are drilled. With the bushings *E* and *F* (Fig. 3) located as previously mentioned, their set-screw holes are now drilled.

The legs are set and marked off on the bed with the aid of a wooden pole having lines scribed on it representing the center line of each inner leg. After these holes are drilled and tapped and the legs bolted on, the bed is next turned right side up for drilling the head-stock clamping bolt holes. The jig for drilling these holes is located on the bed by the keyway *D*, surface *G*, and hub *B*, Fig. 4, so that when the head-stock, which also was drilled by this jig, is bolted on, the feed gear on the spindle will line up with the intermediate feed

gear in the bed, and the head-stock casting will match the end of the bed. This completes the drilling, and the bed is next sent to the assemblers, where the actual work of assembling proper begins.

Scraping the Carriage and Assembling the Tumbler Mechanism

It is the general practice to keep the head-stocks, tail-stocks, carriages, tumbler members, etc., in stock, completely assembled, these units being identical for any length of bed. This method will be considered here, it being assumed that the units already have been brought to the assemblers. Two men usually are employed in assembling a lathe of this size, since a larger number cannot advantageously be used. Two men should be able to assemble such a lathe in 40 hours, total time. The operations of scraping on the carriage and assembling the tumbler mechanism are, of course, carried on simultaneously, one man working on each job; but for the purpose of description, each operation will be considered separately.

The preliminary operations on the bed consist of rough scraping the V's and inside bearing for the tailstock, fastening on the rack, and polishing the sides and top. When fastening on the rack, and polishing the sides, the bed is turned over for convenience of the workmen. The rack, which was temporarily fastened on by the drill-hand, is now removed and all the holes tapped, after which it is screwed fast, the pin holes reamed, and the pins driven in. A carpenter's brace is used for the taps and reamer. As the rack already has been polished on a disk grinder, it is only necessary to rub it with emery cloth to obtain a good finish. The bed is now turned right side up and carefully leveled, using iron wedges. During these preliminary operations the painting and any necessary chipping is done.

For scraping the carriage to fit the bed a special lifting device is used to facilitate turning the carriage over. This device was described by the author in the February issue of MACHINERY. When the carriage is being pulled along the bed for the purpose of finding the bearing, the lifter bolts are slackened off so as to prevent any danger of springing the carriage.

Fig. 6 clearly indicates the method of squaring the carriage with the bed. As will be seen, the sweep bar A is held in firm contact with the angle and bottom bearing of the carriage by means of two flat steel springs B, bent to the shape shown.

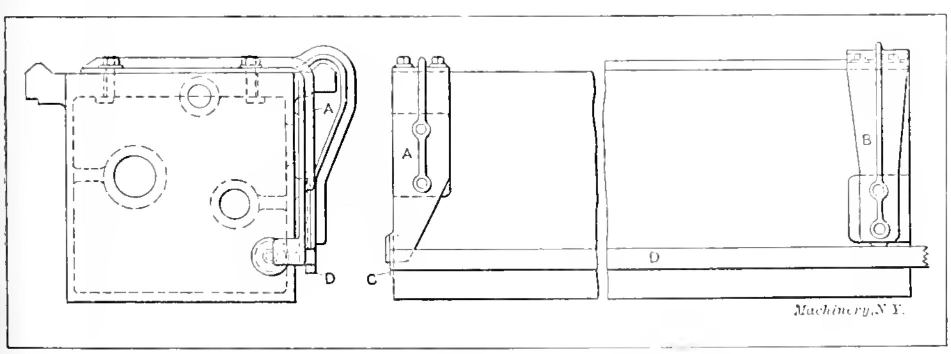

Fig. 5. Jigs used for Drilling Lead-screw Box Bolt Holes in the Bed

Brass shoes C, riveted to these springs, prevent the latter from cutting or scratching the bar. The function of coiled spring D is to hold the sweep bar collar E in close contact with the end of the carriage. With this device, the sweep is easily and quickly applied or removed, more precise measurements are obtained than by having an operator hold it, as is the usual practice; and besides, only one man is required to perform the operation of testing. In operation, micrometer point F is set to one position as shown, using a piece of cigarette paper as a "feeler"; then the sweep is rotated to the opposite side and a measurement taken as before. The carriage is scraped so as to turn the face-plate about 0.001 inch concave.

Very little scraping is necessary on the bed, merely enough to smooth the V's and break up the bearing, the tool marks being visible after the scraping is completed. When this work is accomplished, the carriage gibs are fitted, the apron is bolted in place, and the cross-feed screw, shoe, etc., are placed in position. Next, the tail-stock cricket is placed on the bed and its packing fitted, after which it is pulled the entire length of the bed to determine if the latter is straight. After any high spots on the bed are scraped off, the tail-stock traverse bracket is bolted onto the cricket, and then the tail-stock and its shoes are placed in position.

Referring again to Fig. 3, the tumbler mechanism is assembled in the bed as shown in the illustration, the operation being so simple that no explanation is necessary. Holes in the bed for the oil pipes (not shown) are drilled by means of a pneumatic drill, this being done, of course, preceding the assembling operation. The slot in the interlocking plate H is now marked off, the plate removed, and the slot cut. The position of this slot is determined by having the tumbler gears in a central position between the largest change gears. With the interlocking plate again screwed onto the tumbler, the thirty-four holes in the bed for the tumbler locking pin are now ready to be drilled.

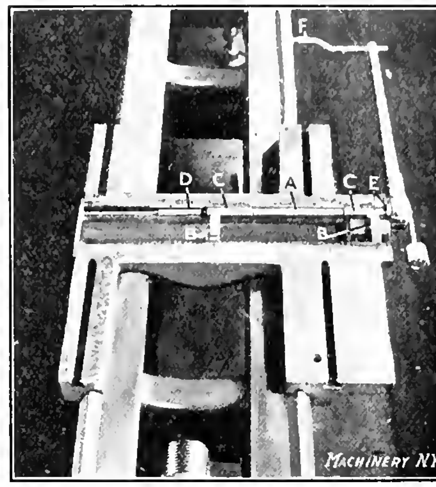

Fig. 6. Top View of Carriage, showing Method of Squaring the Carriage with the Bed. Springs B and D hold the Sweep in Position, enabling One Man to make the Test

Drilling these holes is the most interesting operation on this part of the lathe, the manner of accomplishing it being immediately apparent from Fig. 8, which shows the tools used, some of them being seen on top of the bed. The method of holding the tumbler in engagement with the various change gears while drilling the holes in the bed is clearly shown in Fig. 9. Paper, to the thickness of about 0.005 inch, is placed between the teeth of the engaging gears before they are brought into mesh, and when the jack screw A is tightened sufficiently to hold the tumbler rigidly in place, the gears are in proper mesh. The holes are first drilled with a special drill that fits the locking pin hole in the tumbler and has flutes milled only a short distance up from the point, so as to avoid cutting the hole in the tumbler. Fig. 8 shows this drill in position in the air drill. For finishing the holes, a special rose reamer, shown at B, is used in the same manner.

The tools are fed into the work by means of the bar C, which is pointed on one end so that it can be driven into the floor to prevent slipping. The operator presses his shoulder against the upper end of the bar, holds the throttle of the air drill with the left hand and pulls on the bed with the right hand. Each hole is drilled in succession, alternating between the top and bottom rows. The record for drilling and reaming these thirty-four holes, including the time required to set the tumbler, is 50 minutes. In setting the tumbler for drilling, its lateral movement for the various positions is controlled by the interlocking plate engaging the respective slots in the locking bar. (See Fig. 9.)

To mark off the groove which is seen between the two rows of holes in Fig. 1, a special scriber is used that fits the tumbler locking-pin hole, the tumbler being held in a neutral position by the locking bar. Two circles are scribed, one at each end of the groove to be cut, and then a straightedge is used in scribing lines connecting the two, the lines acting as a guide when chipping the groove with an air hammer. Inserting the handle, chipping the groove, and fastening on the number and index plates completes the operation on the tumbler mechanism.

Lining up the Head-stock and Tail-stock

The bed is now ready to receive the head-stock and while this is being fitted on by one of the assemblers, the other is working on the lead-screw, lead-screw boxes, and change gear sweep. As the head- and tail-stock were tested for alignment before being sent to the store-room, it is now only necessary to line up the head-stock on the bed and fit the taper dowel pins.

The method of testing these parts is interesting, inasmuch as the test arbor used is somewhat out of the ordinary. A jig is used that represents the head-end section of a 24-inch lathe bed. The jig and whole outfit of fixtures used, together with a head- and tail-stock in position for testing, is shown in Fig. 10. As will be seen, the test bar is square at *A*, near each end, the object being to use the indicator on a flat surface when testing the spindle for parallelism with the V's, and on a cylindrical surface when testing the spindle taper hole for concentricity. The two squares are integral with a sleeve that can be turned independently of the bar, and in this way one plane surface can be set at a mean between the "high" and "low" point on the bar. This adjustment is obviously necessary, since the bar is particularly liable to run out at its free end, due to a number of conflicting elements, the error in any one of which may be infinitesimal. When using the plane surfaces, one of these is always trued up with the square *B*, as shown in the engraving.

The reason for providing a plane surface on which to indicate is this: Suppose, for example, that we are testing the spindle for alignment sideways, and further that the axis of the spindle actually is parallel sideways with the bed, but

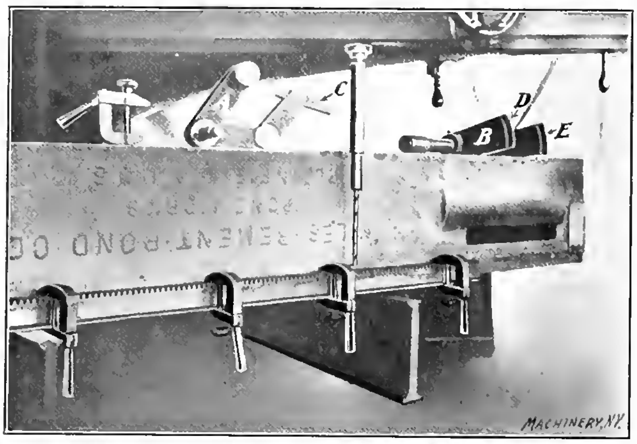

Fig. 7. Special Clamps for Holding Rack in Position when Drilling, and Fixtures used for Locating Tumbler Locking Plate

that the axis does not lie in a horizontal plane, it being high on the front end, say 0.005 inch in the length of the test bar. Then in indicating on the older type of bar with cylindrical collars, the line of motion of the indicator point in traveling from one collar to the other is not parallel with the axis of the test bar and therefore the readings are false. Now, with the form of bar having plane surfaces, assuming the conditions to be the same as regards the alignment of the spindle, the reading will show that the alignment is perfect sideways, because the indicator point is moving on a plane surface.

Referring again to Fig. 10, the fixture *C* is guided on the V tracks of the bed and is constructed so that it is adjustable for holding a Starret indicator *D* either on the side or top of the bar as the case may require. Having explained the use of the tools and fixtures, the method of "lining up" the head-stock and tail-stock, both with reference to the V's and to each other, is to place them on the bed and approximately set the head-stock true sideways by inserting keys in the keyways planed in the head-stock and bed for this purpose.

With the clamping bolts tightened lightly (the bolts have 1/16-inch clearance), the head-stock spindle taper hole is first tested for concentricity by indicating on the cylindrical surface *E* while slowly rotating the spindle. Then with the squares *A* set as previously explained, the head-stock is moved around by knocking it with a babbitt hammer until the reading on both surfaces is the same. The bar is then moved over into the tail-stock spindle hole, and after the set-over screw *F* is adjusted so as to bring this spindle in line with that in the head-stock (the reading being the same as before) the tail-stock spindle is tested for alignment sideways. Now the indicator is set on top of the bar, with the latter turned so as to use the same surface, and then the tail-stock spindle is tested for alignment in a horizontal plane, after which the bar is again set into the head-stock spindle hole and that spindle tested both with reference to the V's and to the tail-stock spindle. It is understood, of course, that if any errors are discovered which exceed the allowable limits of variation, the part at fault is either filed and scraped to bring it true, or machined, if the circumstances warrant.

Turning again to the lathe bed, we will assume that the head-stock is lined up as just described, and the clamping

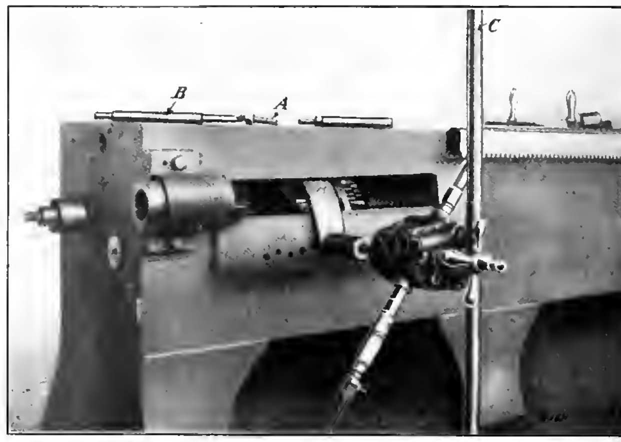

Fig. 8. Method of Drilling and Reaming the Holes in the Lathe Bed for the Tumbler Locking Pins

bolts are tightened down hard. The taper dowel pin holes are then drilled, reamed, and the pins driven in, care being exercised to see that the pins are a good fit. Next the face-plate is screwed on, ready to be turned off.

Lining up the Lead-screw Boxes

As was previously stated, work has been progressing on the lead-screw boxes and other minor details. For the purpose of lining up the boxes and also to test the alignment of the lead-screw bearings in the apron, a short arbor is used that represents the lead-screw. First the apron is tested, and then the lead-screw boxes are bolted onto the bed and lined up with the apron. Sometimes it is necessary to file the apron seats or adjust the boxes to bring them into proper alignment; but with careful planing and thorough inspection of the parts, this should not be required. Two special gages are used to

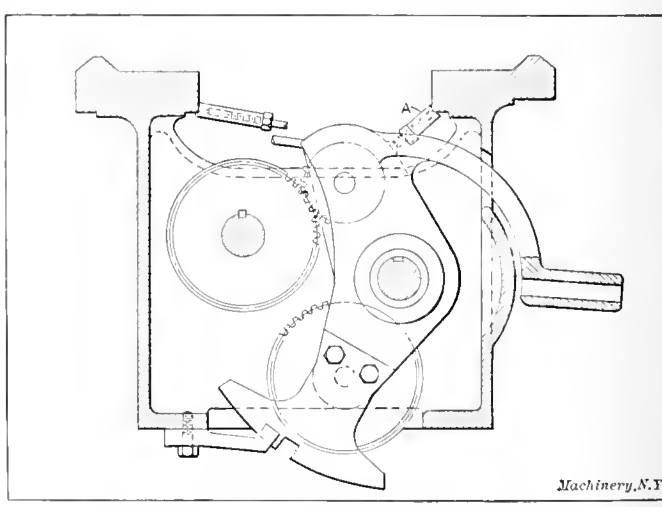

Fig. 9. Method of Holding Tumbler when Drilling and Reeming the Locking Pin Holes by the Method shown in Fig. 8

facilitate the aligning; one gage reaches down from the flat track on top of the bed for horizontal measurements, while another is held against the side of the bed just below the V to test sideways. Both gages are provided with micrometer points to enable the accurate measurement of error.

Referring to Fig. 1, the head-end lead-screw box is set longitudinally when the change gear sweep is in place, so as to line the box with reference to the sweep bearing on the end of the bed. When properly set, the boxes are drilled and reamed for the taper dowel pins; then the lead-screw is put

in place, its checknuts screwed on, and the gears on the sweep brought into proper mesh.

The Finishing Operations and Inspection

With the cone belted up to a countershaft or other source of power, the bearings are thoroughly oiled, and the lathe is run idle for a while preparatory to turning off the faceplate. The V's on the bed and bearings on top of the carriage are now spotted with a scraper, while all other finished surfaces receive their final polishing. The centers and their respective holes in the spindles were fitted to male and female gages during the machining process, so that now it is only necessary to place the centers in position. Clamping on the center-rest is the final assembling operation.

All machines are more or less defective, as it is practically impossible to make anything absolutely perfect. Knowing this, the builder establishes a limit within which the error will not materially affect the working of the machine, and furnishes the inspector with a list of allowable limits.

The inspection is carried on as the work proceeds, so that no part is neglected, and no defective material or faulty workmanship is allowed to pass. Gearing of all kinds is inspected and tested for alignment and smoothness of operation. The fits of all wearing surfaces are tested, as well as the fit of the

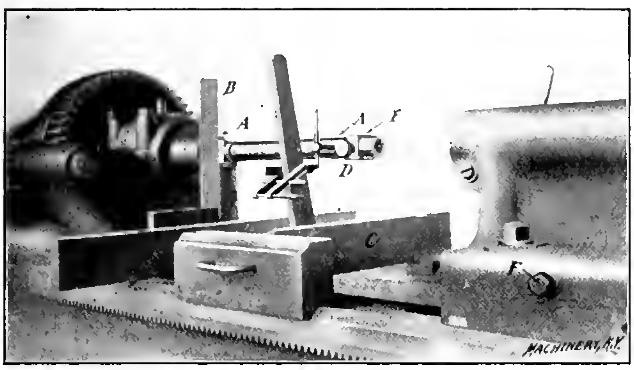

Fig. 10. Special Form of Test Bar for Aligning Head- and Tail-stock. Plane Surfaces are used for Testing Parallelism, and Cylindrical Surfaces for Testing Concentricity

various screws and binding and clamping fixtures. All information obtained from the inspection is entered on a printed form. Each machine is given a serial number, and the reports are filed in the office, so that in case of any trouble arising or any repairs being required for a given lathe, an exact record of its condition when it left the shop is available.

After truing up the face-plate, it is tested by means of a straight-edge and cigarette paper, this kind of paper being the best for the purpose. The spindle is tested for end motion when running, by application of the Starrett indicator to the face of the spindle nose. To prove the alignment of the head spindle with the shears of the lathe and the alignment of the taper hole with the spindle, under actual working conditions, a steel test bar is provided which fits the taper hole and projects 18 inches from the spindle. This bar carries three cast-iron collars, placed one at each end and one in the middle, from which all measurements are taken. A light cut is taken across these collars with a keen diamond-point tool, and the collars are then measured with a micrometer. As it is desirable when boring a hole, to have the taper, if any, large toward the front end, the front end of the head-stock was purposely set slightly toward the rear of the bed so that the outer collar should be found 0.0005 inch larger than the collar next the spindle. The alignment of the spindle in the vertical plane is again tested by attaching the indicator to the tool-post and traversing the carriage along its ways with the contact point of the indicator pressing against the top surface of the collars.

In testing the alignment of the taper hole with the spindle itself, after the collars have been turned off, the test bar is removed, turned half way round and replaced in the spindle; the indicator is then put in the tool-post in place of the turning tool, and with the contact point on the center line the indicator is traversed past the collars, the variation in readings showing twice the error in the alignment of the taper. The alignment of the tail-stock spindle is now tested, the method being the same as in the previous instance.

APPROXIMATE HORSE-POWER FORMULAS FOR GASOLINE ENGINES

In the September 3, 1909, issue of *Industritidningen Norden*, Mr. E. Hubendick reviews the various approximate formulas which have been adopted or proposed by a number of societies and individuals for the horse-power of gasoline engines. In these formulas

D = diameter of cylinder,

N = number of cylinders,

S = length of stroke,

n = number of revolutions per minute.

The French Automobile Club's formula is:

H. P. $= 0.07\ D^2N$, when the diameter is given in centimeters,

H. P. $= 0.45\ D^2N$, when the diameter is given in inches.

In this formula the mean pressure has been assumed to be 5.3 kilograms per square centimeter (75 pounds per square inch), and the piston speed 5 meters (16 feet 5 inches) per second.

The Royal Automobile Club's (British) formula is:

H. P. $= 0.0625\ D^2N$, when the diameter is in centimeters.

H. P. $= 0.405\ D^2N$, when the diameter is given in inches.

Mr. Arnon's formula is:

H. P. $= 0.0061\ D^3N$, when the diameter is in centimeters.

H. P. $= 0.1\ D^3N$, when the diameter is given in inches.

Mr. Faroux's formula is:

H. P. $= 0.0074\ D^{2.4}\ S^{0.6}$, when the diameter is in centimeters.

H. P. $= 0.121\ D^{2.4}\ S^{0.6}$, when the diameter is given in inches.

Another French formula is as follows:

H. P. $= 0.02562\ D^{2.4}\ N$, when the diameter is in centimeters,

H. P. $= 0.24\ D^{2.4}\ N$, when the diameter is given in inches.

Mr. T. Thornycroft's formula is:

H. P. $= \dfrac{D^2\ S^{0.75}\ N}{35{,}000}$, when the diameter is given in centimeters,

H. P. $= \dfrac{D^2\ S^{0.75}\ N}{2{,}700}$, when the diameter is given in inches.

Prof. H. L. Callender's formula is:

H. P. $= 0.0875D\ (D - 2.5)\ N$, when the diameter is given in centimeters.

H. P. $= 0.565D\ (D - 1)\ N$, when the diameter is given in inches.

In this latter formula the mean pressure is assumed to vary in the same proportion as $\left(1 - \dfrac{2.5}{D}\right)$ if the diameter is given in centimeters, and $\left(1 - \dfrac{1}{D}\right)$ if the diameter is given in inches.

The Royal Automobile Club's (Swedish) formula is:

H. P. $= \dfrac{D^2SnN}{250{,}000}$, when the diameter is given in centimeters,

H. P. $= \dfrac{D^2SnN}{15{,}240}$, when the diameter is given in inches.

In this connection the formula of the Association of Licensed Automobile Manufacturers, which has previously been published in MACHINERY, should be included:

H. P. $= \dfrac{D^2N}{2.5}$, when the diameter is given in inches.

H. P. $= 0.062\ D^2N$, when the diameter is given in centimeters

The horse-power of automobile engines, based on this last formula, for various diameters of cylinders, was tabulated in the Data Sheet Supplement accompanying the October, 1909, issue of MACHINERY.

Some of the formulas proposed, with fractional exponents, are more cumbersome to use than would be the exact horse-power formula, and are of very doubtful value for their purpose. It is difficult to understand why one should be given an approximate formula at all, unless the form of that formula be such that it greatly facilitates computations, as compared with the exact formula. In this respect the A. L. A. M. formula is one of the best of those given above.

NORWEGIAN LATHE OF MODERN DESIGN*†

The accompanying half-tone, Fig. 1, illustrates a 20-inch engine lathe embodying some new and interesting features, including a special all-gear head-stock, which has recently been brought out by Brödrene Sundt, Christiania, Norway, one of the most prominent of the Norwegian machine tool building firms.

The special feature of this lathe is the interesting and original design of the gearing in the head-stock. As will be seen from the half-tone illustration, the machine is of the single-pulley all-gear head type; a section through the head, indicating the arrangement of the gearing, is shown in the line engraving in Fig. 2. Through an interesting arrangement of the driving mechanism, the number of gears and shafts in the head-stock is reduced to a minimum, so that only nine gears in all are used to obtain eight different speeds.

Referring to Fig. 2, the gear *A* runs loose on the spindle *K*, while gear *B* is keyed to the spindle and is capable of sliding back and forth, so that it may be either in engagement with gear *C* on the intermediate shaft *L*, or engaged by clutch teeth on its end with similar clutch teeth on gear *A*. Gear *C* is keyed to the intermediate shaft *L* and gear *D* is made in one piece with this shaft. Gear *E* on shaft *M* meshes with gear *C*. It is keyed to its shaft, and is capable of sliding out of engagement with *C*. The rawhide gear *F*, also keyed to shaft *M*, meshes with gear *G*, which runs loose on a bushing on the main driving shaft *N*. Finally, gear *H* is also keyed to shaft *M* and meshes with gear *I* on the main driving shaft. This latter gear is keyed to its shaft, but is capable of sliding so that it may either mesh with gear *H*, or be brought into engagement by means of the clutch teeth on its end with corresponding clutch teeth on gear *G*.

The different speeds are obtained by the operation of the three handles or clutch levers shown in Fig. 1, two in the front of the head-stock and one on the top. One of the handles, which provides the sliding motion for gear *E*, as indicated in Fig. 2, operates also, simultaneously, by means of the rack *P*, the sleeve *O* keyed to shaft *L*, on the end of which clutch teeth are provided, meshing with similar teeth on the projecting hub of gear *G*. Another of the levers operates gear *I*, and the third lever gear *B*.

The eight spindle speeds are obtainable by the following gear combinations:

1st speed—Through gears *I, H, E, C, D* and *A*.
2nd speed—Through gears *G, F, E, C, D* and *A*.
3rd speed—Through gears *I, H, F, G, D* and *A*.
4th speed—Through gears *D* and *A* directly.
5th speed—Through gears *I, H, E, C* and *B*.
6th speed—Through gears *G, F, E, C* and *B*.
7th speed—Through gears *I, H, F, G, C* and *B*.
8th speed—Through gears *C* and *B* directly.

These speeds are doubled by means of a two-speed countershaft running, respectively, at 200 and 260 revolutions per minute. The sixteen spindle speeds thus obtainable by means of the head gearing and the two-speed countershaft are as follows: 9, 12, 15.5, 20, 24, 30, 38, 50, 55, 70, 90, 115, 135, 175, 225 and 290 revolutions per minute.

There is no clearance between the clutch teeth on the various gears. They are milled with an angle of 7 degrees on the sides and can be thrown in mesh without difficulty, under any conditions. When gear *B* occupies its medium or neutral position the spindle can easily be rotated by hand. The driving pulley is provided with a special friction which can be instantly released by operating the friction clutch lever con-

† The following articles describing lathes with geared heads have previously been published in MACHINERY: A New "American" Motor-driven Lathe, December, 1902; A New Motor-driven Lathe, March, 1903; The "Ideal" Engine Lathe with Motor Drive, January, 1904; New Flat Turret Lathe, May, 1904; Sixty-inch Roll Turning Lathe, October, 1904; Thirty-inch American Engine Lathe, October, 1904; Lodge & Shipley Lathe with Motor, November, 1904; American Twenty-two-inch Lathe, December, 1904; Motor-driven Lathe with Geared Head, June, 1905; The Draper Geared Head Lathe, July, 1905; Rapid Reduction Lathe, Nineteen-inch Capacity, July, 1905; Hendey-Norton Lathes, April, 1906; Pratt & Whitney Sixteen-inch Toolmakers' Lathe, March, 1907; New Design of the Lo-swing Lathe, September, 1907; The Full Swing Side Carriage Turret Lathe, December, 1907; Notes from the Olympia Exhibition, December, 1907; Motor Drive Mechanisms for the Le Blond Lathes and Milling Machines, February, 1908; Bridgeford Geared Head Lathe, March, 1908; Libby Turret Lathe, March, 1908; Springfield Motor-driven Brass Finishers' Lathe, April, 1908; Bridgeford Thirty-six-inch Geared Head Lathe, May, 1908; Hendey Single-pulley and Motor-driven Geared Head Lathes, May, 1908; Schellenbach Sixteen-inch Geared Head Lathe, June, 1908; Rahn-Carpenter Sixteen-inch Motor-driven Lathe, June, 1908; Springfield High-power Motor-driven Lathe, July, 1908; British Machine Tools at the Franco-British Exhibition, September, 1908; Lodge & Shipley Heavy Axle Lathe, January, 1909; Prentice Brothers' Sixteen-inch Shaft Turning Lathe, January, 1909; Whitcomb-Blaisdell Single-Speed-Pulley Gear-driven Lathe, January, 1909; Societe Francaise de Machine-Outils Single-Pulley-Drive Lathe, March, 1909; Modern Swedish Machine Tools, March, 1909; Lodge & Shipley Crank-Shaft Lathe, June, 1909; Lodge & Shipley Lathe With Automatic Feed Stops, July, 1909; The Lodge & Shipley "Marvel" Lathe, August, 1909; Bradford Sixteen-inch Motor-driven Engine Lathe, October, 1909; Bridgeford Bevel Gear Turning Lathe, October, 1909.

nected with the rod passing the full length of the machine, as shown in Fig. 1.

The construction of the friction drive in the pulley is briefly as follows: The friction ring *R*, Fig. 2, is made in halves enclosing the spindle driver *S*. Both halves of the ring can be made to grip the spindle driver *S* by means of the tighteners *T*, operated by the fingers *U*. Only one set of these is shown. Two helical springs hold the rings away from the driver *S* as soon as the friction is released.

The clutches in the geared head are so arranged that two different speeds can never be applied simultaneously, and therefore there is no danger of breakage to the gears due to the carelessness or ignorance of the operator. All the speeds can be changed without stopping the belt or motor.

The bed of the lathe, as seen in Fig. 1, is of deep box construction, and is ribbed on the inside at short intervals with strong cross ribs. The spindle is forged of Bessemer steel and runs in journals of phosphor bronze. As shown in Fig. 2, there is a hole clear through the spindle. The end pressure is taken up by hardened steel and phosphor-bronze washers, cased in so as to be perfectly dust-proof. All the bearings are provided with automatic lubrication, and as the spindle is free from belt pull, the accuracy of the work done on the lathe is not affected by this influence.

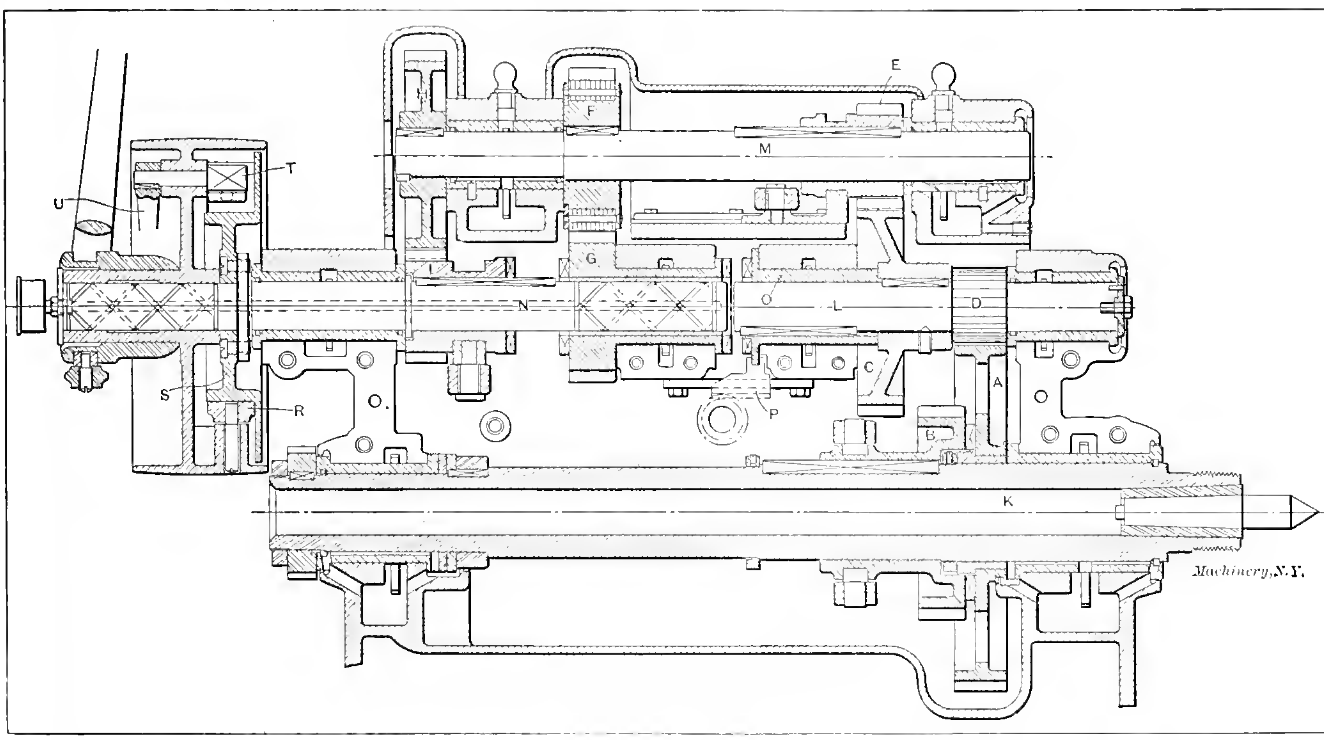

Fig. 2. Section of Head-stock, showing Geared Drive of Norwegian Lathe

The screw cutting and feed arrangement is through a feed gear box operated by two handles. Thirty-seven different pitches can be obtained for thread cutting without changing any gears or stopping the machine. The carriage is of heavy construction; the gears in the apron are cut and of steel, the same as all the gears in the head-stock. The studs for the gears are hardened and ground on the bearing ends. There is no separate feed rod, the lead-screw being splined, and the half-nuts disengaged when the lathe is not used for thread cutting, the rack-feed being used for ordinary feed of the carriage. Provision is made for preventing simultaneous engagement of the lead-screw and rack-feed, and the feeds are reversed directly from the apron. As will be seen in Fig. 1, all gears are properly protected by guards.

The general dimensions of the lathe are as follows: The swing over the bed is 20 inches, and the swing over the carriage 13¾ inches. The length of the bed is 10 feet, and the maximum distance between the centers, 5 feet 6 inches. The hole through the spindle is 1¾ inch in diameter. The machine can be either belt-driven from a countershaft, or provided with direct motor drive. A five horse-power motor is required. The approximate weight of the machine is 5,100 pounds. A 22-inch size of the same design is also made by the builders.

THE CREATION OF MACHINISTS*

Referring to the title of the paper, namely, "The Creation of Machinists," I will merely mention the matter of apprentices, because the subject of this paper is more to show how to create machinists without passing through an apprenticeship, because of the extreme shortage of machinists throughout the whole United States.

A few years back we found that we were unable to obtain boys as apprentices, for the reason that they could get better pay in other trades, such as shoe factories, tobacco factories, tanneries, dry goods and other stores, and this caused us to raise the hourly rate, which was originally 5 cents, to 8 cents. But at that time we were allowed to use boys between the ages of 14 and 16 years. Since then a law has been passed in Ohio prohibiting boys working more than eight hours when under 16 years of age; and in order to comply with this law, we discharged all boys who were under 16 years. We then found, speaking for our own company, that in order to get a sufficient supply, the rate must again be raised from 8 cents to 9 cents per hour.

Simultaneously with this difficulty of obtaining boys, came the great activity among the builders of automobiles. This occurred during the time that business was very dull in the machine tool line. When business became active once more, having the addresses of all of the machinists who were formerly employed by us, we sent to each one a letter, stating that they could return to work, and we were surprised to receive almost no responses; and we then saw that we would be obliged to go into the creation of machinists on rather a large scale. Advertising in the daily papers and in the *American Machinist* brought comparatively no results. We then decided to re-arrange our work and divide it into very much smaller items than heretofore, arranging the parts so that they could be machined with the greatest possible simplicity, and then set about inquiring for men, not machinists, and the following advertisement was put in the daily papers:

WANTED—Young men between the ages of 20 and 30 years. Fair wages and good opportunities for advancement. Men accustomed to safe making or carriage making preferred.

The first day following this advertisement we obtained twelve out of possibly thirty applicants. They were selected largely because of their former experience, and somewhat upon their personality, personal appearance and address. These twelve men were placed, one in each of twelve departments, with instructions to the foremen as to the pieces they

* Paper read before the National Machine Tool Builders' Convention, New York, October 12, 1909.

should be taught how to produce. We found that by this method the first installment of twelve were readily assimilated, so that within one month we were ready for similar installment.

Now I will give you an idea as to how we proceeded in the matter: We arranged with a first-class machinist who has been with us a long time, in whom we have a great deal of confidence, and who possesses the art of knowing how to teach, to go from one man to another, see how he was performing his part of the work, set him right when he was wrong, and give him further explanations when an additional piece was added to the work he had already been taught. All of this involved the installment of some new tools, and in the beginning a slower production; but as these young men became better acquainted with the work, we advanced them from 15 cents to 17½ cents per hour, and some of them to 20 cents per hour, and it now appears that quite a number of them within a very short time may be advanced to 22½ cents, from that to 25 cents, and so on. As this advance takes place, they will, of course, have been taught how to do additional pieces.

All of this taxes the patience of the foremen quite considerably, and results of course in more spoiled pieces of work, but the final result of obtaining a sufficient number of men to run the establishment is brought about. There is the further advantage that men with the limited knowledge that these men must necessarily have, do not have the confidence to change into other shops so readily as the regular machinist.

There is another reason why machinists are so scarce, and that is the many fields to which they are called, and which fields do not make machinists. Let anyone call to mind how many machinists are now employed in hotels and large office buildings for running the elevators and electric light plants; how many are now taken for street railroads; besides all those who are taken into the office and drawing rooms or who are sent out on the road. Every consumer of machinists should be a producer; in the trades mentioned they are not producers, and consequently it is advisable for every machine shop, regardless of business conditions, to start more beginners than they need. The shop itself will require an increased number when the beginners graduate; some will drop out, some will be dropped, and others will be enticed into new enterprises which must have machinists ready-made. Beginners once obtained should be encouraged at every step. They should be given as little disagreeable work to do as practicable. They should be given the best work that they are capable of doing. They should be made machinists at once if their capabilities permit of it. A vacancy for even one hour in a higher place should be filled for that hour by one from a lower place. All the employes should be given all the encouragement possible that would take them into night schools, trade schools and correspondence schools. Wherever there is a serious shortage the men in your employment should be asked to invite any of their acquaintances to make application for employment in the machine shop.

To carry out the above recommendations it is necessary to make the machine shop something of a school. It is not likely that young men with a very limited knowledge of the machine making business will know just where the points of excellence are wanted, and in order to place the matter before them permanently, rather than to depend upon their foreman telling them, certain instructions, which are issued in any event to the inspectors, should be issued to each and every one of the men in the establishment, or if not, then at least they should be hung in such a position that each and every man and boy may read them.

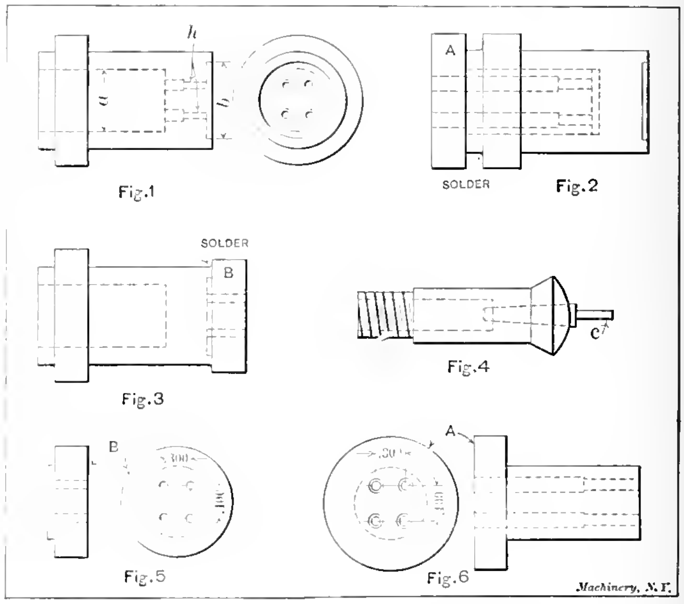
Very strict orders should be given to all foremen and superintendents to make every endeavor to retain any man who wants to leave, or anyone they are inclined to discharge. This is of the utmost importance, as otherwise it keeps a regular stream of men coming into the place and leaving it. One of the manufacturers in Detroit told me a few days ago that he was obliged to discharge and take on seven hundred and fifty men every month. It is not to be expected that we can create machinists in a short space of time without giving the method of doing it a great deal of care, and unless the man is a drunkard, or has an exceedingly bad disposition, good treatment and a sufficient amount of tact and patience will retain a great many who are otherwise discharged.

MACHINE SHOP PRACTICE*

JIG AND DIE WORK IN THE BENCH LATHE—1

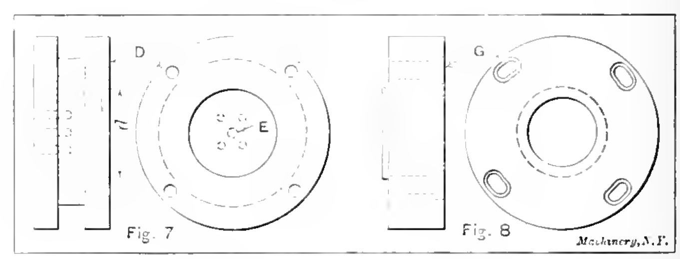
A. L. MONRAD†

In the manufacture of fine machinery, and for the finer work of the tool-room, the bench lathe is found invaluable, as the ordinary engine lathe is too large and unwieldy for this class of work. As the bench lathe is used exclusively for light precision work, it is made with great accuracy, and it is usually equipped with milling, grinding, screw-cutting and other attachments which make it suitable for a wide range of work. As an example of the kind of work for which



Figs. 1 to 6. Die and Jigs for Drilling it

the bench lathe is adapted, we have selected and will describe in detail the way in which two small jigs are made, which are to be used for drilling the holes *h* in the die shown in Fig. 1. As the inner half of each of these holes is enlarged, the drilling is done from each side of the die, the jigs *A* and *B* being inserted as shown in Figs. 2 and 3, respectively. Jig *A* is used for the larger holes, and *B* for the smaller ones. These jigs, which are shown in detail in Figs. 5 and 6, are made of brass. While they are being turned, they are held in a universal chuck screwed on the bench lathe spindle. The shoulder on jig *B* is fitted accurately to the recess *b* in the die, and the body of jig *A* is also turned to a close fit for the hole *a*. In order to bore the holes in each of these jigs in exactly the same relative positions, a steel master-plate *D*



Figs. 7 and 8. Master Plate and Attached Piece used in drilling Holes in Jigs, Figs. 5 and 6

(Fig. 7) is first made, the use of which will be explained presently. This plate should be first turned in an engine lathe; it is then strapped to the face-plate *F* of the bench lathe (Fig. 9), and both sides are faced so that they are exactly parallel. The outside of the master-plate should be set perfectly true by the use of a test indicator, after which a central hole *E* is bored and reamed to fit a plug gage 0.050 inch in diameter. The master-plate is then removed, and the four outer holes shown in the end view are laid out from the center hole to the dimensions given in Figs. 5 and 6. The centers of these holes are next drilled and tapped for 1/32-inch screws, which are to be used for holding indicator buttons in place. These buttons are small cylindrical pieces which are

* With Shop Operation Sheet Supplement.
† Address: 58 Connecticut Boulevard, East Hartford, Conn.

used by tool-makers for accurately locating work. Four of the buttons are fastened to the plate with small screws, and then by working from a plug in the central hole, the buttons are shifted until their center distances exactly coincide to those given in Figs. 5 and 6. When the buttons are accurately set, the master-plate is again strapped to the face-plate, and a test indicator is used to set one of the buttons perfectly true. This one is then removed so that a hole may be bored and reamed. In the same way the other three holes are bored and reamed, and the size of each is made to coincide with that of the central hole *E*. It will be seen that if the buttons are accurately set, the center distances of the holes will also be accurate, as they are bored concentric with the buttons. A piece of wire *C* (Fig. 4) is next turned to fit the taper hole in a collet, as shown, after which both the collet and wire are placed in the lathe spindle, the face-plate is removed, and the end of the wire is turned to a close fit for the holes in the master-plate. The face-plate is again screwed on the lathe spindle, and the master-plate is strapped to it with the wire plug *C* in its center hole. The recess *d* (Fig. 7) is now turned in the plate after which it is removed

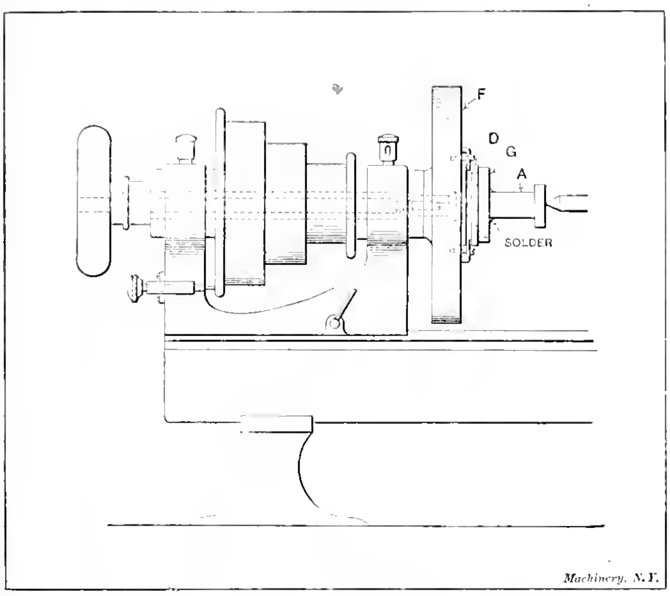


Fig. 9. Master Plate and Jig strepped to Face-plate

so that the four 3/16-inch screw holes shown may be drilled and tapped in its outer flange. A brass piece *G* (Fig. 8) is next turned and a shoulder is formed on it which is an accurate fit in the recess *d* in the master-plate. Four elongated holes are also milled in a piece *G* to match the holes in the flange of the master-plate. Piece *G* is then fastened to the master-plate, and the latter is strapped to the face-plate of the lathe, with the wire plug *C* in its central hole. A recess is then bored in *G* to an accurate fit for the small end of jig *A*, which is then soldered to *G* while the tail center is against the end, as shown in Fig. 9. The master-plate is now shifted so that one of the four outer holes fits over the wire plug in the spindle. When the master-plate is changed to a new position, care should be taken to see that no dirt or chips get between it and the face-plate, as these would, of course, impair the accuracy of the work. One of the four holes is now bored, reamed and counterbored in jig *A*. In the same manner the remaining three holes are finished, and, obviously, their location will correspond to the holes in the master-plate. When the holes are finished, the jig is easily removed by turning off the solder with a side tool. The master-plate should now be placed in its central position and a larger recess turned in *G* to fit the shoulder on jig *B*. This jig is then soldered to *J*, and four holes are drilled in it in the same manner as described for jig *A*. In a continuation of this article, a method of drilling holes in a hardened die, which was employed for special reasons, and also the way in which the drilled holes are ground, will be explained.

* * *

Plans have been approved by the Swiss State Railways for building the Hauenstein Railway, which will shorten the route from St. Gotthard to Basilea by about 40 miles.

INDUSTRIAL EDUCATION—INCREASING THE SUPPLY AND EFFICIENCY OF MACHINISTS—THE CINCINNATI PLAN*

F. A. GEIER†

The rapid development of the manufacturing interests of our country during the past decade, particularly in the metal-working lines, is yearly increasing the problem of finding an adequate supply of labor, and of a proper degree of efficiency. The system of education in this country has not, until the recent past, taken cognizance of the change of the requirements of labor that has come about through this industrial development. Manufacturers have for some time realized that the efficiency of the labor that offers itself for employment is not as high as it should be. To a large extent this is due to the fact that the great majority of applicants have not gone beyond the elementary schools, and are not prepared to meet the problems that confront them upon entering the manufacturing establishments. The courses of these elementary schools, have not been such as to hold the interest of the boys, a great many leaving the schools entirely too young and with a very poor foundation even in the rudiments of education.

Manufacturing processes are becoming more highly organized and while there is a greater subdivision of labor, I believe it is true that we need a working force to-day of greater general intelligence than in the days when simpler machines and simpler processes were employed in producing our work. A careful analysis of the conditions in any manufacturing plant, will reveal a tremendous waste, because of the abuse of machinery and tools, a low standard of work, spoiled pieces, etc., a great part of which waste could be eliminated if there were a higher degree of intelligence on the part of the workmen.

America has led the world industrially, because of the natural advantages of a large home market, and of its superior advantages as to cost of raw materials. Europe and notably Germany, largely offset our natural advantages by a superior training of its employes. Our advantages as to sources of raw materials are lessening year by year. If we are to increase our home and foreign trade we must train our employes better. The movement to this end has begun, and I am asked to speak to you more specifically as to what has been done in Cincinnati.

Cincinnati has the oldest mechanics' institute in this country. This institution, with its night classes, has been doing pioneer work along these lines for many years. It is, however, not a natural condition for young men to be compelled to get their education in this way. Boys attending these schools, tired out from the day's work, cannot make the progress that they should, and often become discouraged.

About four years ago the Board of Education of Cincinnati established manual training in the elementary grades. Two magnificent technological high schools are about completed, and in these schools such training will be given as will be exceedingly useful to the boys, as they subsequently enter manufacturing establishments. The courses comprise woodworking, metal working, foundry work, mechanical drawing, and such allied branches as physics, chemistry, etc.

You all know about the cooperative course for engineering established three years ago at the University of Cincinnati, in which boys who have passed through the high schools can enter this six-year course, working one week at the shop, and one week at the university, earning, during the period of six years, about $1,800. About 200 of these boys are now employed in Cincinnati shops. While there are exceptions to the rule, as a class, these boys have surprised their employers as to the character and quality of work they are able to do. In fact, the experience has been very satisfactory. Right in the beginning there was considerable skepticism on the part of the manufacturers and a reluctance to accept these boys. The shops to-day are offering to take on more new men than the university facilities can take care of at present.

In our own plant, we have found some of these boys available for some of our difficult work, and this is also true in

* Paper read before the National Machine Tool Builders' Convention, New York, October 12, 1909.

† President of the Cincinnati Milling Machine Co., Cincinnati, Ohio.

other shops. I call attention to this because the experience with these engineering students has practically demonstrated to the Cincinnati manufacturers the value of educated and properly trained young men. The great mass of our employes, however, in the future, as in the past, will be supplied from those who only complete the elementary courses.

About three years ago the firm of Houston, Stanwood & Gamble established a school in their own shop, giving instructions to their apprentices during shop hours. Their experience was so profitable that about a year later the Cincinnati Milling Machine Co. established a similar school. We first attempted to operate this school at night, but because of the difficulty of insuring an attendance ou the part of the boys, we soon decided to also operate this school during working hours. These two schools were noticed by other manufacturers, and were also brought to the attention of the Board of Education. After a number of conferences between the manufacturers and the members of the Board of Education it was decided, beginning with September, to operate a continuation school under the auspices and at the expense of the Board of Education. It was agreed by the manufacturers that they would send their apprentices and other young men to this school four hours per week, paying regular wages while the boys were in attendance. Over 200 boys are now enrolled and as fast as additional teachers can be provided, there is no doubt that this enrollment will be very greatly enlarged. You must remember that at present the boys that attend the Cincinnati school are all employed in machine shops. The course has not yet been brought to embrace the other industries in Cincinnati. These classes of this continuation school are limited to about 20 boys. They are taught elementary and higher mathematics, including problems in geometry and trigonometry. The whole plan of the school is to teach directly the problems that the boy encounters in the shop. The catalogues and blue-prints of the machine manufacturers of Cincinnati are the text-books, and through the cooperation of the superintendents and engineers employed in the shops of Cincinnati, the work done at this school to-day is probably more practical and more effective than of any school in this country and Europe.

The efficiency of these boys in the shop is already showing substantial improvement, and will increase as the teaching force and courses at this continuation school are amplified.

So much for the efficiency. Now as to the increase in the supply of labor. It was formerly exceedingly difficult to secure a sufficient number of candidates for apprenticeships. You can readily see that parents whose attention is now called to this new plan appreciate at once that here is an opportunity for their sons to learn a trade, and at the same time to supplement their education. It also appeals to the boy. He wants to go to work, and while heretofore he has been indifferent to his studies at school, he now finds instruction that is alive with interest. The supply, therefore, of young men to learn the trade is more than sufficient. So much already has been accomplished that I look forward to the future with much hopefulness, and I sincerely trust that other communities will rapidly imitate Cincinnati.

Let me repeat, that the big problem before manufacturers of this country is to secure a larger and more efficient supply of labor. Industrial education is the remedy.

* * *

Young (college) men who work in any first-class establishment find that men who cannot talk grammatically, that men who chew tobacco, slouch along the street with greasy overalls on, who hardly look up, who are scarcely willing to speak to you politely as you go along, are intellectually as clear as they are. That is what the young men learn. I remember very distinctly the perfectly astonishing awakening at the end of six month of my apprenticeship, when I discovered that there were three men in the paintshop, I being the fourth, who were all smarter than I was. Now when a young man gets it clearly in his head that he is made of the same clay as those other men, then his only hope, not to be outstripped, is in better education. He sees clearly enough, if he uses his eyes, that it is energy, grit, pluck, determination, ability to stick to it, character, which makes success in the manufacturing and in the engineering world.—*F. W. Taylor.*

INDUSTRIAL EDUCATION—INCREASING THE SUPPLY AND EFFICIENCY OF MACHINISTS—THE FITCHBURG PLAN*

M. A. COOLIDGE†

The Fitchburg‡ plan of cooperative education, or cooperative industrial education, as applied to mechanics, is an arrangement between the high school and the manufacturers of metal machinery, saws, engines, pumps and condensers, and other metal products, for a four years' course of apprenticeship, the first year all school work, the next three years school and shop work, one week in school and one week in the shop. The boys work in pairs—as an example, if a shop takes eight apprentices it has four working at all times. The boy going to work next week goes to the shops on Saturday before closing time, for an hour or half hour, according to the nature of the work, and watches the job his alternate is on, and then is prepared to take up on Monday morning the operations he has previously made himself familiar with, having obtained the additional information he may need from his foreman.

When the shops are able to take a sufficient number of operatives under this system, the course can be very much improved, we believe, by a special instructor in each shop whose only duty will be to attend to his boys, giving them all the time and attention necessary. We expect to carry out this feature shortly.

The Fitchburg plan differs from the trade school idea where any student may enter and go wholly through a three years' course without regard to his mechanical ability or fitness for such work, whereas we drop out the dead wood and try to bring out every boy a good, high grade mechanic. In one trade school they wanted some plumbing done in the school itself and, though they taught plumbing in this very school, they had to send out and get a plumber to do the work. With the exception of the Williamson school in Philadelphia it is, as far as I have heard, the only one where the shop part is made at all prominent.

Manual training schools have also failed in their effort to do practical work along the line of the Fitchburg plan primarily, I believe, for two reasons: They have failed to put the shop part on an equality with the academic and were not able to work under real commercial conditions. Under the Fitchburg plan the boys are paid for their time in the shops 10 cents per hour the first year, 11 cents the second year, and 12½ cents the third year. The young man taking this course has just the same standing in the high school on the football team, athletics, lectures, and all advantages as the other students and put it all over the other boys by always having some real money to do as they wish with, and enjoying that feeling of independence, human in us all.

The apprenticeship or school year commences July 1 and for two months it is a trial period exactly the same as in our former apprenticeship systems. If the boy does not care to continue he may stop, and if the manufacturer feels that he will not make good as a mechanic, he is told so. If he continues, he is under the same apprenticeship bond to go through the three years' course as formerly. We believe this form of bond, or obligation, is just as valuable as formerly, and is kept in mind by the apprentice that he has entered into a business agreement, approved and guaranteed by his parents.

The four years' course follows:

	Periods per Week
First year, all school work—	
English	5
Current events; industrial history	2
Arithmetic, tables and simple shop problems	5
Algebra	5
Mechanics, simple machines	3
Freehand drawing	6
Second year, school and shop work—	
English	5
Industrial history, civics, American history	3
Shop mathematics	7
Physics	4
Mechanism	5
Freehand and mechanical drawing	6
Third year, school and shop work—	
English and industrial history	5

* Paper read before the National Machine Tool Builders' Convention, New York, October 12, 1909.

† President of the Fitchburg Machine Works, Fitchburg, Mass.

‡ See MACHINERY, October, 1908, and August, 1909.

Shop mathematics	5
Physics	4
Chemistry	4
First aid to injured	1
Mechanism	5
Freehand and mechanical drawing	6
Fourth year, school and shop work—	
English	5
Shop mathematics	5
Physics, electricity	4
Chemistry	4
Commercial geography and business methods	2
Mechanism	4
Freehand and mechanical drawing	6

The above scheduled studies, detailed as follows, show how interesting and instructive the school work may be made:

English: Throughout the four years' course in order that he may speak and write intelligently, forms of business papers, shop terms and spelling.

Mathematics: Simple tables, lengths, areas, volumes, metric system, circular measure. General shop mathematics dealing with problems on cutting speeds and feeds, gearing, belting, strength of material. Algebra to facilitate in working out shop formulas.

Mechanism: Parts and construction of different shop tools, gearing, cutting threads, forms and action of cutting tools.

Freehand drawing: For quick shop sketching.

Mechanical drawing: To help in reading blue-prints and make up shop drawings if necessary.

Industrial history: History of iron industry, factory system and labor problems, new inventions, reading mechanical journals to keep in touch with progress in mechanical affairs.

Physics and chemistry: As applied to everyday shop practice, simple and common methods of testing iron and steel, hardening and tempering.

Commercial geography: Centers of machine manufacture, source and cost of materials, labor conditions, railroad systems, waterways and cost of transportation.

William B. Hunter, a technology man, with ten years practical shop experience, is the special instructor in charge of this work, and the subjects taught in the course as just outlined are from special text books following the shop work very closely, cutting out the old academic studies entirely.

Joseph G. Edgerly, for thirty-five years superintendent of the Fitchburg schools, has done everything possible to make this cooperative plan a success, and it has proved, up to date, that this idea as outlined is the best course along cooperative lines.

The city authorities, high school committee, high school principal, teachers, citizens, and various organizations, have done all possible to make it such a success that the apprentices, their parents, and the manufacturers seem pretty well satisfied that here is a line of study and work on an actual commercial educational basis.

The scheme is adopted and worked out to fit our conditions along University of Cincinnati lines, as conducted by Prof. Herman Schneider, to whom we owe a great courtesy for the attention he has shown us.

* * *

HOW JOHNNY FORCED IMPROVEMENTS

E. B. GAFKEY*

At one time when the writer was roving around the eastern part of the United States, he happened to find a position with a firm that manufactured a line of small machinery and factory supplies. The man that built the shop had the foresight to take advantage of an unfavorable location, for the factory was located on the side of a hill, with the railroad siding on top. The shop was two stories high on the railroad side, and four in the rear. Our heavy tools, erecting and shipping rooms were on a level with the shipping platform, while the light tools were placed in the two stories below and were connected with the receiving platform by slides or chutes lined with light tank plates. The company used a vast quantity of small castings and forgings, which they did not make. These were received in barrels and boxes which were unloaded from the cars to the platform and thence down the slides to their respective departments where they were machined, finished, and placed in storage bins for use when wanted.

Our superintendent was a man, who, according to the way he talked, had never had a man in his employ who had ever done a fair day's work for the firm. He said they always worked and walked as though they were going to a funeral; but as no one paid any attention to him, we took it for granted that he was a natural grumbler, and let it go at that. However, one day things took a change, and it all happened on account of a small casting and a sharp order to hurry up, and the order didn't come from the superintendent either. That particular day my partner and myself were assembling a machine, when one of the parts used proved to be defective, and our helper, whose name was Johnny, was told to go downstairs and get another, and to be quick about it. He was quick, all right. Instead of going down the elevator or stairs, of which there were two of each, he went into the gangway at the top of the chutes where someone had left a scoop. Here was a chance. What's the use of going down two flights of stairs or waiting for a pokey elevator? Why not slide down? So suiting the action to the word, he seized

"The superintendent tried to dodge, but couldn't make it, and Johnny caught him just below the midship section"

the scoop, and after firmly seating himself therein, he placed the casting in his lap and "cut loose." Well, I suppose everything would have been all right, but when Johnny reached the bottom he had attained a speed of about fifty miles an hour, and it happened, at that instant, that the superintendent was just in the act of crossing his path. The superintendent tried to dodge, but couldn't make it, and Johnny caught him just below the midship section. The next instant there was a deafening crash as superintendent and Johnny landed in a pile of empty barrels stored near by. About two seconds later, Tom, the foreman of that floor appeared with "What the h—l is that leather-headed clerk sending material down here for without letting me know?" But there was no material in sight. Johnny managed to get out of the wreck first, and then stood in open-mouthed wonder, his eyes as big as moons, expecting to get fired; but nothing of the kind happened. The superintendent, with Tom's help, managed to scramble to his feet, and as he shook the loose barrel hoops from his person, straightened up as far as his one unbroken suspender would allow and says, "Well, I'll be d——d. There is nothing so important around here that any one has got to be so quick that they have to use that blamed slide."

Johnny got his casting and returned, while the superintendent went home to change his dishevelled appearance, but inside of fifteen minutes after the affair happened, the shipping clerk posted two big, glaring notices about the danger of using the slides, and that afternoon the millwright put up a sliding gate in front of them, with an electric bell at the bottom that would always ring when the gate was up. But that was not all. The next day, a gang of electricians appeared on the scene and installed a complete telephone system connecting the different departments.

One day shortly after, my foreman came to me and said: "Ted, that helper of yours deserves a medal. By using the superintendent to break up a few old barrels, he got more improvements in five minutes than all the foremen in the shop have been able to get in the last five years." We never heard any more talk of "moving faster" from the superintendent.

* Address: 16023 Hilliard Road, Lakewood, Ohio.

LETTERS UPON PRACTICAL SUBJECTS

Articles contributed to MACHINERY with the expectation of payment must be submitted exclusively

DEFECTS IN JIG DESIGN

The first consideration of the jig designer should be to determine what degree of accuracy is absolutely essential in the part that is going to be produced and also whether absolute interchangeability is necessary. This information will be a guide for the economical production of the jig. The designer should also consider any operations which are to be performed on the work prior to the one for which the jig under consideration is intended; for while this preliminary machining may not need to be accurately done, inaccuracy or ununiformity may result in improperly locating the work in the next jig, which should be so designed as to locate the part with the required accuracy. The writer's experience is that many jigs have been designed by those who have not considered the points mentioned in the foregoing.

Again, the locating parts of any jig should be such as to allow as wide a range of inaccuracy on any preceding operation which may be performed, as is compatible in the part. For example, if the part has to be turned to say a limit of 0.001 inch, it will require more skill and time than if a limit of 0.005 of an inch is allowable. Again, as far as practicable, the portion of the work that requires to be the most accurate should be used in locating it in the jig for the succeeding operation. Often a surface is selected to locate from which,

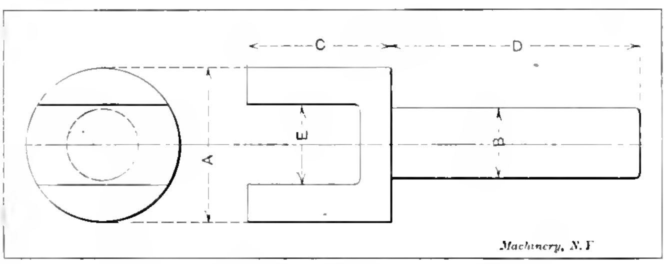

Fig. 1. Work which is milled as indicated at E

in consequence, has to be machined to an accurate limit, but which accuracy otherwise would be unnecessary. This, of course, only adds to the cost of production. After considering the points mentioned, the best method of arranging the details of the jig so that it has as few dimensions as possible requiring absolute accuracy, should also receive attention. That is, the jig should be as simple as possible, and still be so

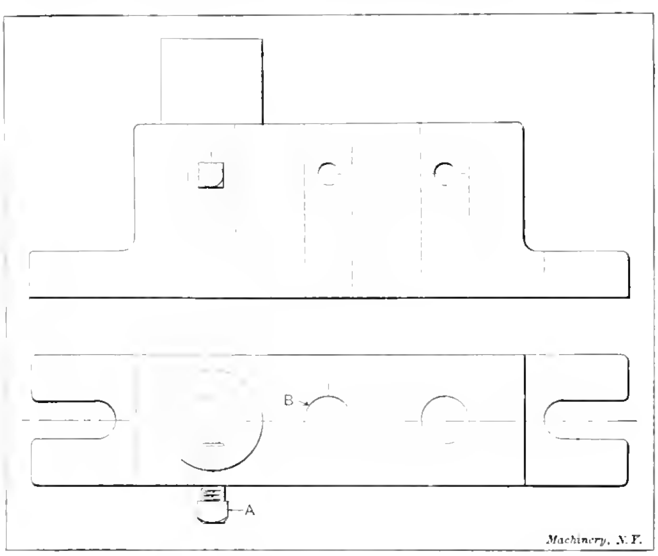

Fig. 2. Defective Design of Fixture for Holding Piece shown in Fig. 1

designed as to accurately locate the parts to be machined. Sometimes jigs are so designed that owing to the arrangement of the details, much time is expended in making test pieces to determine their accuracy.

In Figs. 2 and 3 are shown two jig designs which will serve to illustrate the points we have in mind. The part for which a jig is required is shown in Fig. 1. In the preliminary machining operation the work is turned to diameters *A* and *B* and to lengths *C* and *D*. The limit of accuracy required on end *A* is — 1/64, or any diameter from 1 39/64 inch as a minimum to 1⅝ inch. For end *B* a finer limit of — 0.002 is necessary, so that this end should be used as the locating part for the next operation; *viz.*, the milling out of the slot *E* which must be central with the part *B*. A design

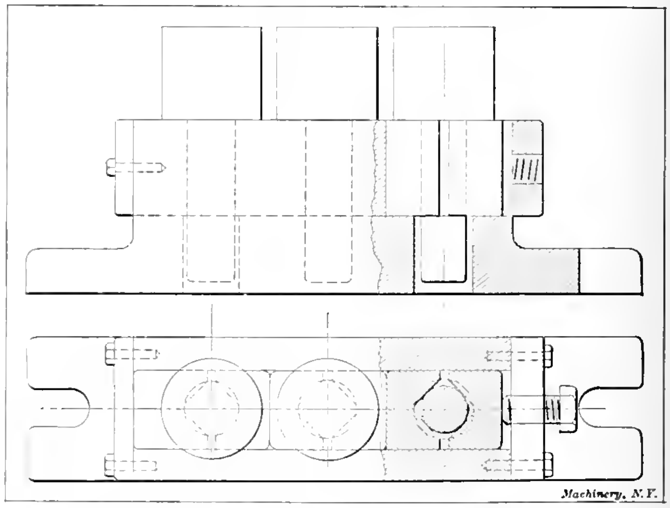

Fig. 3. Fixture which will hold a Number of Pieces, Fig. 1, properly, even though Diameters of Locating Parts vary

such as shown in Fig. 2 is not uncommon for this operation, and with it fairly accurate results will be secured; but if we assume that the locating diameter on the work is slightly small, say 0.002 inch, then forcing the piece over to one side by the locking screw *A* will result in an inaccuracy in the milling operation. The locating holes *B* must be the exact size of the locating part of the work, and unless every piece is a push fit (which is unnecessary accuracy in the part) the location is not accurate as the work is clamped against a

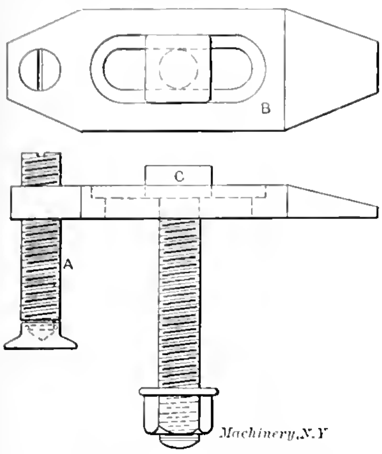
Fig. 4. The Way the V-blocks for the Jig, Fig. 3, are planed

small area on one side of the hole and the point of the setscrew on the other. This can be avoided by locating the part against V-blocks as shown in Fig. 3, which locate each shank central, irrespective of the variations in their diameters. The construction of this jig illustrates the points which have been referred to. The V-blocks provide four lines of contact, and the part is secured very rigidly in a central position irrespective of the variations in the diameter of the locating part. This jig, though more expensive than the one shown in Fig. 2, is quite simple in its construction. A central slot is machined to a width which need not be to any particular dimension as the steel V-blocks will be accurately fitted to this slot. Steel plates are secured to the ends of the jig after machining the slot as shown. By closing these ends after the slot is machined, the tool has a clear passage through, which, of course, would be impossible were the ends cast on. The V-blocks are planed in one piece, as shown in Fig. 4. The only important dimension is the width of the block. The exact position of the V in relation to the sides is immaterial provided that after the blocks have been sawed off they are inserted in the slot in the jig with the long or short sides together. To avoid trouble from this source, one side of the slot and a corresponding side on the blocks should be marked to ensure the correct insertion of the latter. In the event of a design requiring the V's to be strictly central with the sides, the cost would, of course, be increased, as much more care would be required in machining. The jig shown in Fig. 3 is for holding three of the pieces shown in Fig. 1 at one time. Obviously, this number could be increased as desired.

CONTRIBUTOR.

AN ADJUSTABLE STRAP

One of the neatest and most convenient face-plate straps that I have seen is shown in the engraving. How tiresome it is to hunt around the shop after blocks and pieces of the right height to line up the strap to a parallel position with the work to be machined. As will be seen, the rest *A* of this strap is easily adjusted to the proper height. Another desirable feature is that the oblong hole for the clamp bolt permits the strap to be located in the most desirable position by sliding it to and fro. A set of these straps of different sizes can be made with little extra expense, which will be more than offset by the saving in time. The strap *B* should be made of tool steel so that it will stiff, and the elongated hole should be milled to fit the head of the bolt *C* in order to avoid the use of two wrenches and facilitate the handling of the work. The end of the strap is drilled and tapped for a suitable sized screw *A*, which has a shoe on the bottom to prevent marking the face-plate. This shoe is held in place with a pin to keep it from dropping off. A. L. Monrad.



An Adjustable Strap or Clamp for the Face-plate

East Hartford, Conn.

A LATHE SPINDLE KINK

There is one very simple point in connection with the manufacture of lathe and milling machine spindles which builders in general would do well to consider, as I think it would result in great good to the Christianity of machinists and toolmakers, as well as being a profit producer to users of these machines. In order to briefly state the case I will relate a circumstance that occurred in actual practice, which is similar to several others of my own experience.

A new lathe had been in the shop for a considerable time, and when I had occasion to put the face-plate on the spindle I found it to go extremely tight, in fact it would not go up to the shoulder, which was, of course, aggravating and also a hindrance to progress; then I proceeded to take it off and spend about five minutes trying to clean the dirt out of the internal threads, though not succeeding very well. I finally wound up by getting out of patience and doing the job with the face-plate standing away from the shoulder. At my first opportunity I said to a toolmaker: "What is your private opinion as to the proper shape for the starting end of a thread on a lathe or milling machine spindle?" to which he replied: "It's a small question, I never gave it a thought." Then I told him of my grievances with the tight face-plate and he told me that when that lathe came into the shop the chuck and face-plate both went on all right and it was his opinion that someone must have strained the first thread. My convictions on the subject were that if the end of the thread were cut off straight instead of being left wedge-shaped (as it commonly is), the blunt end of the thread would scrape all the dirt out of the chuck thread as it entered; therefore there would be no dirt left to wedge in the thread, which was the cause of the tightness. The toolmaker was open for conviction and asked me to show him, so I took a small chisel and started at the place where the thread came to its full size and cut out a piece of the first thread about one inch long, which left a gap or open space in the thread. We then put the face-plate on and found that it went easy clear up to the shoulder. When the face-plate was taken off again, the gap in the thread was nearly filled up with dirt and chips which the end of the thread had scraped out. This spindle will always clean the thread ahead of itself and it is a source of permanent economy.

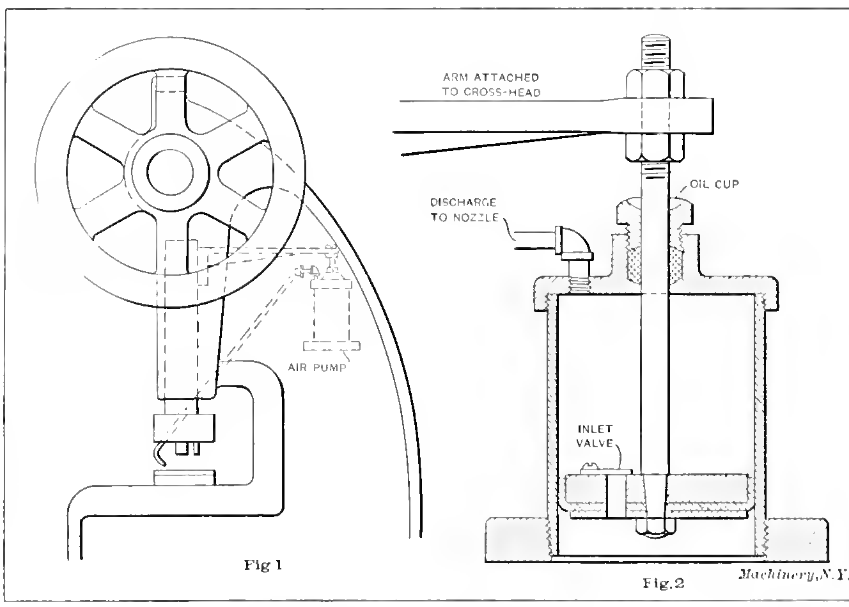
We take it for granted that a man should not put a chuck or face-plate where it will get dirt into it, but that does not change the fact that he will do it just the same; first because of carelessness, and second because he has something else to do besides taking care of the tools. Then again, even though all possible care is used, dirt will sometimes get into the threads so that it is better to adopt this simple method and put a stop to all future troubles in this line.

Here is another valable pointer concerning threads. In many cases where case-hardened finished nuts are used on soft bolts for the planer, slotter, milling machine, or almost any machine in the shop (especially where oil is used) the finer chips will accumulate in the nut with the result that the nuts are soon tight, and someone is blamed for straining the bolt. After a hand die is run over the bolt, if the nut is still tight, some have been known to get the tap and try to put it through the case-hardened nut. Here is a little kink that will overcome the difficulty: Take the corner of a file and file a notch down to the bottom of the thread of the bolt and in the majority of cases the nut will go on easily. The notch does not need to be large enough to damage the strength of the thread very materially.

Bridgeport, Conn. H. E. Wood.

EJECTING WORK FROM THE PUNCH-PRESS WITH COMPRESSED AIR

The article by Mr. Barnes in the August number of Machinery descriptive of an arrangement for blowing away finished stock from a punch-press, recalls to the writer's mind a device designed and built by him to accomplish the same result. As there was no compressed air of sufficient pressure



Side Elevation of Punch Press with Air Pump attached, and Enlarged Section of the Pump

available, an independent pump was attached to the press, as shown in Fig. 1. The piston-rod of this pump is connected directly to the cross-head of the press, and, consequently, the pump has the same stroke as the throw of the crank-shaft. The air is compressed on the up stroke, and it is delivered against the work by means of a ¼-inch pipe which is fitted on the end with a nozzle. The pump cylinder is made of a piece of 3-inch brass tubing which is screwed into a base-plate, as shown in the enlarged sectional view, Fig. 2. This tubing is fitted with a head containing a stuffing box, and a ¼-inch pipe outlet. The piston is a regular 3-inch hydraulic cup, and a piece of leather belting is used as packing. A piece of leather fastened by one screw to the inside of the piston, covers a ¾-inch hole and acts as an inlet valve. The finished work has an upturned portion on the front end, and the nozzle is

placed so as to direct the blast against this point. This arrangement has also been used to blow away small scrap.

Baltimore, Md. Benjamin E. Teale.

HANDY TABLE FOR THE SOLUTION OF RIGHT-ANGLE TRIANGLES

The table below gives in a convenient form the rules necessary for solving right-angle triangles. To the toolmaker or apprentice who has not had the privilege of becoming familiar with trigonometry, it is put up in a very handy form for reference. There are a great many who do not understand the meaning of "square" and "square root," and who will find

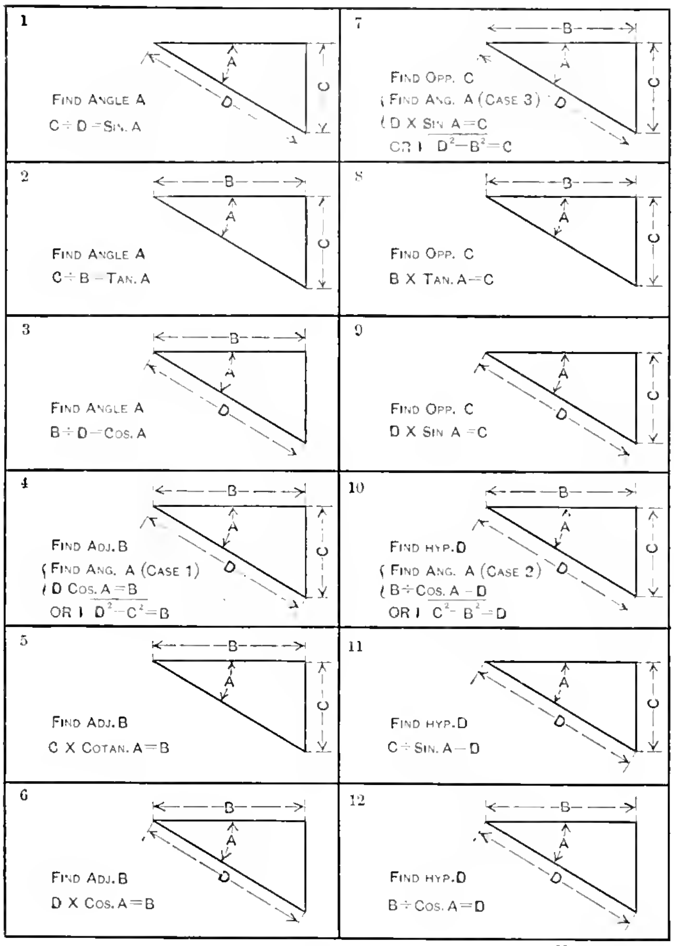


Table for Solution of Right-angle Triangles

it easier to first find the angle when two sides are given, and then find the required measurement of the third side from the angle by the rules as stated. It will be noted, however, that the formulas giving the length of the third side when two sides are given in the form of a square root is also included.

Wenham, Mass.

FILING DRAWINGS

Commenting on recent articles by Mr. Breath and Mr. Davis on the sizes and filing of drawings, permit me to say that I have been employed where this matter was long ago settled in a very satisfactory manner. The filing cases used are 17 x 23 inches inside, practically, the intention no doubt being to have them 18 x 24 inches outside measurement. They are made of very heavy cardboard, cloth covered, and are sold by nearly all dealers in office supplies. Their supposed use is for the filing of legal documents, etc., as well as maps and drawings.

The largest drawings used are 16 x 22 inches, with a half-inch border all round, thus reducing the space inside the border to 15 x 21 inches. Then there are other drawings 8½ x 11 inches, the size of an ordinary sheet of letter paper. The filing cases cost a dollar and a half each, and open along one edge in a manner that permits of easy withdrawal of the contents. These filing cases are placed in a case on their back edges, so the contents are always in a vertical position. They occupy a minimum of office space in this way, and are very convenient for reference. The drawings are divided by subjects, and heavy folders such as are used in vertical filing cabinets are made from detail paper. The boxes containing the smaller sized drawings have a thin partition down the middle. When the scheme was started it was alphabetic and each envelope had on it the name of the work contained on the sheets of drawings in it. Now, however, the system is a numbered one, and there is a card index for reference.

Small drawings have come to stay because of their convenience, and this filing scheme I mention is certainly inexpensive and being on the vertical plan with heavy paper folders, is capable of indefinite expansion.

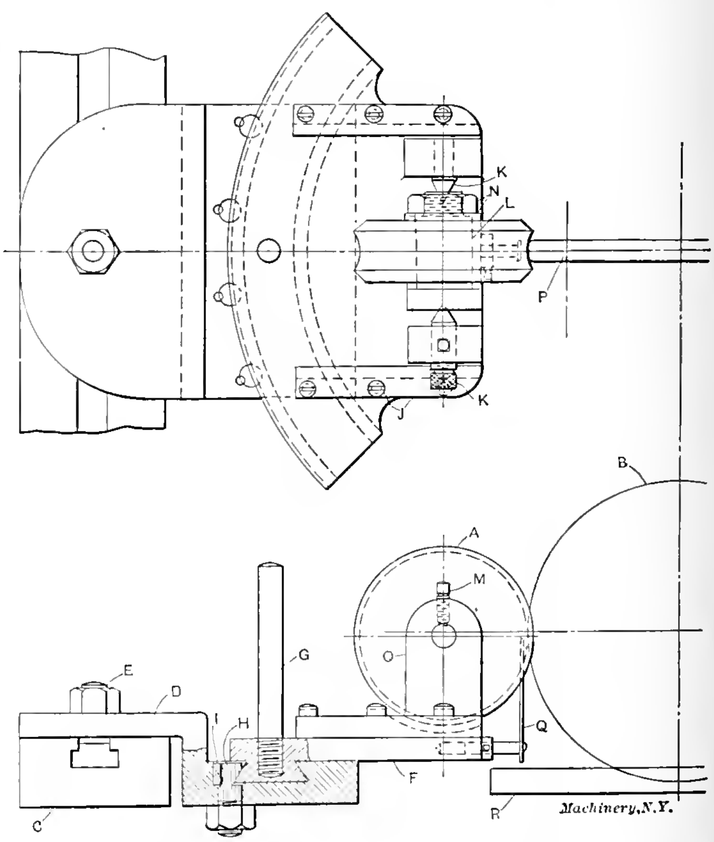
Chicago, Ill. James Davios.

FIXTURE FOR GRINDING RADIUS CUTTERS

Some of the parts on our automobile transmission which have to be milled can best be done with radius cutters, and as it is necessary to use an old grinder to keep these cutters sharp, this necessitated a fixture of rather an odd design.

The reason for this odd design in the fixture is that the grinder has no fixed method of adjustment, and this feature was rather hard to overcome, as it was absolutely necessary to have an adjustment to take in several sizes of cutters, and get a circular movement; provide for clearance; do without a pivot, and all perpendicular adjustment.

The construction of the fixture can be understood by referring to the engraving which shows a plan and a side view partially in section. The lines *A* represent the largest size cutter, and *B* the standard size of emery wheel for this grinder. *R* is a fixed table and *C* the platen with a horizontal



Special Fixture for Grinding Radius Cutters

motion only, which in this case was required to remain stationary. Thus it is seen that this grinder was not convenient for this class of work. The stationary support *D* for the fixture is clamped to the grinder by T-bolt and the nut *E*. *F* is a movable body, *G* a steel stud to be used as a handle in moving *F* back and forth in a semi-circle, *H* brass studs which are prevented from turning by dowel pins *I*, and which are beveled to fit the projecting tongue on *F*. As the four studs *H* are brass against cast iron, and in a corresponding radius to the tongue on *F*, provision is made for wear and accurate adjustment, while a circular or radius motion is obtained without a pivot. In this particular case a pivot

joint would necessarily come in the way of either the cutter *A*, emery wheel *B*, or table *R*.

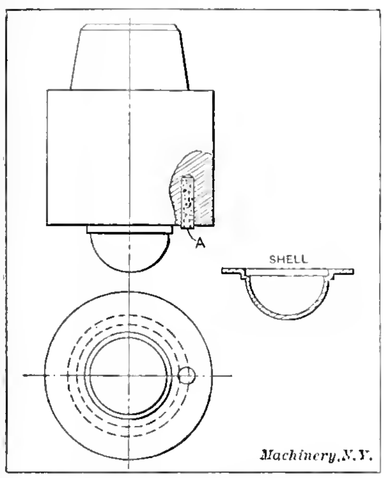
The required horizontal adjustment for the various size cutters is obtained by moving cutter holder *O* toward or away from the center *P*. This holder is clamped in place by side strips and screws *J*. The cutters are fitted to arbor *L* and clamped by a nut and washer *N*. The arbor is mounted on centers *K*, one center being movable for removing or replacing the arbor. The correct spacing is provided for by adjustable stop *Q*.

This gave us a practical fixture for this work on a machine of little value, and thus the fixture soon paid for itself.

JIG AND TOOL DESIGNER.

STRIPPING SHELLS THAT ADHERE TO THE PUNCH BY OIL CONTACT

A simple and very successful method used in connection with the drop press for stripping small shells that adhere to the punch by oil contact, is illustrated in the accompanying sketch. The principle is the same as that of the method described by Mr. C. Howell Dockson in the August number of MACHINERY, for stripping cup-shaped drawn shells, although perhaps of a cruder nature. The stripper consists of a stiff piece of rubber *A* inserted in a small hole in the punch, the end of which projects 1/32 inch below the surface of the punch. This rubber should be of proper size to hold itself in place by friction. In some cases it is preferable to locate the rubber in the center of the formed portion of the punch. Of course, the rubber has to be renewed occasionally on account of deterioration. The frequency of renewal depends on two things: Namely, the amount of pressure required to strip the shells and the grade of rubber used. It is safe to say that one rubber will do for from 1,500 to 2,000 gross of the piece being formed, without renewing. Rubber of the right size should be kept on hand so that worn-out pieces may be quickly replaced.

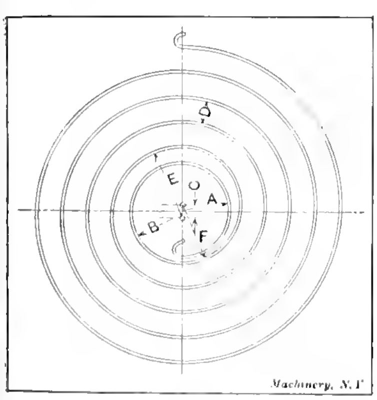


Punch with Rubber Insert A, which Sheds the Shell held by Oil Contact

Winsted, Conn. CHARLES RICHARDS.

LAYING OUT A SPIRAL

It is seldom that a draftsman has occasion to draw a spiral of many turns (like a watch spring) and when the occasion does arise, recourse is had to some handbook which usually gives the method of four centers. The use of the two center method with semi-circles, I find to be sufficiently accurate, much more rapid, besides giving a smoother job by reason of fewer joints. While this method is not at all new it does not seem to be commonly known. The engraving shows a drawing of a spring, made by this method. Starting at the inside with radius *A* from the actual center, draw a semi-circle at the right of the vertical line. With radius *B* (equal to *A* plus thickness of spring) find center below true center from which the arc will connect with the arc struck by *A*, and draw the semi-circle at left of vertical, thus completing the first turn. Having decided on the pitch *D*, two centers are next located on the vertical, one being ¼ *D* above true center, the other ¼ *D* below true center; thus $C = \frac{1}{2} D$. From the upper center with a radius *F* draw the semi-circle at the right of vertical and from the lower center with a radius *E* connect with end of arc *F*, and draw the semi-circle at the left. By thus changing centers and increasing the radii the spiral is easily produced. RALPH W. DAVIS.

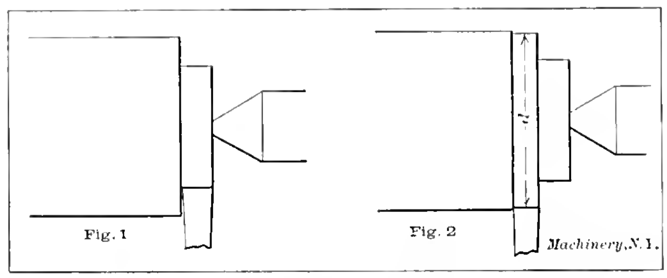


A Spiral Laid Out by the Two-center Method

Rochester, N. Y.

CUTTING A DOUBLE THREAD

Among machinists it is generally known that when the number of threads per inch of a screw being cut is an exact multiple of the number of threads per inch of the lead-screw, the split-nut may be disengaged at the end of each cut and re-engaged at random when beginning a new cut, there being no need to stop or reverse the lathe. In the case of screws having a number of threads which is not a multiple of the number of threads per inch of the lead-screw, it is necessary to have recourse either to some means of insuring the correct re-engagement of the split-nut and screw, as by the use of an indicator designed for the purpose, or by keeping the lead-screw and nut always in mesh and reversing the lathe, thus bringing the carriage and thread tool back to the starting point. It may not be generally known, however, that when the lead of a double-threaded screw is exactly twice that of the thread on the lead-screw of the lathe, such a screw can be cut without stopping or reversing the lathe or employing timing or other devices. To illustrate, if a double-threaded screw having say, ½-inch lead were being cut on a lathe, provided with a lead-screw of ¼-inch lead, the split nut could be engaged at any time and the tool would always follow in one of the two thread spaces.



Figs. 1 and 2. End of Blank turned to Depth of Thread and to Depth of First Cut

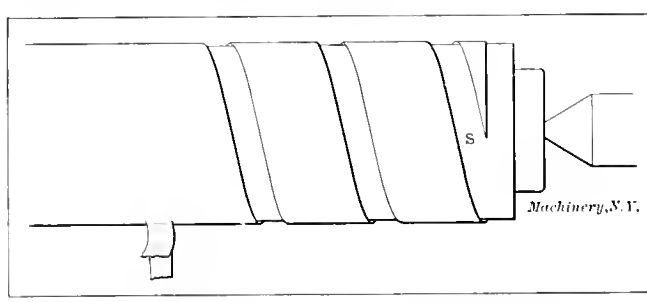


Fig. 3. Tool taking the First Cut on a Double-thread Screw

The accompanying engravings illustrate the method employed by the writer when cutting double threads, the lead of which is twice that of the lead-screw, which enables the work to be done very quickly. As shown in Fig. 1, the end of the work is first reduced to the diameter of the bottom of the required thread. In repetition work, this operation would first be completed on all the pieces to be threaded. It could, however, be omitted entirely if the lathe is equipped with an indicator or stop to give the exact depth. The practical man will no doubt have observed that in cutting a square thread, the moment the tool meets the work, it lags behind slightly. This is due to the fact that the tool is held up or is cutting at this moment only on its leading edge; consequently it yields more or less according to its stiffness or rather lack of stiffness. Hence it is often necessary to cut away a portion of the leading end of the screw. When performing the operation indicated in Fig. 1, allowance should be made for this distortion of the thread.

The next step is to reduce the end, as shown in Fig. 2, an amount equal to the depth of one cut. The split-nut is then engaged with the lead-screw at random, and the first cut taken along the work as shown in Fig. 3. When the carriage is brought back (by hand) to the starting point, the tool is set against the reduced end, as in Fig. 2, and the split-nut is engaged with the lead-screw immediately after the opening of the thread space S (Fig. 3) has passed the point of the tool. The tool will now take a second cut midway between the turns of the first, as shown in Fig. 4, and the depth of the second cut will also be equal to that of the first. When the tool is again started the diameter d (Fig. 2) is reduced an

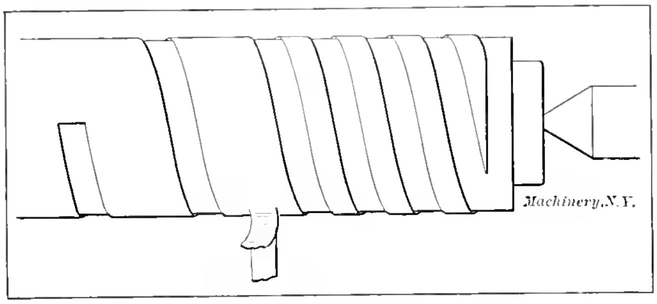

Fig. 4. Tool taking the Second Cut

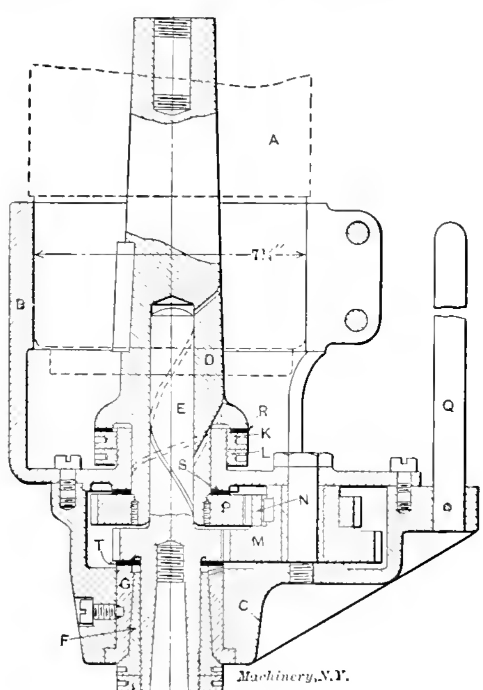
amount equal to the desired depth of the cut, and the split-nut engaged at any point. Then when the succeeding cut is taken, it is again necessary to engage the split-nut at the proper moment; that is, when thread space S has just passed the tool. This operation is repeated until the thread is cut to the correct depth as shown by the coincidence of the tool point with the reduced end, or by a stop if the lathe is so equipped. In one instance within the writer's experience, the replacement of the old method by the one here described reduced the time per piece from about one hour to twenty minutes, or an increased output of 300 per cent.

Coventry, England. FRANCIS W. SHAW.

SPEEDING HEAD FOR VERTICAL MILLING MACHINE

The high-speed milling attachment illustrated herewith was designed to fit an Ingersoll milling machine, the spindle speed of which was too slow for some classes of work. The attachment is designed so that it is easily attached or removed

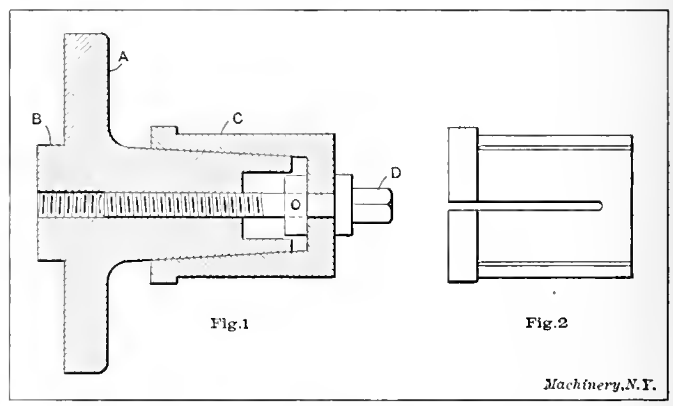


High-speed Attachment for the Vertical Milling Machine

from the machine. The following is a description of the construction of this attachment as made in the Thomson-Houston shop of the General Electric Co. The casting B was bored to fit the outside of the spindle A. The part B is fastened to the spindle by two bolts as shown. The gear case C is centered with the spindle by a boss on B, and it is bored out to receive the brass sleeve G, which forms a bearing for the conical, tool steel, hardened sleeve F; the latter is screwed on the milling cutter holder E. The upper end of E has a bearing inside the part D which fits into the spindle and is keyed to it. On D is fixed a gear P, which drives the holder E through the gears N and M. The attachment is prevented from turning in either direction by a stud Q, which comes into contact with the machine head. The box C forms a reservoir for the oil into which the hardened steel gears run constantly. Spiral grooves are cut in all bearings, and fiber washers are used at R, S and T as thrust washers. The nut H permits compensating for the wear that may take place in sleeve G. This device, as before stated, is very easily attached to the machine, and the only change that was necessary in the latter was to cut a keyway inside of the spindle for the key which drives the shank D. P. P. F.

FIXTURE FOR TURNING AND FACING COLLARS

As we have quite a number of collars to make, the fixture shown in the sectional view, Fig. 1, was made for holding them while they are being turned, faced and polished. This fixture has a disk A which is fastened to the lathe face-plate and centered by a boss B. The projecting end of this disk is turned to a taper of ⅝ inch per foot, and on this tapered part



Fixture with Expanding Sleeve for Holding Collars while Turning and Facing them

is fitted a flanged sleeve C. This sleeve has six ⅛-inch slots cut into it, three being cut from each end and extending to within ⅜ inch of the opposite end, as shown in Fig. 2. These slots permit the sleeve to expand when it is forced upon the tapered part by the screw D, which fits into A. As the collars for which the fixture was made are slightly longer than the expanding sleeve, they can be turned on the outside and faced on the end at one setting of the tool. They can also be very quickly placed on or removed from the fixture by simply turning the screw D in the proper direction. The ends of the collars can be easily polished, as it is not difficult to get in the corner with the polishing stick as when using an ordinary mandrel. One hundred collars were made on this fixture in ten hours' less time than was required when a mandrel was used. L. J. GETZ.

Salem, O.

DON'TS FOR SCREW MACHINE OPERATORS

Don't use a box tool for a roughing cut; use a hollow mill.

Don't use a cut-off tool without some top rake.

Don't put an extension on a wrench when trying to make a tool hold; if the tool slips after tightening with the proper wrench something is wrong.

Don't use a steel hammer for adjusting tools; have a copper one handy and some pieces of brass of different sizes and lengths.

Don't use a monkey-wrench; show the boss how much cheaper it is to standardize the screw heads and furnish proper wrenches.

Don't put a new bar of stock into the machine without measuring the first two or three pieces that come off.

Don't measure up a piece of work without measuring all of the dimensions.

Don't change collets or jaws without cleaning out the spindle nose.

Don't put a screw-driver into the slots of a feed finger to loosen it; use a spanner or a pin in the holes provided.

Don't use a cut-off tool which is too narrow; a wider one can be pushed faster and it will stand up better and leave a better finish.

Don't throw in the feed until you are sure everything about the machine is all right.

Don't let the first few pieces get by without looking to see if the feed finger is scratching the work.

Don't move a tool after measuring just one piece; it is better to measure two or three, as any automatic will make a piece now and then which will be out.

Don't put a new bar of stock into an automatic in a haphazard manner; different jobs require different ways of starting a new bar.

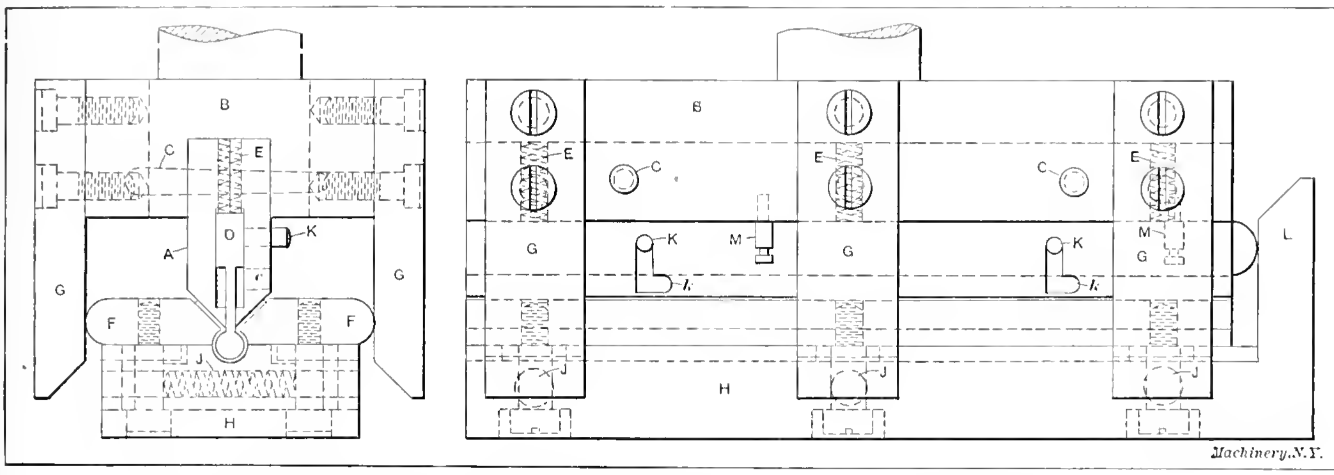


Fig. 1. Side and End Elevation of a Bending and Forming Die for Forming in One Operation the Piece shown in Fig 2

Don't let your machines run without measuring the work often.

Don't take two roughing chips if one is possible; use a little finer feed and only take one chip.

Don't let the tools get choked up with chips; clean them out once in a while.

Don't say you can't do a hexagon or a square job just because you haven't a collet; a round one will hold both square and hexagon on a pinch.

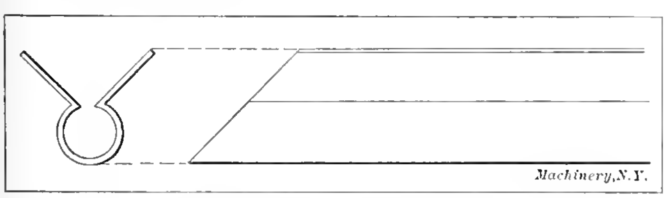

Fig. 2. Corner Piece formed by the Die shown in Fig. 1

Don't run the feed belts too tight; when a trifle loose, if something sticks they will slip and not smash things.

Wilkes-Barre, Pa. PAUL W. ABBOTT.

PRESS TOOL FOR BENDING CORNER PIECES

A press tool is shown in Fig. 1 for forming in one operation the copper corner-piece for lamp frames illustrated in Fig. 2. These corner pieces vary in length from 8 to 36 inches. The copper from which they are made comes in rolls cut to the width required, and they are cut to the right length in the press with an ordinary punch and die, which also forms the ends so that they will fit together when placed in position on the lamp frame.

The construction of this bending and forming die is clearly shown by the side and end elevations, Fig. 1. The forming punch *A* is fixed into punch-holder *B* by taper pins *C*. This punch is made in two pieces as shown in the end view. The punch *D*, which also acts as a mandrel on which the cylindrical part of the corner-piece is formed, is made a sliding fit in *A* The two forming slides *F*, which fit in slots in the casting *H*, are normally held open by helical springs *J*, which are compressed between fixed studs.

When the press is on the upper part of its stroke, punch *D* is forced to the bottom of the slot in *A* by the springs *E*. As this punch descends, it bends the stock to a U-shape between the slides *F*, which are then forced inward by the finger-cams *G*, thus forming the corner-piece against the lower ends of *D* and *C*, to the required shape. While the slides *F* are at work, punch *D* moves upward with relation to the slot in *A*, and, at the end of the downward stroke of the press, it occupies the position shown. In order that *D* will not begin this upward movement as soon as it comes into contact with the stock and begins bending it, pins *K* are inserted into it which fit into the right-angle slots cut through one side of the punch *A* as shown in the side elevation. When the downward stroke begins, these pins are in the part *k* of their slots. When it is time for *D* to begin its upward movement, it is forced to the left by cam *L* so that the pins *K* are brought in line with and can ascend the vertical parts of the right-angle slots. When the press begins the upward stroke, *D* begins to descend, being forced downward by the springs *E*. When pins *K* reach the bottom of the vertical part of their slots, springs (not shown) which are attached to them and to the pins *M* in the punch-holder, draw punch *D* to the right. The pins are then once more in the right-hand end of the horizontal part of the slot, or in position *k*; the punch is then ready to begin bending a new piece.

The gages or stop-pins for the stock are not shown, but are fixed on the slides *F*. These two slides come against a dead stop each time they are opened by the springs *J*. The punch *D* should be an easy fit in the slot in *A*, and the cam *L* should come in contact with this punch before it can bind the stock against the die, so that it can slide freely to the left or in a position that will enable *A* to descend. This tool should be used in a press having at least a 2- or 3-inch stroke, as it would not work well in a press having a shorter stroke than this. C. PETITJEAN.

London, E. C.

LATHE ATTACHMENT FOR BACKING OFF TEETH OF STEPPED REAMER

We had orders for about 200,000 gas cocks, the bodies of which had to be drilled and reamed. When this work was started there was considerable trouble as the reamer would clog up with chips and break because it had to remove so much stock in reaming the large end of the hole. In addition, the hole was distorted so much that there was always trouble when grinding the seats. This trouble, however, was eliminated after the tool shown in Fig. 1 was designed, which enabled the drilling and reaming to be done in one machine, and at the rate of 8 per minute or 480 per hour. This combined drill and reamer prevented the breaking of the finishing reamers and made it possible to grind the plugs in the body in one quarter the time previously required. It was necessary in order to secure satisfactory results to have the cutting edges on each side for the different steps, in the same plane, and in Fig. 2 is shown a diagrammatical view of the attachment used for backing off the cutting edges of the different

steps. It consists of casting *A*, which is threaded to fit the lathe spindle, carrying on its face two raised surfaces or cams *B*, which for this particular job are located 180 degrees apart. The shape of each of these raised surfaces corresponds to the required shape for the clearance. Bearing against the plate *A* and in line with cams *B* is a roller *C*, mounted in a shank which in turn is fastened to the cross-slide of the lathe carriage. The work *D* is held in a hole in the center of the casting *A* by suitable means. When the lathe is to be set for cutting clearance on the reamer, the roller *C* is brought in contact with the highest point of one of the cams as shown

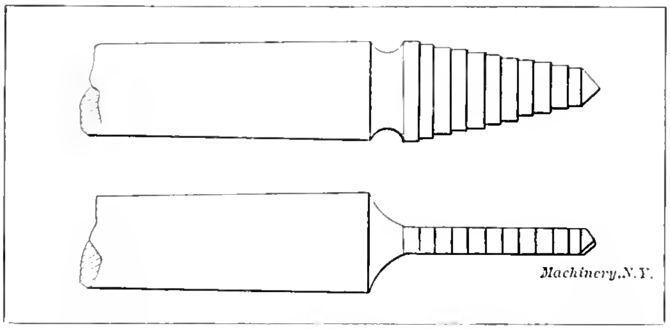

Fig. 1. Combined Drill and Reamer after the Turning and Milling Operations

in the illustration. The cutting point to be backed off and the turning tool are then set so that they just touch each other. By keeping a constant pressure on the hand-wheel at the side of the carriage, the cams as they come in contact with the roller will cause the carriage to advance and return at just the proper moment to give the required form to the cutting edges. Of course, if the work has more than two cutting edges to be turned, it will be necessary to have as many cams

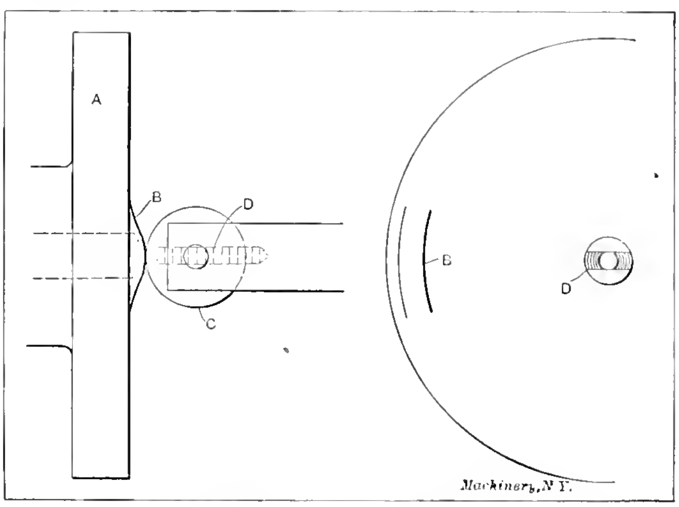

Fig. 2. Diagrammatical View of Special Lathe Attachment used for Backing Off the Reamer Teeth

as there are flutes. I have used this attachment for making forming drills for a large variety of brass cast work and it is the best thing that I know of for backing off cutting edges of tools of this type. JOHN M. FRUIN.

Waterbury, Conn.

DRAWING WITH CROSS-SECTION PAPER UNDER TRACING CLOTH

In the April number of MACHINERY there is a note telling about the use, in England, of tracing cloth with cross-section rulings. As many offices may not find it advisable to obtain a supply of this special cloth the following will doubtless be of interest. Take a sheet of first-class section paper with black ruling and fasten to the drawing board with small tacks. Place the regular tracing cloth over the ruled paper and draw directly on the cloth. In many lines of work it is possible to make the complete drawing in ink without the use of a pencil. I have seen entire switchboards of large size drawn in this manner. When drawing the detail parts such as angle irons, copper bars, rods, etc. (when the dimensions are important and the picture only a place to hang them) the ruled paper beneath the tracing will prove a great time saver. It is, of course, necessary for the draftsman to have his work clearly in mind, or a rough sketch before his eyes. RALPH W. DAVIS.

Rochester, N. Y.

BENDING FORM FOR SPIRAL SCROLLS

While visiting a small railing shop, where considerable scroll work is done, I saw a number of pieces with spiral ends, as shown in Fig. 1, and I could not imagine how they were

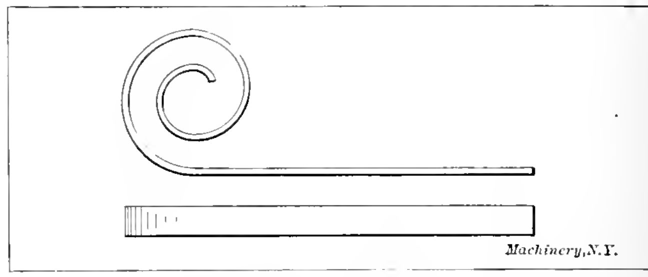

Fig. 1. Scroll which is bent on the Form shown in Fig. 2

bent, as it was a shop without power and equipped only with a few hand tools; yet the scrolls were an example of good workmanship. I began to look around and ask a few questions, when I found that the method of bending these scrolls was "as easy as rolling off a log." A piece of straight, flat stock was heated to a dark red, and then bent on a form, similar to that shown at *A* in Fig. 2, which was held in the vise. The work, after being removed from the form, was

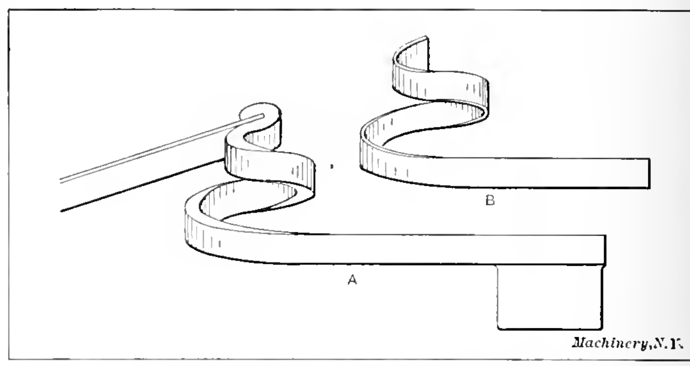

Fig. 2. Bending Form and Shape of Work before it is flattened

then in the shape of a conical spiral, as shown at *B*. In order to form the scroll shown in Fig. 1, the piece was simply flattened down on a straight plate. HERMAN JONSON.

New York City.

NATIONAL MACHINE TOOL BUILDERS ASSOCIATION CONVENTION

The National Machine Tool Builders' Association held its eighth annual convention at the Hotel Astor, New York, October 12 and 13, with the following official organization: President, Fred L. Eberhardt; first vice-president, C. A. Johnson; second vice-president, E. P. Bullard, Jr.; treasurer, W. P. Davis; and secretary, P. E. Montanus. The list of members including the concern admitted to the association at this meeting follows on the next page.

President Eberhardt in his address referred to the Hudson-Fulton celebration and the great advances in transportation that this celebration commemorated. He referred to the position of the association favoring the reduction of the tariff on the metal-working classifications; and expressed the conviction that the government authorities in Washington—Department of Commerce and Labor—were impressed by the movement initiated in New York last year to bring to their attention the size, importance and needs of the machine tool industry. He expressed confidence in the future of the industry, it being evident that the trade depression has been passed and that good times are in sight. Paul E. Montanus, chairman, presented the report of the committee on standardizing electric motors as applied to machine tools, which was discussed by Mr. Lodge. The report in part was as follows:

"Regarding the maximum speed of motors, both constant and variable, and the peripheral speed of gears, the committee finds quite a diversity of opinion. From the report we find

that for constant-speed work the majority seem to favor 1,200 revolutions per minute on most of the smaller motors, at least up to five horse-power. There was, however, a difference ranging from 900 to 1,800 revolutions per minute. Where rawhide pinion is used it was found that the maximum speed was somewhat higher, but that still 1,200 revolutions per minute was most commonly used. With metal pinions this was somewhat lower.

* Admitted at this meeting.

"It is with respect to the speed of motors and their variations we found the greatest difficulty at the joint meeting with the Electrical Association. The speeds were so arranged and based on the following suggestions: That the starting basis of constant speed of the A. C., 60 cycles be used as the basis of the D. C. constant-speed motors, and also that this be used as a basis for the working out of the variable speed requirements. The speeds suggested are 600, 720, 900, 1,200 and 1,800 revolutions per minute. These figures are not absolutely correct for the above condition, but are approximately close enough for discussion purposes. In all the speed tabulation it is understood that the variation of five per cent up or down can be allowed. The table which we submit below is the first and the basis upon which the two committees are working.

VARIABLE SPEED MOTORS

H. P.	Max. Speed	Range: 4 to 1	3 to 1	2 to 1	1½ to 1
1	2200	550	740	1,100	1,480
2	2200	550	740	1,100	1,480
1	1800	450	600	900	1,200
2	1800	450	600	900	1,200
3	1800	450	600	900	1,200
5	1800	450	600	900	1,200
7½	1800	450	600	900	1,200
10	1800	450	600	900	1,200
2	1500	375	500	750	1,000
3	1500	375	500	750	1,000
5	1500	375	500	750	1,000
7½	1500	375	500	750	1,000
10	1500	375	500	750	1,000
15	1500	375	500	750	1,000
15	1200	300	400	600	800
20	1200	300	400	600	800
25	1200	300	400	600	800
30	1200	300	400	600	800
20	900	225	300	450	600
25	900	225	300	450	600
30	900	225	300	450	600
40	900	225	300	450	600
30	720	180	240	360	480
40	720	180	240	360	480
50	720	180	240	360	480

"In order to explain this table, we will take the 2-H. P. size. In it we will suggest the maximum speed as 2,200; the 4 to 1 range would therefore be 550 to 2,200; 3 to 1 range, 740 to 2,200; 2 to 1 range, 1,100 to 2,200; 1½ to 1 range, 1,480 to 2,200. This would require four motor frames to carry out this standard. If any manufacturer should decide that 2,200 revolutions is entirely too high, he has the following option:

"If he uses a 2 to 1 motor, he can use a speed variation as low as 500 to 1,100 or 740 to 1,480. If the 3 to 1 is required, he could use 550 to 1,480, or at least that frame. Therefore, it would seem that while the table may be somewhat high, the number of combinations which could be taken therefrom would be sufficient to meet the requirements of nearly every motor manufacturer. In this table he could also take a 2-H. P. motor with maximum speed 1,800 revolutions. With this he could get a 4 to 1 speed variation, 3 to 1, 2 to 1, and 1½ to 1, with maximum speed of 1,800, 1,200, or 900 for a 2 to 1 motor. This is also sufficiently large to meet nearly all requirements."

A paper entitled "The Creation of Machinists" presented anonymously was interesting to the majority of the members of the association inasmuch as it outlined a plan that has been successfully followed by a machine tool builder in Ohio in training young men to become skilled in the operation of machine tools under conditions that differ materially from those ordinarily surrounding the education of apprentices. In an address on the same subject made by E. P. Bullard, Jr., he referred to his experiences with the partial apprenticeship system successfully used in his company, the Bullard Machine Tool Co., for training men of mature years to become skilled machine men. The following papers were also presented:

"Industrial Education—A Source of Supply Increasing the Efficiency of Machinists," by Mr. F. A. Geier, who described the Cincinnati plan, and M. A. Coolidge on the Fitchburg plan. (See another part of this issue for the text of each.) Dr. W. H. Tolman, director of the Museum of Safety and Sanitation, New York, gave his famous stereopticon lecture "The Perils of Peace, or a Safer America." Dr. Tolman's remarks and views strongly impressed the machine tool builders, and when it became known that he had an itinerary that covered the manufacturing districts of the Middle West, arrangements were made by a number of the western leading machine tool builders to accord him a hearty welcome. The concluding paper delivered on the afternoon of Wednesday was "Reinforced Concrete Construction from the Machine Tool Industry Standpoint," by J. P. H. Perry. This paper was illustrated with stereopticon views showing the features of construction details of interest to those contemplating the use of concrete for manufacturing structures.

The following officers were elected: President, F. A. Geier, Cincinnati, Ohio; 1st vice-president, Fred L. Eberhardt, Newark, N. J.; 2nd vice-president, P. E. Montanus, Springfield, Ohio; treasurer, George W. Fifield, Lowell, Mass.; secretary, Charles E. Hildreth, Worcester, Mass. Rochester, N. Y., was chosen as the meeting place for the spring convention next year.

MACHINERY'S SEVENTH ANNUAL OUTING

Following the convention of the National Machine Tool Builders' Association in New York, MACHINERY gave its annual outing October 14 to nearly 500 invited representatives of the machine tool trade and closely allied industries. The steamer *Sagamore*, chartered for the day, was loaded with eatables, drinkables and "smokables" appropriate for the occasion. The party met at the Battery shortly before noon, and with some misgivings on the part of those inclined to be seasick, the steamer started on a course south by southeast through the choppy waters of the upper bay, Narrows and lower bay. After a somewhat windy trip Sandy Hook was sighted and taken by assault, notwithstanding the presence on the dock of Col. Rogers Birnie of the Ordnance Department of the Sandy Hook Proving Ground, Col. H. L. Harris, of the Coast Artillery Corps, and other officers. Yielding gracefully to the inevitable, the officers guided the invading host through a well-equipped machine shop, where the weapons of war are repaired and supplied with missing members, to the proof battery where the big and little machine tool builders were finally gathered together and photographed *en masse* with the result noted in the accompanying illustrations—but "the worst was yet to come."

The party was ordered to climb up on the five concrete parapets back of the proof battery where the big guns are tested, see Fig. 2, and after being cautioned to stop their ears when the whistle sounded, a 12-inch gun was fired with 270 pounds of nitro-cellulose powder. The 12-inch shell was hurled through two sets of vertical wires about 100 feet apart, comprising part of the Le Boulenge chronograph apparatus used for determining the velocity, and far out to sea, where it was seen to ricochet twice before disappearing. Adequate description of the sight and the sensation produced is quite impossible; it must be seen and felt to be appreciated. Following the firing of the 12-inch gun came the firing of a 6-inch gun mounted on a 6-inch disappearing carriage. Two rounds of shrapnel were followed by one common 7-inch steel shell filled with explosive "D" fired into a sand parapet about 500 yards from the proof battery.

The party of visitors then divided into two groups, one

Fig. 1. MACHINERY'S Steamer "Sagamore" approaching Sandy Hook

Fig. 3. Machine Tool Builders, Members of the Machine Tool Trade on MACHINERY'S Outing, October 14

taking the train on the Sandy Hook R. R., the only railroad owned by the U. S. Government, to the spot where the 16-inch gun is located, while the other party inspected the fortification known as Battery Richardson and mortar battery, Battery Granger, and each party in turn visited the objects of interest

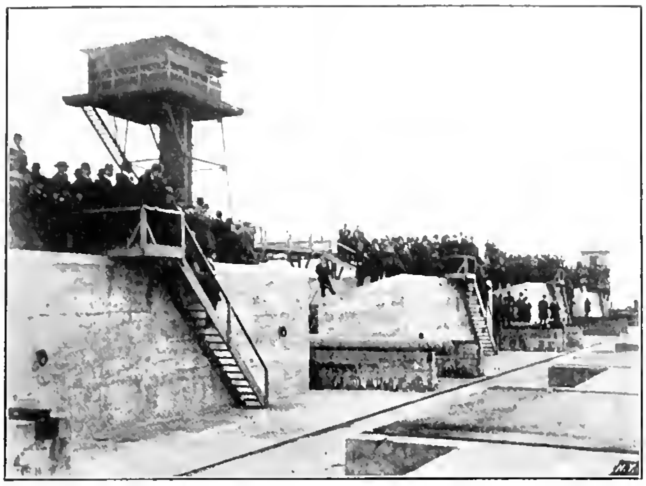

Fig. 2. Machine Tool Builders watching the Firing of Big Guns at Sandy Hook Proof Battery from the Concrete Parapets in the Rear

The inspection of the 16-inch gun under the direction of Col. Birnie was made enjoyable especially by his interesting account of the history and construction of the gun, with some remarks on the experiments made with the Gathmann gun, on a nearby armor plate and with a regular 12-inch gun on 5- and 6-inch armor fitted to a section of a battleship's hull. The 16-inch gun, which is the largest in the world, firing a projectile weighing 2,370 pounds with a velocity of 2,300 feet per second, has been discharged about fifteen times. No duplicate has been built and none is likely to be made because the great weight of the gun makes manual operation practically impossible. (See MACHINERY, December, 1903.) The lighter 12-inch, and the 14-inch guns recently authorized can, if necessary, be operated by hand, which is a great advantage, as defects in the operating machinery are likely to develop when the total disability of a gun might mean great disaster. The fortifications, Battery Richardson and Battery Potter, facing the main channel, are built of monolithic concrete behind a bank of sand and are practically invisible from the sea. The guns are mounted on disappearing carriages, and beneath the barbettes are ammunition rooms in which shells and powder are stored. Automatic hoists, driven by electric motors, convey the ammunition to the guns when in action.

The party returned to the Battery about 5:45 o'clock after having spent the afternoon on the desolate strip of sandy land

grouped on the Proof Battery, Sandy Hook. Picture taken just prior to the Firing of the Big Guns

seen by the other. Opportunity was given to a limited number to inspect the workings of the range-finding towers in which the positions and distances of vessels miles out at sea are accurately determined, and from which the angles of elevation are telephoned to the batteries.

near New York that is frequently mentioned in the public press, but on which very few Americans have ever set their feet, it being a government reservation to which admittance is usually denied. The fortifications, of which only a fraction were inspected, are said to be the strongest in the world.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

THE BRYANT CHUCKING GRINDER

A great many interesting machine tools built in the small machine tool manufacturing towns in Vermont have from time to time been illustrated and described in MACHINERY. The latest interesting machine brought out by the machine tool builders in this state, is the Bryant chucking grinder, built by the Bryant Chucking Grinder Co., of Springfield, Vt. The inventor of this machine is Mr. W. L. Bryant, for eight years chief draftsman of the Jones & Lamson Machine Co., of the same town. Its purpose, though perhaps not the full intent of its field, is indicated by its name. The ingenious features of its construction and mechanism will be made manifest as the description proceeds.

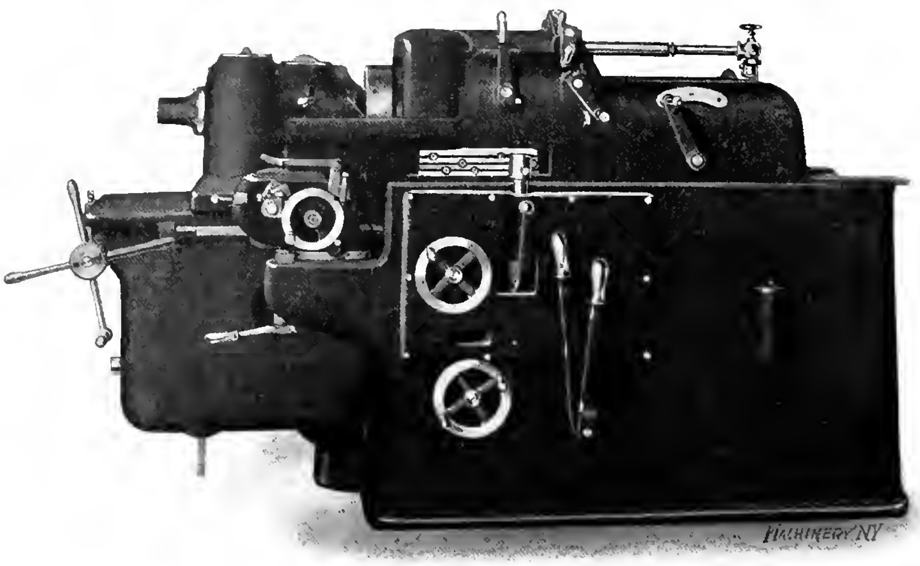

Fig. 1. The Bryant Chucking Grinder, for completing Several Grinding Operations at One Setting

General Description

Briefly, this machine is intended for work held in the chuck, and on such work presents the advantages, first of a number of wheels, constantly set, and each of suitable grain, grade, shape and surface speed for its work; second, of a number of convenient stops, for both longitudinal and cross adjustments, making the accurate duplication of lengths, thicknesses and diameters an easy matter; thus permitting, also, the performing of several operations at one chucking; and, finally, it offers those conveniences of feed and speed change, adjustment and control which make the turret lathe such a profitable investment in a well-managed machine shop.

The general design of the tool will be understood best from a study of Figs. 1 to 4, inclusive. The bed of the machine is a massive casting, A, of rigid box form. On its upper surface it is provided with one V and one flat way, on which slides the wheel-carrying head, B, carrying three spindles, any one of which may be adjusted outward to permit its wheel to operate on the work without interference from the other two. To the left of the main bed in Figs. 1, 3 and 4, is swiveled the bracket C, about the vertical axis of pivot E. The angle is read by a graduated circle, and the swivel is brought back to parallel position against a positive stop. Lever L_2 binds this adjustment. This bracket C, in turn, supports the work spindle head D; the swiveling about the axis of E thus gives provision for grinding tapers. A longitudinal adjustment of the head on the bracket, by pilot wheel E_2, against any one of three adjustable stops, permits a change of adjustment to agree with the length of the work projecting from the chuck; a cross adjustment at this point gives control of diameters, and feeds the work across the cup wheel for facing cuts. This cross feed is operated automatically from the power traverse of the wheel spindle head. Having thus briefly described the structure of the tool, we are prepared fot a detailed description.

The Wheel and Work-driving Mechanism

The whole machine is driven from a constant speed pulley F. No complicated overhead works are required, the machine may be located without strict reference to the countershaft space, and the motor-driving problem is reduced to its simplest terms.

Pulley F is keyed to shaft G, which, in turn, is keyed to drum H. Over the latter passes a belt which runs over a series of tight and loose pulleys (see J and J_1) on the wheel spindle driving shafts. These are so arranged that the shifting of the driving belt connecting drum H with pulleys J, J_1, etc., transmits the power to either the rear, or facing wheel, the center or internal wheel, or the front or external wheel. Lever K and belt shifter L control the driving belt for this purpose. Drum H and shaft G are mounted in a swing cradle, to keep the driving belt tight. The adjustment for this cradle is shown at M in Fig. 3. It should be noted that the driving belt does not pass directly over the pulleys on internal spindle N. Instead, the pulleys on this spindle are driven at an increased speed from pulley Z_1 on the idler shaft. The central position of lever K normally stops all the wheel spindles, but by the operation of lever O, the internal wheel may be started or stopped.

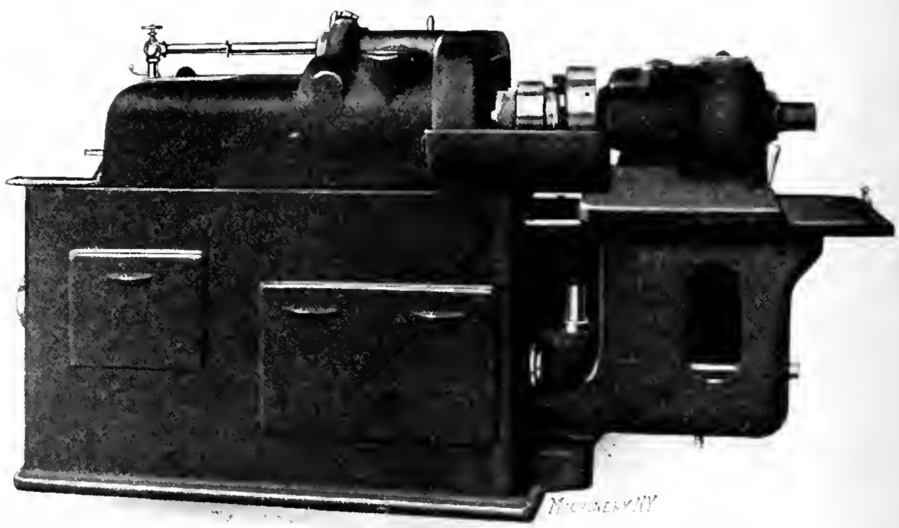

Fig. 2. Rear View of Grinder, showing Massive Construction

Levers P, P_1 and P_2 are connected with the wheel spindle quills by a rack and pinion movement, which allows them

to be projected or withdrawn, as required for clearance. These levers are provided with positive adjustable stops for this movement, permitting the duplication of the adjustments on each successive piece of work. Lever O binds or loosens all the quills simultaneously, for making this adjustment.

in which is journaled a drum, connected by spur gearing with shaft V. From this drum a belt passes around idler X, and over driving pulley Y on the work spindle. A spring Z (see Fig. 3) keeps the drum in the swinging yoke drawn down, so the belt is always taut. Lever A_1 controls a reversing

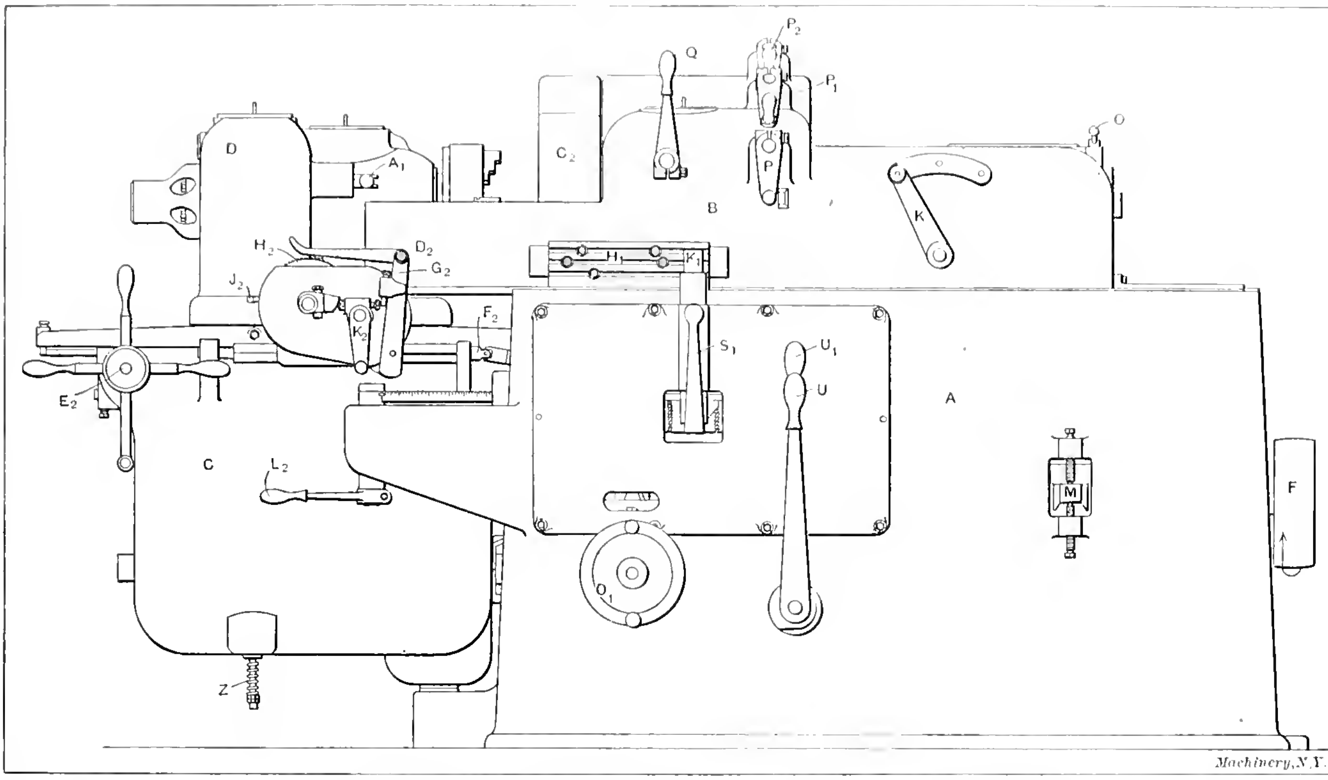

Fig. 3. Front Elevation, showing Arrangement of Slides, Controlling Levers and Hand-wheels, etc.

Shaft G, see Fig. 4, carries also a small pulley R for driving the usual water pump, and also the pinion S, which meshes with the driving gear for the work speed changing mechanism. This latter is mounted as a unit in an oil bath casing, and is of the double clutch, silent ratchet type made familiar in the spindle drive of the Hartness flat turret lathe. It is

mechanism for the work spindle, operating through shaft B_1, and the connecting gearing shown. This is employed for certain cases in which the rear or facing wheel spindle is used for cylindrical or internal surfaces. The same lever A_1 is used for stopping the work spindle, and is connected with a brake for doing this expeditiously.

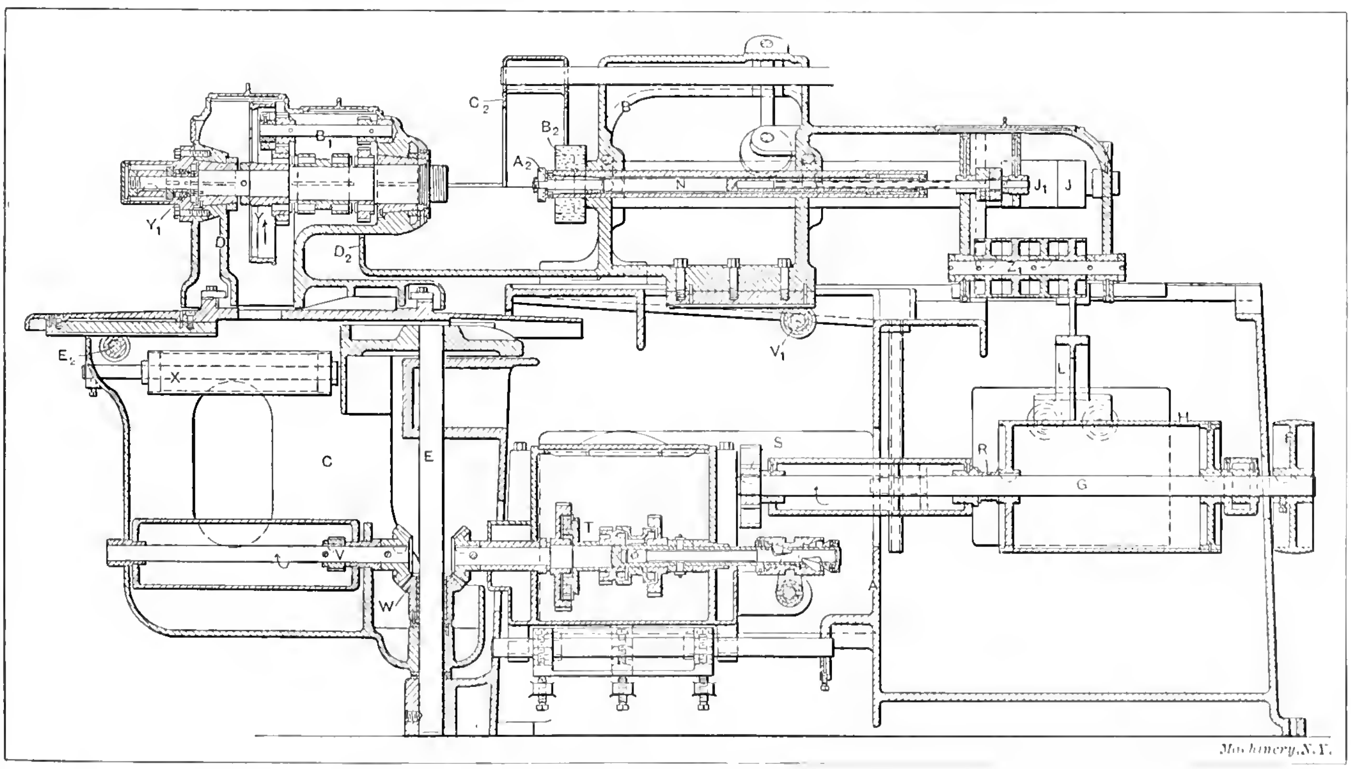

Fig. 4. Longitudinal Section, showing Work and Wheel-driving Mechanism, and General Structure of the Machine

incompletely shown at T, in Fig. 4. The nine changes of speed are controlled by the two levers U and U_1.

From the speed box, the motion is transmitted to shaft V in swiveling bracket C, through the angular bevel gear drive at W, about the axis of E. About shaft V is pivoted a yoke,

The Longitudinal and Cross-feed Mechanisms

The variable feed mechanism for operating the traverse of the wheel spindle head is best seen in Fig. 5. It is connected by a train of gears with the driven shaft of the work speed change mechanism, so that the linear feed of the wheel per

revolution of the work is not affected by changes in work speed. The variation in feed is obtained by the Hartness modification of the Sellers friction disks, in which a very slight swing of the female disks changes the point of contact so rapidly as to effect a great change in the feed. The male or driven disk is shown at C_1, in Fig. 5. The change of feed is effected by a cam connected with hand wheel D_1 in Fig. 3.

Disk C_1 is connected with shaft E_1 by a bevel gear reverse F_1, controlled by the clutches at G_1. At H_1, on the side of the wheel spindle slide are cut three T-slots, in which are clamped

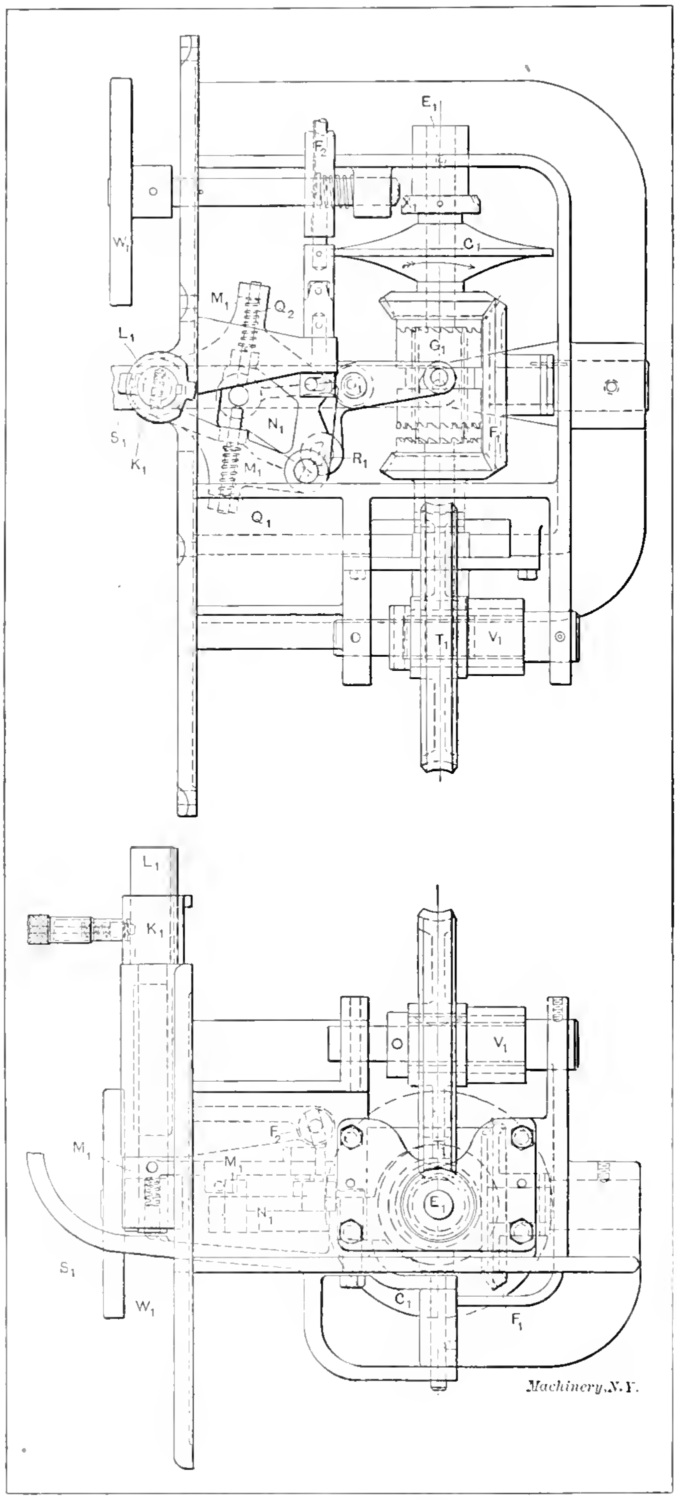

Fig. 5. The Wheel Head Traverse Mechanism

three sets of automatic reverse dogs, one for each wheel. These dogs strike a projection on collar K_1, which may be raised or lowered on rock shaft L_1 to line with the set of dogs it is desired to use. To L_1 is keyed the sector M_1, which is one member of a "load and fire" mechanism for controlling clutch G_1; its purpose is to prevent the clutch from stopping on dead center. It is the simplest in construction of any mechanism of this kind the writer remembers having seen.

Clutch G_1 is shifted to the right or left by a fork and sector N_1, pivoted at O_1. In the position shown, when sector M_1 is swung to the left by the reversing dogs, spring Q_1 is thereby compressed against a pin in sector N_1 tending to throw it to the left, and thus throw the clutch G_1 to the right, reversing the movement. This is prevented for the time being, however, by the interference of the ledges milled in the faces of the pins at R_1, one of these being fast in sector M_1 and the other in N_1. When M_1 has been turned so far to the left, however, that spring Q_1 is properly compressed, these pins snap by each other on the further side, allowing the clutch to be thrown.

Going in the opposite direction, this process is reversed. The dog at H_1 swings sector M_1 to the right, compressing spring Q_1 against the pin in N_1. The swinging of the latter under this spring pressure is resisted as before by the pins R_1, which finally snap by at the end of the movement. The pivot O_1 of segment N_1 is mounted in lever S_1, which thus furnishes means for stopping and starting the traverse movement at any point in the travel, independently of the automatic reverse.

The motion from the reverse clutch at G_1 is transmitted to the wheel spindle head through worm gearing at T_1 and a

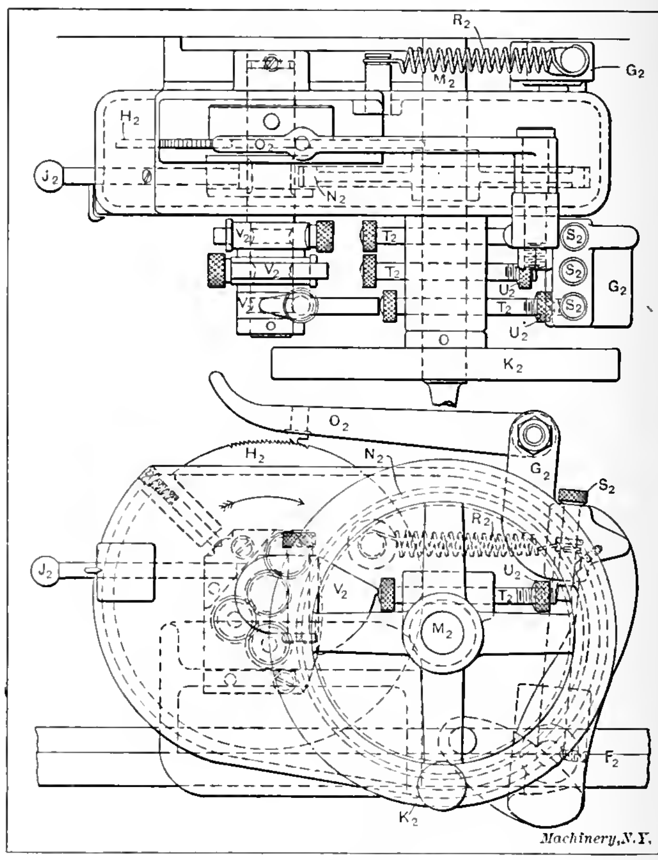

Fig. 6. The Cross-feed Mechanism, with Automatic Diminishing Device and Stop

pinion at V_1, which engages the rack under the slide. Fine hand adjustment for facing, etc., is effected when the power feed is thrown out, by hand wheel W_1, through bevel gears at X_1. This hand wheel is shown in Figs. 1 and 5, but not in Fig. 3, the latter being incomplete in this respect. When not in use, it is withdrawn until bevel gears X_1 are out of engagement, and the wheel is free.

A telescopic shaft, F_2, leads from the automatic traverse mechanism on the main base of the machine, to the cross feed mechanism for the work spindle head on the swiveling bracket. This shaft is rocked at each end of the stroke by a cam surface on sector M_1, which is, as we have seen, controlled by the reversing dogs at H_1. The telescopic shaft transmits this movement properly at whatever angle the swiveling bracket and work spindle may be set.

The cross feed screw M_2 (see Fig. 6) has mounted on it a hand wheel K_2 (a crank is shown in Fig. 3) and a spur gear N_2. This latter is connected with ratchet wheel H_2 by a tumbler gear arrangement, controlled by lever J_2, which thus provides for reversing and throwing out the feeds. The

ratchet wheel is operated by a pawl O_2, pivoted to lever G_2, which in turn receives its movement from rock shaft F_2 shown in Figs. 3 and 5. This movement is positive in the direction which operates the ratchet wheel H_2, and through it the cross feed. In the other direction it is drawn back by spring R_2 until the point of plunger S_2 brings up against the adjustable stop T_2. As the position of T_2 allows a greater or less amplitude of movement to the swinging of lever G_2, a greater or less cross feed is effected at each stroke.

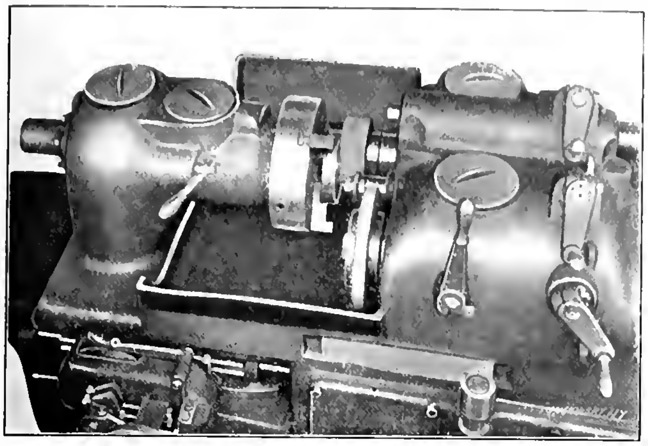

Fig. 7. The Facing Wheel in Use

The position of stop T_2, and the consequent amount of feed, is governed by two things. In the first place, the knurled nut U_2 furnishes a check to its backward movement, and thus regulates the rate of cross feed. Screwing this nut out increases the feed—screwing it back decreases it. In the second place, the feed is controlled by cam V_2, which is adjustably clamped on the shaft of ratchet wheel H_2, and revolves with it in the direction of the arrow. As the feeding progresses, the lower edge of V_2 comes into contact with the left-hand end of stop T_2, gradually limiting its movement from that permitted by the adjustment of U_2 until finally, in the position shown, the swinging of lever G_2 is stopped altogether, thus stopping the cross feed. The diminishing depth of cut thus provided for, as the desired finished diameter is approached, gives the best results obtainable from the standpoints of accuracy and finish.

It will be noted in the top view in Fig. 6 that there are three each of stop cams V_2, stops T_2, feed adjusting nuts U_2 and plungers S_2. Any one of these three latter may be pressed down into working position, thus giving a separate cross feed stop and rate of feed for each of three operations.

Salient Points in the Design

The reader might perhaps be pardoned for skipping the detailed description of the mechanism just given. It is made necessary by the fact that the machine is new from "the ground up," so it has to be described in the same way, there being no similar machine with which mental comparisons may be made. The reader, however, should not fail to examine certain noteworthy features of the design which are of universal interest, being applicable to machines of other types, made for other purposes.

One of the points of interest in the machine is its strength and rigidity. This is rather unusual in the matter of weight alone, which is about 4,200 pounds. Rigidity has been secured by very careful design. This might not seem to be important in a grinding machine, where the strains are light as compared with machines of the lathe and miller type. If

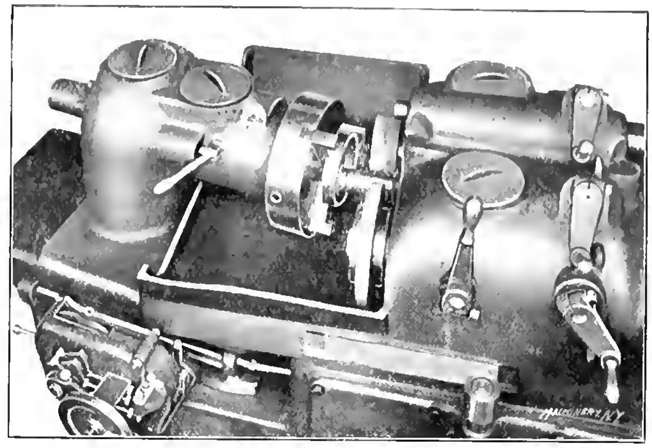

Fig. 8. The Work Head Swivelled for Taper Work

there are no heavy strains to contend with, however, there is liable to be enough of vibration to cause serious trouble, and weight and stiffness are needed to counteract this.

In the matter of rigidity, note first the heavy box-like form of the main castings. This form also serves, of course, to protect the mechanism from emery dust and other grit. Then again, the solid, long bearing of the swivel adjustment should be compared with that found on the ordinary design of universal grinder. All unnecessary sliding surfaces are

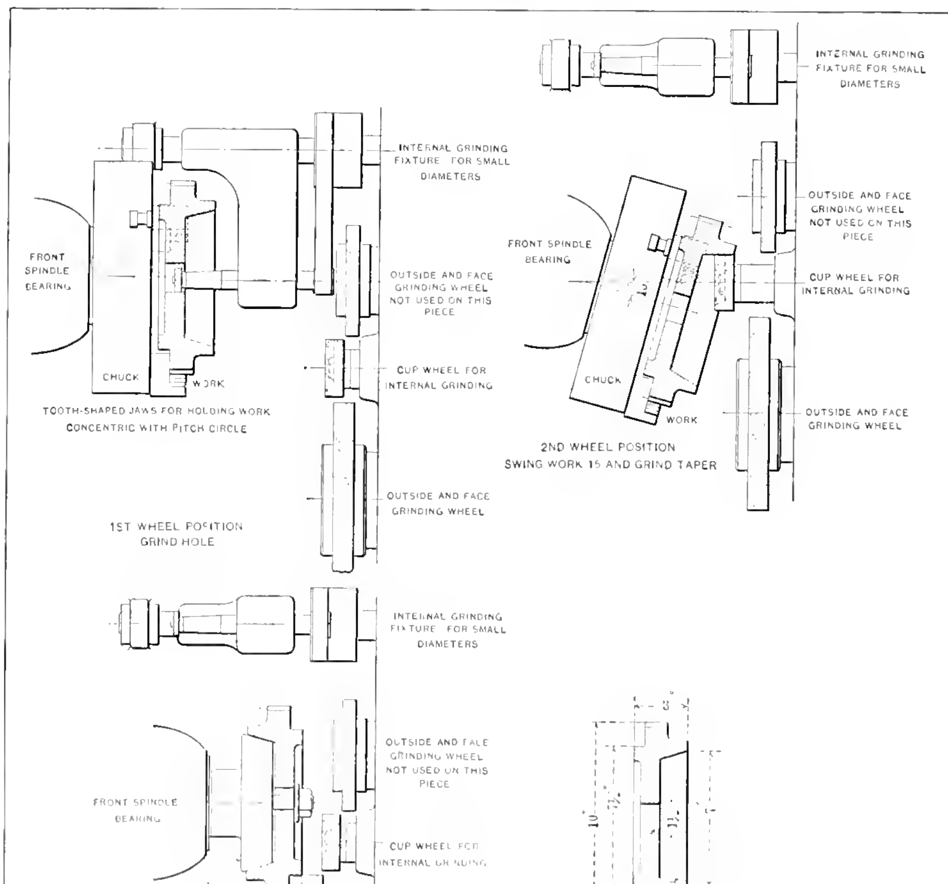

Fig. 9. Diagram showing the Method of Finishing a Hardened Gear with Conical Clutch Surface

avoided, and the connection between the work and the wheel, through the main castings, is strong and direct, there being a notable absence of built-up constructions.

An interesting point, along this line, should be noticed. The work spindle head slides crossways on a thin platen, which, in turn, slides longitudinally on the top of swinging bracket *C*. This platen at first sight appears to be an example of the built-up construction which the designer tried to avoid. This is not the case, however. It is thin and flexible, receiving its stiffness from the head and bracket to which it is gibbed. Furthermore, the gibbing points for this platen on the upper member are directly over those for the lower member, so that strains are transmitted in direct tension and compression, with no possibility of the deflection strains (even in this thin platen) which usually "raise hob" with rigidity.

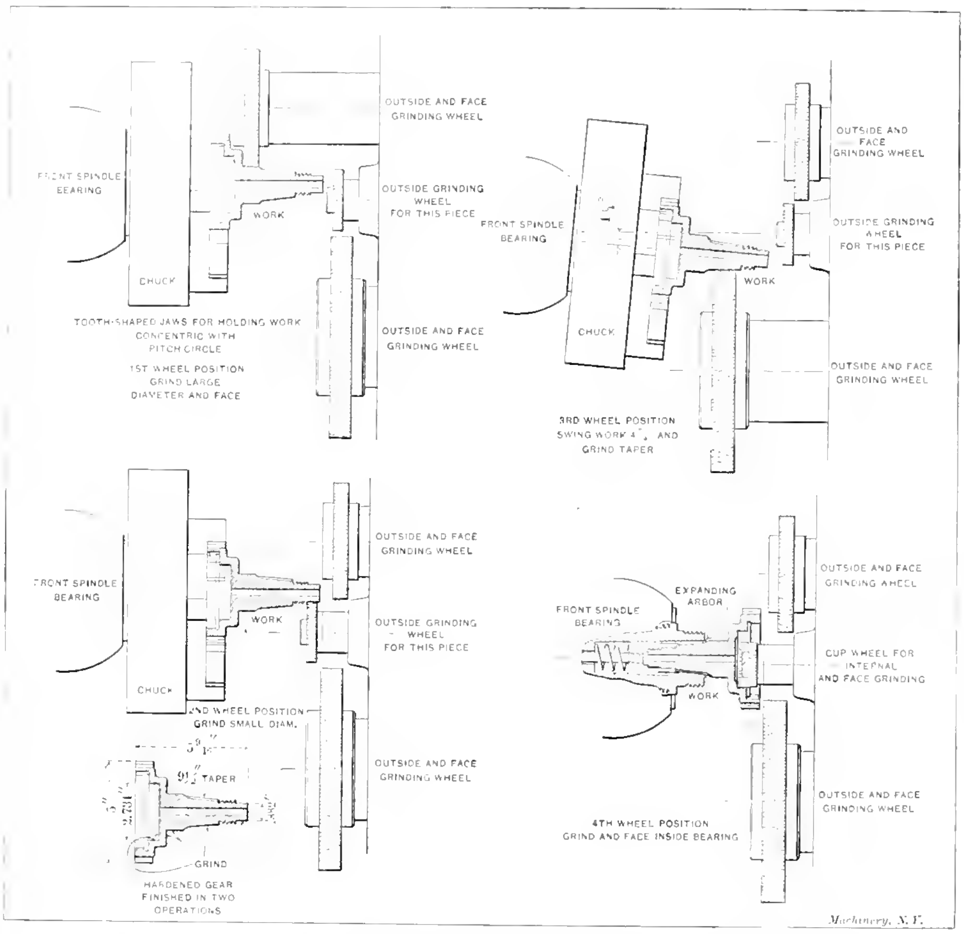

Fig. 10. Method of Finishing a Piece requiring Two Settings, and having Cylindrical, Face and Taper Surfaces to be ground

Criticism might perhaps be directed toward the large overhang of the work spindle. This is given to permit the entrance of guard D_2 to catch the water and dust. This overhang is apparent only, however, as the base of the head is extended to a long bearing out under the working point. It is similar in this respect to the spindle heads used on the Beaman & Smith duplex cylinder boring machines, having the advantage, however, of having the head and extended slide one solid casting, instead of being bolted together, as is necessary in the other case.

Another point shown, though not very plainly, in Fig. 4 at Y_1, is a device used for taking up the end movement of the work spindle. This is very necessary in accurate face plate and chuck work, whether in the lathe or grinding machine, as every good mechanic knows. It is not possible to do it well enough or to do it permanently by adjusting the take-up for the thrust bearing. It is therefore common practice, wherever possible, to put a stick against the center of the work, and bring the tail center up against it, thus taking out the slack. This machine has the stick incorporated in it. Springs at Y_1 are always in action, forcing the spindle up to a firm bearing on the end thrust.

Typical Operations

In Figs. 9 and 10 are shown diagrams which illustrate the use of the machine quite clearly. The first of the parts, in Fig. 9, is a cast iron gear with a conical clutch surface. This has to be ground, as shown, in the bore, the clutch surface, and on one face and outside diameter. In the first operation the work is held by tooth-shaped jaws which hold it concentric with the pitch line. Here the bore is ground with a supplementary internal attachment, as shown, provided for work having small holes. (This supplementary spindle may also be used for buffing and polishing with rouge and a soft wheel.) In the second wheel position the work spindle and the bracket on which it is mounted are swiveled to the angle of the conical surface 15 degrees, as shown, which is finished with the regular internal wheel. For the second operation and third wheel position (which finishes this piece) the work is held by its finished clutch surface on a taper arbor mounted in the work spindle. This arbor may be ground in place to insure absolute accuracy.

The piece of work shown in Fig. 10 is also a gear, but of much more complicated form. It is made of hardened steel. For the first operation (including the first three wheel settings) it is held in gear-tooth chuck jaws the same as in the case shown in Fig. 9. In this first operation all three of the regular wheels are used, all on external surfaces. First the large bearing is ground with the rear wheel, then the small outer bearing is ground with the central wheel, and finally, in the third position, the 9½-degree taper is finished with the outside wheel. This operation shows quite plainly that only a small lateral adjustment of the work spindle is required for the different positions. This will be seen by comparing the center lines of the work and of the central wheel spindle in each case. This is due to the fact that the three wheel spindles are located in this natural position, and to the fact that the swiveling adjustment for taper grinding is about an axis which approximately passes through the point of contact of the wheel and work.

In the fourth wheel position and the second operation, the work is held on the conical shank by a special expanding chuck, made to fit it. For this operation the middle or internal wheel only is used, this being employed for both the grinding of the hole and the facing of its internal seat.

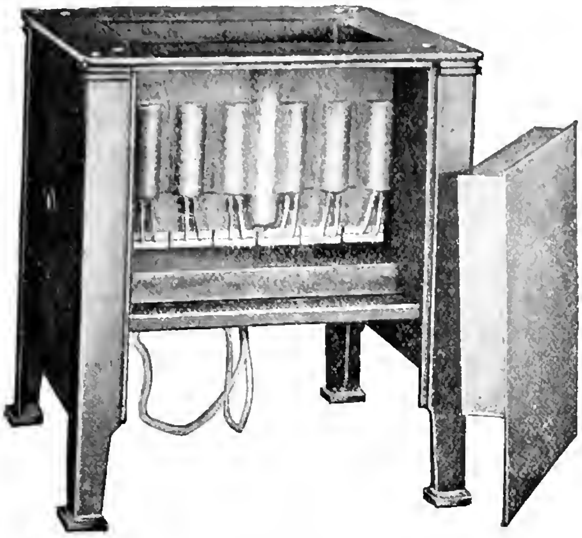
The Field of this Grinding Machine

These two examples will serve to show the convenience and time-saving qualities of this design of grinder, with its three (or four) wheels permanently mounted in place, its variety of adjustments, and its conveniently controlled stops, feeds, speeds, etc., for each operation.

It will readily be seen that this chucking grinder bears the same relation to the standard universal grinding machine, that the turret lathe on chuck work does to the standard engine lathe. Its field is thus a large one, though its particular adaptability to automobile work will be at once recognized. It is entirely conceivable that it may open up a new field of its own, in finishing certain parts from rough turned, or even rough castings and forgings. Mechanics will readily recognize its advantages, as a labor- and time-saving machine, and being, as it is, radically new in its design, it will undoubtedly create considerable interest among machine users.

ELECTRICALLY-HEATED OIL TEMPERING BATH

The accompanying illustration shows an electrically-heated oil tempering bath manufactured by the General Electric Co., Schenectady, N. Y. The bath is contained in a cast iron tank or pot, having 12 lugs evenly spaced around the sides. These lugs are drilled to receive standard cartridge units, and by thus distributing the units an even temperature can be maintained



Electrically-heated Oil Tempering Bath, made by the General Electric Co., Schenectady, N. Y., showing Removable Cartridge Units

in all parts of the oil. Around the pot is placed a heat retaining jacket, consisting of an inner and outer wall of sheet metal, the space of three inches between the walls being filled with mineral wool. The jacketing on the back side of the tank is easily removed, thus allowing quick access to the internal connections of the units. Around the top of the tank a wide flange is provided, to which four cast iron legs are screwed. A drain pipe controlled by a globe valve provides a means for drawing off the oil. A protected recess is provided in one end of the tank in which a thermometer may be placed for indicating the temperature of the oil bath.

Two methods are in vogue for using the oil bath. In the first method the temperature of the oil is raised to 250 degrees F., and then the work is placed in the bath and the full current turned on. When the oil reaches the desired temperature, the work is removed and the current turned off. The second method is to turn on the full heat at once, and bring the oil to the required temperature, and then to introduce the work, and by means of regulating switches, maintain the temperature constant for any required length of time.

A cast iron basket or tray may be supplied in which the work can be placed. This basket has eye-bolts at each end to facilitate its handling, and the bottom is perforated with ⅞-inch holes to permit free circulation of the oil. Short legs are provided on the bottom of the basket which keep the work about an inch above the bottom of the bath.

Any desired temperature is obtained by throwing in the necessary number of units to give the approximate heat. Close regulation is then secured by varying the voltage on one of the units by means of a rheostat. Three sizes of tempering baths are made, the smallest having a capacity of nine gallons of oil, the medium size, of 11 gallons, and the largest, of 37 gallons, the first requiring 6 K. W. per hour, the medium, 7.2, and the largest size, 20 K. W. for its operation. This energy consumption is sufficient to heat the oil to a temperature of 450 degrees F. in less than one hour, when starting cold. The lengths of the three sizes are 22, 18, and 30 inches, respectively; the widths, 12, 12, and 16 inches, and the depths, 8, 12 and 18 inches. The smallest oil bath weighs 420, the medium, 475, and the largest, 900 pounds.

CINCINNATI-BICKFORD 20-INCH GANG DRILL

The accompanying illustrations Figs. 1 and 2 show front and rear views, respectively, of a new arrangement of 20-inch sliding head drills operating in gang, and manufactured by the Cincinnati-Bickford Tool Co., Cincinnati, O. As shown in the illustrations, four individual drills, each fitted with power feed, automatic stop, and quick return, have been placed on a common base pedestal. The rear view, Fig. 2, shows the driving arrangement, transmitting the power through a continuous shaft provided with clutches, admitting of the throwing in and out of any one drill at any time. The continuous shaft is provided with a tight and loose pulley at one end, as shown. The lever for operating the clutches by means of which each spindle can be stopped independently, is bent over towards the front, so that the operator at the front of the machine can conveniently reach it.

These drill presses are provided with sliding heads and the table has also a sliding movement as shown in Fig. 1, so that it can be operated up and down by means of a crank on ways planed on the face of the column, giving the table a rigid support and bearings at points far apart. The arrangement of sliding heads in combination with a vertically movable table gives the machine a considerable range for handling pieces of comparatively large proportions. The table is continuous across the whole front of the machine as shown, and is provided with two T-slots. The sliding heads are balanced

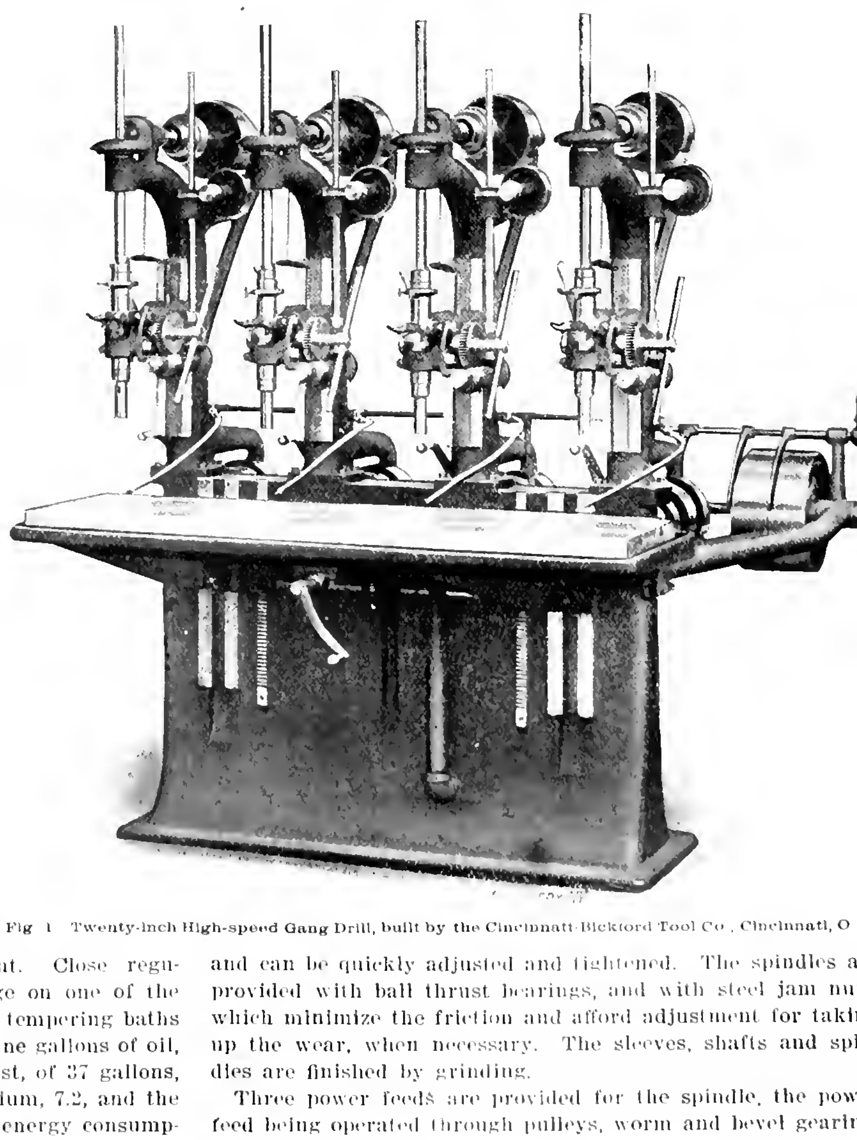


Fig. 1. Twenty-inch High-speed Gang Drill, built by the Cincinnati-Bickford Tool Co., Cincinnati, O

and can be quickly adjusted and tightened. The spindles are provided with ball thrust bearings, and with steel jam nuts, which minimize the friction and afford adjustment for taking up the wear, when necessary. The sleeves, shafts and spindles are finished by grinding.

Three power feeds are provided for the spindle, the power feed being operated through pulleys, worm and bevel gearing.

The worm operating the worm-wheel on the pinion shaft in the head revolves in an oil bath contained in the worm casing, thus insuring long life to the worm gearing. All the bevel gears are planed so as to provide proper contact between the teeth and silent running. Proper guards are provided for all exposed gearing. The spindle sleeve is graduated, and on

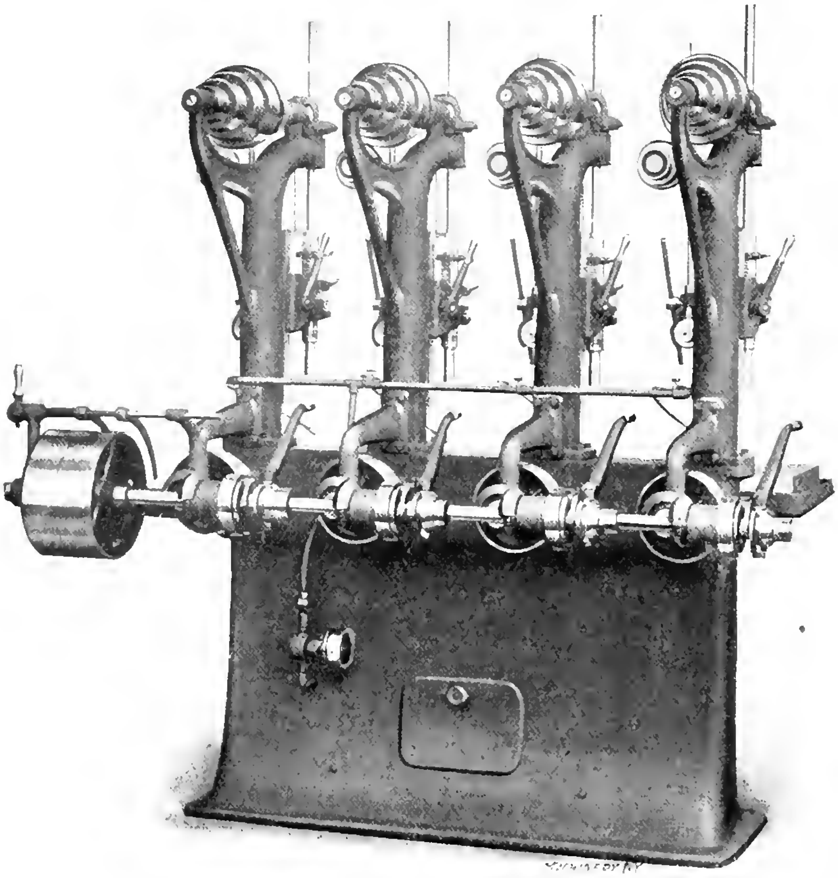

Fig. 2. Rear View of Gang Drill, showing Arrangement for Driving with one Continuous Shaft

the power feed machines provided with automatic trip, this graduation affords a means for setting accurately the automatic trip collar.

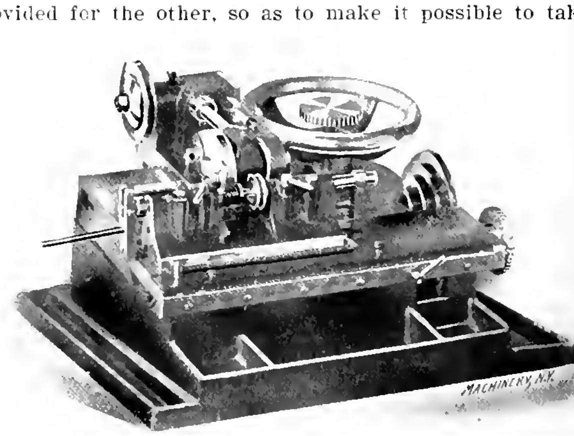
These machines are also furnished without power feed and can be arranged in gangs with any number of spindles from two up. They are also furnished on individual base columns, both with and without power feed construction, and with a variety of tables furnished according to the needs and requirements of the customer. An oil pump and the necessary piping is provided as shown, and a tank or reservoir for the oil is placed within the base.

WALTHAM AUTOMATIC STAFF TURNING MACHINE

The machine shown in the accompanying illustration has recently been brought out by the Waltham Machine Works, Waltham, Mass. It is built for automatically turning several shoulders on small work, such as the staffs of watches clocks, etc., at one setting. The general design of the machine is as follows: Two slides are provided, one of which carries the work supported on dead centers and driven by a dog from a belt-driven plate. The other slide has a motion at right angles to the first, and carries the tool or tools. A vertical shaft at the rear of the machine carries two cams, one for each slide, the cams actuating the slides by means of sliding wedges which are in contact with hardened rolls on the slides. These latter are kept up against the wedges by springs and the wedges are kept in contact with the cams by similar means. The angles of the wedges are such that the longitudinal movement of the wedge transmits a reduced movement of the slides. For watch work the movement of the work slide is made one-quarter, and of the tool slide one-eighth, of the longitudinal travel of the wedge, but for larger work a different reduction may be made. This arrangement is advantageous, inasmuch as it makes it possible to greatly reduce any small inaccuracies in the cams, the rises of which are several times the required travel of the slides.

The head- and tail-stock spindles which carry the dead centers have longitudinal adjustment in their bearings, and are so designed that when the head-stock center is in its proper position, the other can be withdrawn for changing the work, by means of the lever at the left of the tail-stock. In this way staffs can be turned with all the lengths gaged from the same end, thus throwing all of the errors of the blank to the extreme of the other end where they can be easily rectified. The centers are kept in contact with the work by light springs. For watch work and other work where the total length of the blanks is less than three-quarters inch, the head- and tail-stock are made in a single casting so that correct alignment is more easily maintained. For larger work, however, they are made separately adjustable on a bed plate. In both cases a screw adjustment is provided so that a slight swivel motion is possible for bringing the axis of the centers parallel with the work slide.

A worm and worm-gear drives the cam shaft, and a friction clutch connects the gear with the shaft. This clutch, when released, permits the shaft to be turned by the hand-wheel at the top, so as to make it easier to set the tools. The cams can be cut so that the tools will turn either straight or tapered work, or partly straight and partly tapered. A screw adjustment on each side permits the diameter of the most particular part and the distance of the most important shoulder from one of the ends to be obtained very accurately. The other diameters and lengths will be in correct relation, and duplicate parts can be turned as long as the tool retains its cutting edge. For very delicate watch work and also for work where a considerable amount of stock is to be removed, two cuts should be taken over the work. In order to facilitate this operation a two-tool turret has been provided. This turret is automatically indexed on the completion of each cut. The position of one of the tools in the turret is determined by the screw on the slide, but a separate screw adjustment is provided for the other, so as to make it possible to take the



Automatic Staff Turning Machine, built by the Waltham Machine Works, Waltham, Mass.

finishing cut with independent adjustment. With this arrangement only the finishing tool is required to have the keen point necessary for delicate work, and as but a small amount of stock is removed in the finishing cut, the tool will hold its edge for a long time.

The operation of the machine is briefly as follows: The blank is dogged by the operator, who places it between the centers and starts the machine by a foot treadle. The tool follows the course determined by the cams, turning and squaring all the shoulders on one end of the staff. In a sin-

gle-tool machine the tool then returns to its original position, and the machine stops for the insertion of a fresh blank, which has been dogged by the operator while the machine was running. In a two-cut machine the turret is automatically indexed on the return, bringing the finishing tool in position, and the movements are repeated, the machine stopping first after the completion of the finishing cut, but with the turret indexed again and the roughing tool in position for the next blank. With the two-cut, or with the one-cut machine on long work, the operator can take care of two machines. The capacity of the machines when arranged for larger work is up to $2\frac{1}{2}$ inches long between the centers, and up to $\frac{1}{2}$ inch diameter, but the longest total turning is $1\frac{1}{2}$ inch. The base of the machine is 15 inches square, and the weight about 140 pounds. The machine can be made to take either rectangular or circular tools, as required by the user.

KEARNEY & TRECKER UNIVERSAL MILLING ATTACHMENT

The accompanying line engraving Fig. 1 and the half-tones Figs. 2 to 5 show the construction and application of a uni-

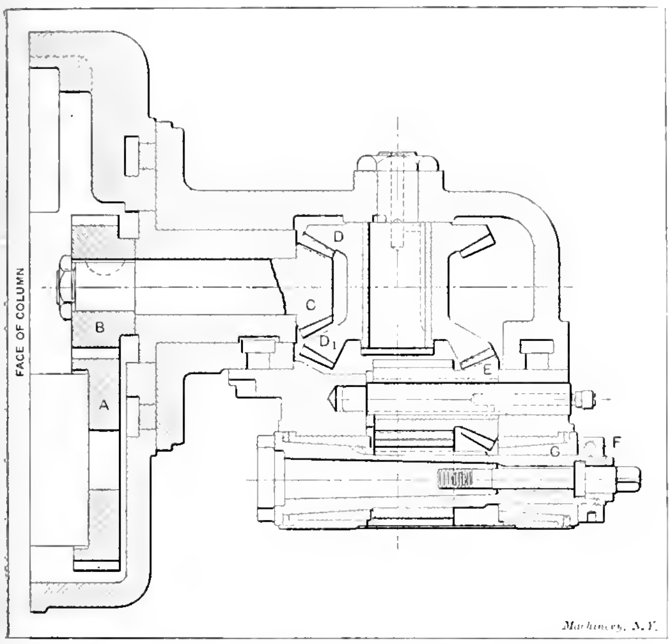


Fig. 1. Section through Universal Milling Attachment made by the Kearney & Trecker Co., Milwaukee, Wis.

versal milling attachment which has recently been brought out by the Kearney & Trecker Co., Milwaukee, Wis. Referring first to the line engraving, Fig. 1, showing a section of the device, it will be seen that the gear *A* is attached to the regular horizontal spindle of the milling machine, and drives

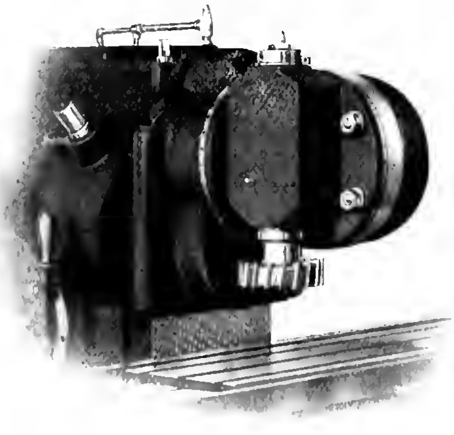

Fig. 2. The Attachment in Position for Vertical Milling

gear *B* keyed to a horizontal driving shaft on the end of which is cut a bevel pinion *C*; this pinion drives the bevel gear *D*, which latter is made in one piece with the bevel gear D_1. This arrangement permits the pinion *E* to revolve to any position without interfering with the driving pinion *C*. The bevel pinion *E* is cut on a steel sleeve on which also are cut spur gear teeth of wide face meshing with a similar gear provided on the cutter spindle of the attachment. All of the gears as well as the cutter spindle are made from hardened steel, the spindle being ground on the outside as well as in the tapered hole.

The wear on the bronze boxes is taken up by an adjustment nut or collar shown at *F*. The bushing *G* rotates with

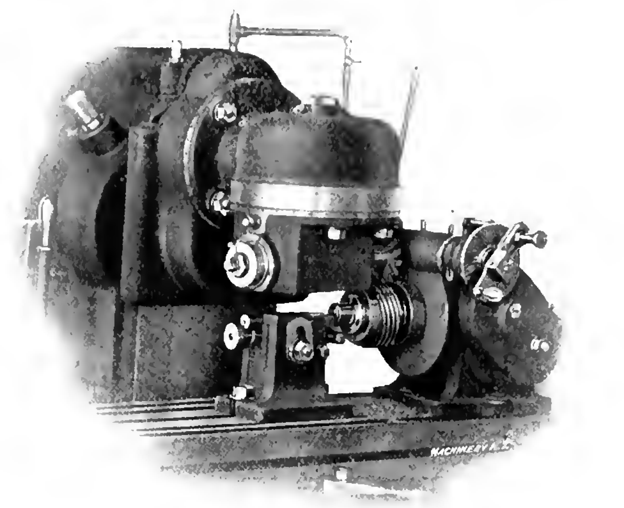

Fig. 3. The Attachment used in Connection with the Spiral Head

the spindle, it being keyed to the latter, although this is not shown in Fig. 1. Thus when the nut *F* is tightened, this bushing slides forward, and the spindle is at the same time drawn back into the taper box of the front bearing. The end of the spindle is provided with a slot or keyway for driving arbors carrying face mills and large milling cutters in general. The attachment has been made unusually heavy and rigid, and the object in bringing it out has been to provide means for using the milling machine on all kinds of unusual

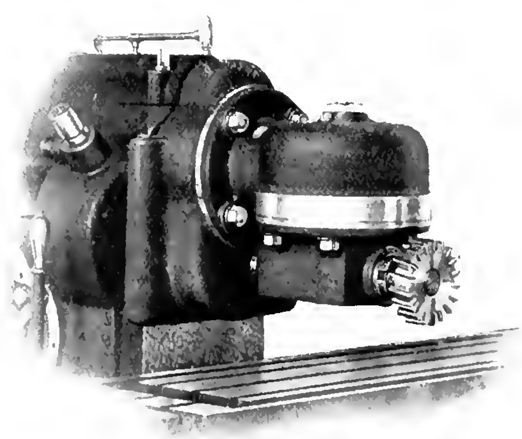

Fig. 4. Using the Attachment for Horizontal Milling at a Slight Angle with the Axis of the Main Spindle

jobs that from time to time arise in every shop, and which the ordinary machines with regular equipment are not sufficient to handle. The attachment will fit all sizes of milling machines built by the makers. It is held in place by being clamped to the knee slide on the column of the machine, the same as the vertical spindle and other attachments of this type, and it can be attached or removed very quickly and without difficulty.

In Fig. 3 the attachment is shown applied to the machine, with its spindle at right angles to the axis of the regular milling machine spindle but parallel with the table. It is here shown operating in connection with the spiral head. In Fig. 2, the attachment is shown in position for vertical milling, and in Fig. 4, for horizontal milling but in a position at a slight angle with the axis of the main spindle. Finally in Fig. 5 it is shown set for angular milling.

This device in connection with the regular horizontal milling machine makes it possible to do all classes of milling on this type of machine, and due to the fact that the attachment has been built along heavy lines, it is possible to perform vertical and angular milling practically to the full capacity of the main spindle of the machine. It has a capacity for face milling with cutters up to 6 inches in diameter. The attachment is made in three different sizes, all being

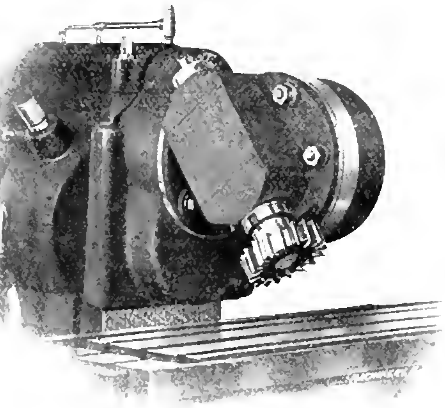

Fig. 5. The Attachment in Position for Angular Milling

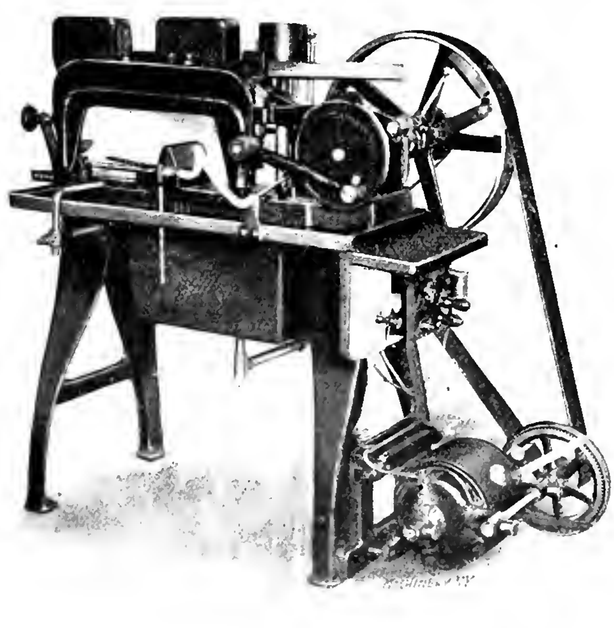
provided with No. 10 Brown & Sharpe taper hole in the spindle. The distance from the center of the spindle to the bottom of the attachment does not exceed 1 9/16 inch, and the distances from the center of the spindle to the face of the column when used for vertical milling is 10⅞, 11¼ and 11½ inches, respectively, for the three different sizes. The net weights of the attachments are 265, 290 and 325 pounds, respectively.

RACINE MOTOR-DRIVEN HACK-SAW MACHINE

A hack-saw manufactured by the Racine Gas Engine Co., Racine Junction, Wis., was illustrated and described in the New Machinery and Tools department in the July, 1908, issue of MACHINERY. This machine has now been equipped with direct motor-drive, as shown in the accompanying illustration.



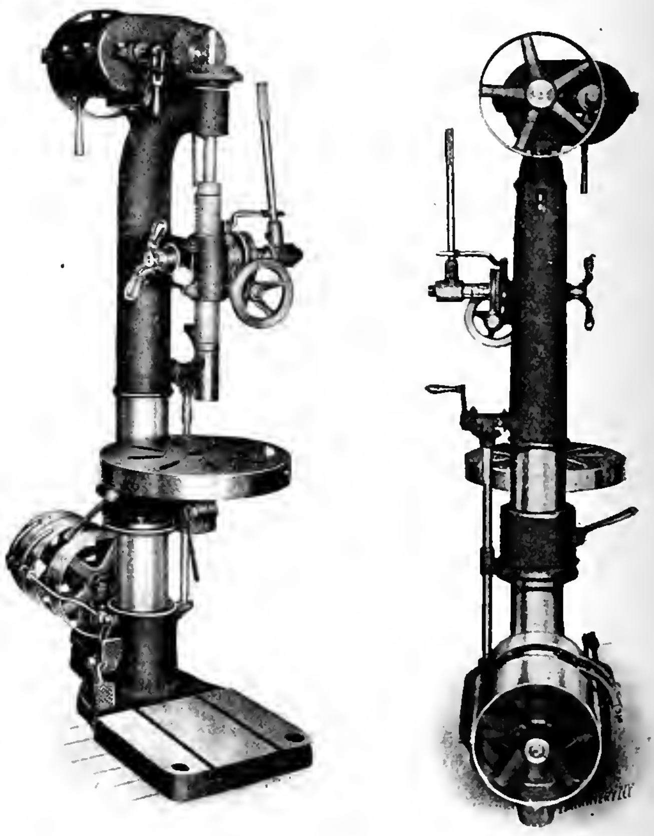
Motor-driven Hack-saw Machine, manufactured by the Racine Gas Engine Co., Racine Junction, Wis.

An important feature in this machine is that means are provided for lifting the saw from contact with the work on the back stroke, thus lengthening the life of the saw and increasing the rapidity of the cutting as well as leaving a smooth surface on the ends of the cut-off work. As will be seen in the illustration the motor is mounted on the lower part of one of the legs of the machine, reduction gearing being provided, and a belt transmitting the motion from the small lower pulley to the large driving pulley. As examples of the capacity of the machine it may be mentioned that a 1½-inch round cold-rolled steel bar can be cut off in 1½ minute, using common hack saw blades, no special blade being required in the machine. Another example of the capacity is that a 70-pound steel rail can be cut off in six minutes.

A special arrangement has been introduced for lubricating the saw while cutting. As seen in the illustration, a rubber hose connects a pipe to the right, which is fed directly from the oil pump, with an adjustable spout over the saw. As will be seen, this spout is mounted on the top of a rod which passes through the side of the bed and is held in position by means of a thumb screw. At the top of the rod a bracket is provided so that the spout can be swiveled about it. This combination makes it possible to raise or lower the spout as well as turn it to any position required.

SIBLEY HIGH-SPEED DRILL PRESS

The accompanying illustrations show a front and rear view of a high-speed drill press recently brought out by the Sibley Machine Tool Co., South Bend, Ind. It has been designed es-



Figs. 1 and 2. Front and Rear Views of 24-inch Drill Press, built by the Sibley Machine Tool Co., South Bend, Ind.

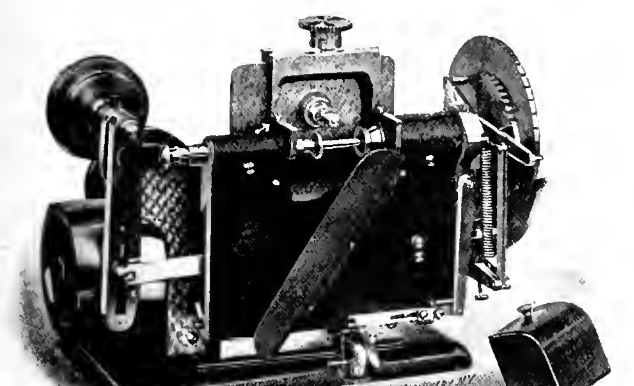
pecially with the view of meeting the demands of the automobile trade, and is provided with some features, new in upright drills, the most prominent of which is the location of the change gear box, which is placed on the top of the column, thus eliminating cone pulleys entirely, the drive being by means of a single constant-speed pulley. The gear box permits of eight changes of speed, and the construction is such that any speed can be thrown in instantly while the machine is running. The change speed gears in the gear box run in oil. The machine shown in the illustration is provided with combined hand-wheel and lever feed, but the machine is also made with geared power feed, if desired. The spindle is fitted with a hole for No. 4 Morse taper, and is provided with ball thrust end bearings. All running bearings are made of bronze. The machine has ample power to run high-speed steel drills of 1½ inch diameter up to the limit of their capacity.

WALTHAM AUTOMATIC GEAR-CUTTING MACHINE

In the June, 1908, issue of MACHINERY an automatic precision gear cutting machine built by the Waltham Machine Works, Waltham, Mass., was illustrated and described. The

accompanying engraving shows an improved design of this machine, differing from the one previously described in many important details. The machine is especially well adapted for cutting brass gears on account of the complete protection from chips provided for the indexing mechanism, the cams and the slides; but it is also suitable for other work and will cut steel gears and pinions of fine pitches satisfactorily. The protection for the working mechanism is obtained by means of a plate attached to the cutter slide and held in contact with the back side of the hood on the work slide. A removable cover also completely encloses the work and cutter, except for an opening below the work through which the chips fall.

During the return of the work slide, after the cut is taken, the cutter is lifted from the work so that the indexing can take place on the return stroke without loss of time. The location of the work slide in relation to the cutter can be adjusted laterally, and the depth of the cut is adjusted by a small handwheel, provided with graduations, at the top of the cutter slide. A large index plate is provided so as to insure accuracy of the divisions, and the different divisions are obtained by the adjustment of a single screw.



Automatic Gear-cutting Machine for Small Work, built by the Waltham Machine Works, Waltham, Mass.

With a "one-cut" machine, *i. e.*, a machine intended to cut to full depth at once, the feeding of the slides and the indexing of the work is continued automatically until all the teeth have been cut, and then the machine stops. With a "two-cut" machine, after the completion of one revolution of the work, the cutter is fed downwards a little deeper for a finishing cut, and the operations are continued another cycle, the machine stopping first after the completion of the second revolution of the work. This feature is of great value when cutting fine pitch teeth or very smooth work, as a finishing cut can, in this way, be made automatically without the attention of the operator.

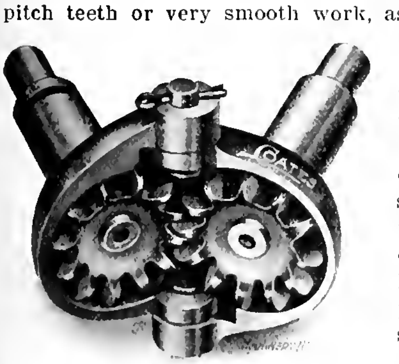


Fig. 1. Universal Coupling Drive operating at any Angle, made by the Coates Clipper Mfg. Co.' Worcester, Mass.

Two sizes of this machine are made; the smaller size is adapted for work up to 1¼-inch diameter, 32 diametral pitch in brass, and 48 diametral pitch in steel. The longest stroke of the work slide in this machine is 1¾ inch. The base of the machine is 9½ x 12½ inches, and the weight is 115 pounds. The larger machine cuts up to 3 inches diameter, 24 diametral pitch in brass and 32 diametral pitch in steel, the longest stroke of this machine being 3 inches. The size of the base is 11½ x 19½ inches and the weight 285 pounds. If required, a pump and a pan base will be provided for steel work.

COATES MONGREL GEAR UNIVERSAL COUPLING DRIVE

The problem of a satisfactory universal joint, which will work well and transmit power without excessive losses, whether the two shafts to be connected are entirely in line or at a very acute angle with each other, has always been an interesting one to machine designers. A great many universal joints have been brought out which will work very satisfactorily as long as the angles between the two shafts connected do not become too great; but few universal drives will work well when the angle of deviation of the axis of one

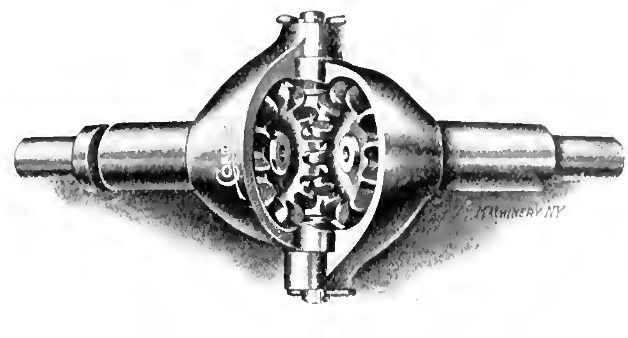

Fig. 2. The Universal Coupling in a position where the Two Shafts are more nearly in Line than in Fig. 1

shaft to the axis of the other becomes more than 45 degrees. The accompanying illustrations, therefore, of the Coates mongrel gear universal coupling drive, will be of particular interest.

This device is manufactured by the Coates Clipper Mfg. Co., Worcester, Mass., and its construction makes it possible to transmit power between two shafts either when they are practically parallel, or at a very acute angle as in Fig. 1, or when more nearly in line as in Fig. 2. When the two shafts are entirely in line, as in Fig. 3, the joint becomes practically a positive coupling, while in Figs. 1 and 2 the action is that of bevel gearing, the teeth cut on the parts keyed to the ends of each of the two shafts engaging with each other. The action and construction of the device is very plainly seen from the illustrations and there is little to be said in this respect. The cutting of the teeth in the gears is an interesting operation, and may deserve brief mention. The teeth are cut automatically on one of the Standard Mfg. Co.'s automatic gear cutting machines, shown in the May, 1906, issue

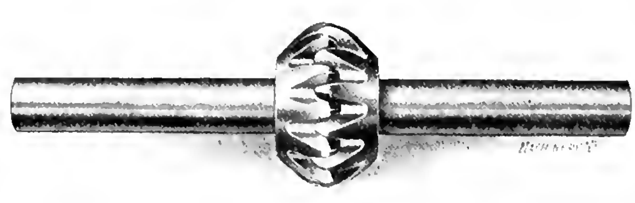

Fig. 3. The Mongrel Gear used as a Postive Coupling

of MACHINERY. This machine is provided with special cams so that the peculiar form in the bottom of the teeth which is not a straight line but a convex curve may be obtained while the cutter passes once across the work. By means of this machine it is possible to, automatically, first feed the cutter forward and then downward, thus obtaining the required shape of tooth.

Owing to its peculiar construction and the possibilities of drive which present themselves in this device, it will undoubtedly be of interest to mechanical men, as it is possible by means of this combination to use angular drives that would be difficult or impossible for regular universal joints or couplings.

DRAFTING TABLE

A new type of draftsman's table has recently been added to the line of drawing-room appliances manufactured by the Washburn Shops of the Worcester Polytechnic Institute, Worcester, Mass. The particular features of the table are the means for vertical adjustment, and the fact that the table or drawing board proper can be tilted to any angle desired. The top is made of well-seasoned white pine and is cleated to prevent warping, the cleats being so arranged that the shrinkage and expansion are taken care of. Universal drafting machines and parallel rules may be applied to the board if desired.

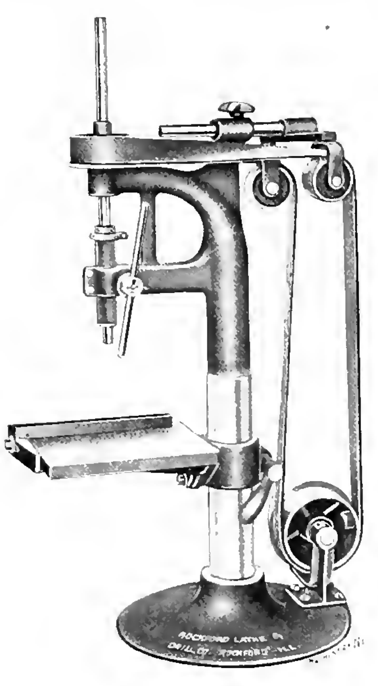
On the under side of the table two cast iron brackets are fastened, these brackets swiveling on the ends of the upright spindles. These swivels are clamped by two nuts operated by means of the small hand-wheel shown on the right-hand side directly below the board. The raising and lowering of the table top is accomplished by the hand-wheel shown near the right-hand upright. Two pinions meshing into racks set into

Draftsman's Table, built by the Washburn Shops of the Worcester Polytechnic Institute

the spindles are keyed to the hand-wheel rod. The raising and lowering feature is rather unique in that the spindles are always automatically locked in position and yet by simply turning the hand wheel in either direction the locking arrangement is released and the top is raised or lowered. The locking device is simple and requires no adjustment, and it has been shown by actual tests that it will stand 1,300 pounds pressure before slipping.

ROCKFORD TEN-INCH BENCH DRILL

The 10-inch sensitive bench drill illustrated in the accompanying half-tone engraving is manufactured by the Rockford Lathe & Drill Co., Rockford, Ill., formerly Rockford Machine & Shuttle Co. The countershaft for this drill can be placed either on the wall or on the ceiling, the driving cone being placed on the base of the machine to prevent vibrations. The driving belt from the pulley at the base to the pulley on the spindle passes over two idler pulleys. These are mounted in an adjustable bracket, so that by means of this adjustment the belt can be tightened as required. The table of the machine can be swung around the column, and can also be tilted to any position, making it very convenient in drilling angular and irregular work. A supporting bracket, as shown in the illustration, is provided, which can be placed on the table when drilling holes at an angle, for supporting the work and preventing it from slipping. The bracket can also be used for preventing work being drilled from revolving.



Ten-inch Bench Drill, made by the Rockford Lathe and Drill Co., Rockford, Ill.

The spindle is ¾ inch in diameter, its length being 17 inches. The lever feed of the spindle is 3 inches, and the vertical adjustment of the table 7¼ inches, the greatest distance from the spindle to the table being 10¾ inches. The table is square, 8 × 8 inches. The driving pulley on the countershaft is 5 inches in diameter for a 1½-inch belt, and the speed of the countershaft is 550 revolutions per minute. The weight of the machine is 112 pounds.

BARNES 24-INCH UPRIGHT DRILL

The 24-inch upright drill illustrated herewith, has recently been brought out by the Barnes Drill Co., 602 S. Main St., Rockford, Ill. This machine is of the same general design as the 20-inch upright drill which was illustrated and described in the May, 1908, issue of MACHINERY, and which has now been on the market for more than one year, during which time it has proved exceptionally satisfactory. The 24-inch drill, while of the same general appearance is, of course, stronger and more powerful. It is of the all-geared type, and is capable of handling as heavy work as the ordinary belt-driven 28-inch drill. The machine has 20 changes of positive power feeds, ranging from 0.0015 to 0.031 inch. All the feed changes can be made instantly by the operator from his position in the front of the drill, without stopping the machine.

Twenty-four-inch Upright Drill, built by the Barnes Drill Co., Rockford, Ill.

The speed changes, including the throwing in and out of the back-gears, can also be made when the machine is running.

The capacity of the drill is up to 2-inch high-speed steel drills, drilling steel. As an example of the power of the machine it may be mentioned that a 2 9/32-inch hole has been drilled in one minute with ordinary carbon steel drills through 2 inches of cast iron at the highest back-geared speed (64 revolutions per minute), or at a feed of 0.031 inch per revolution. In another case a 1 29/32-inch carbon steel drill was pushed through steel 1 inch thick in 55 seconds at a speed of 100 revolutions per minute and a feed of 0.011 inch per revolution. This, in fact, was all that the carbon steel drill could stand. With a 1-inch high-speed steel drill, the machine will drill through 1½ inch in steel in 23 seconds without the back-gears, at a speed of 258 revolutions per minute.

The machine is regularly furnished with back-gears and positive power feed box, but if desired, it can be supplied without the back-gears and the power feed. The machine can also be supplied with back-gears, but without power feed. The table of the machine is provided with T-slots as shown in the engraving, or elongated holes or slots through it, as required. When an oil pump is provided with the machine, it is furnished with a square table, having an oil channel around the edges.

The total height of the drill is 78 inches. The distance from the column to the center of the table is 12¼ inches. The maximum distance from the spindle to the table is 30 inches, and the maximum distance from the spindle to the base is 44½ inches. The diameter of the table is 20 inches, and the diameter of the spindle is 1¾ inch. The spindle is provided with a No. 4 Morse taper hole. The vertical travel of the spindle is 14 inches and of the table 19¾ inches. The ratio of the back gears is 4 to 1. The driving pulley, which is 12 inches in diameter by 4 inches wide, should run at 325 revolutions per minute. The floor space, exclusive of the tight and loose pulleys, which overhang 10½ inches, is 44 by 20 inches. The net weight of the machine complete is 1080 pounds.

LANGELIER SIX-SPINDLE GANG DRILL

The accompanying half-tone illustrations, Figs. 1 and 2, show a front and rear view, respectively, of a sensitive six-spindle gang drill recently brought out by the Langelier Mfg. Co., Providence, R. I. This machine embodies some rather interesting features, the principal one of which is that any of the drill spindles may be brought down independently by operating the foot lever shown in Fig. 1. The machine is not intended for work requiring the drilling of six holes at once, but the object of the machine is to perform six drilling, tapping or reaming operations when they occur in the same piece of work; each spindle performs one operation and the jig or work is passed from one spindle to the other, successively. In a machine of this type it is evidently desirable that all the spindles be brought as close to each other as possible, so that the operator sitting in front of the machine can perform the work without moving from his seat. In order to make this possible, however, it is necessary for each of the spindles to be brought down independently of the others when it is performing its work, so that there is no interference between the other spindles and the jig or the work. This is accomplished by operating the foot lever which actuates the feed for each spindle separately in rotation.

Fig. 1. Six-spindle Sensitive Gang Drill, built by the Langelier Mfg. Co., Providence, R. I.

The connection between the foot lever and the spindles consists of a segment gear which meshes with a ratchet gear on the cam shaft, shown in the rear part of the machine. On this cam shaft is mounted a feed cam for each spindle, these cams being adjustable so that the feed of the spindle can be actuated in any desired manner. The ratchet arrangement prevents the cams from returning to their original position when the pressure on the lever is released so that in this manner one spindle after the other is successively brought into operation by the foot lever. Each spindle has also a hand feed acting independently of the foot feed and an adjustable stop is provided for regulating the depth of holes when drilling.

The spindles are fitted with No. 11 Skinner chucks and are capable of drilling 3/16-inch holes in steel. The vertical feed of the spindles is 2¼ inches. The distance from center to center of the spindles is 3¼ inches. The table of the machine has a working surface of 8 x 28 inches, and is adjustable vertically 4½ inches. The greatest distance from the end of the chucks to the lowest position of the table is 7 inches. The tight and loose pulleys on the countershaft are 5 inches in diameter for 2-inch belt, the countershaft running at 200 revolutions per minute. These machines may be made in gangs with any number of spindles from two up to six, inclusive, and the distance between the centers of the spindles can be made to suit the requirements of the customer.

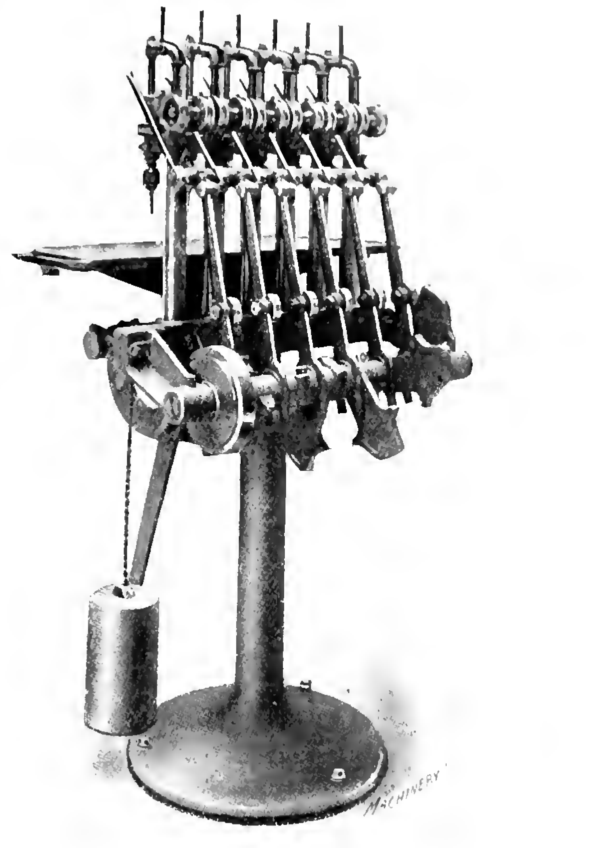


Fig. 2. Rear View of Gang Drill, showing Cam-shaft and Cams for actuating each Drill Spindle independently

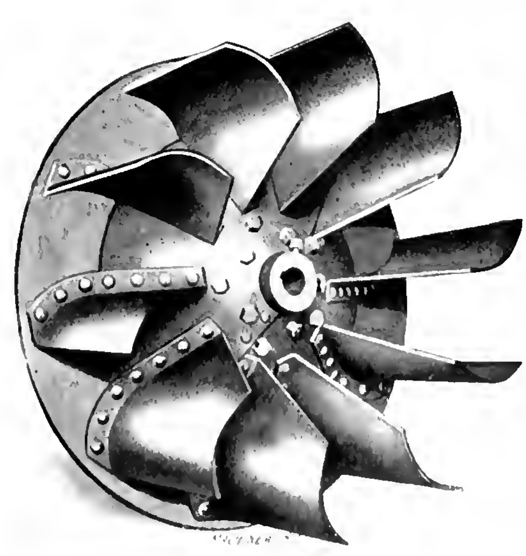
BUFFALO SLOW-SPEED EXHAUST FAN

A slow speed exhaust fan, designed particularly with a view of reducing the power consumed for driving, has recently been brought out by the Buffalo Forge Co., Buffalo, N. Y. The fan is known as the Buffalo slow speed low power exhaust fan, and runs at a 20 per cent lower speed than standard exhausters of the same size. It will, however, perform the same work as the standard fans with a 10 per cent reduc-



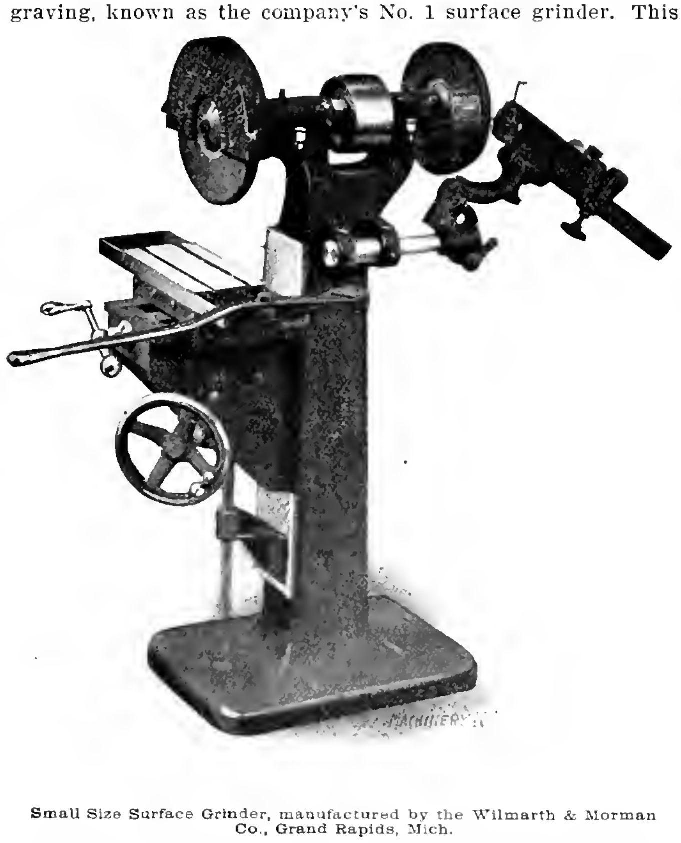
Slow-speed, Low-power Exhaust Fan, made by the Buffalo Forge Co., Buffalo, N. Y.

tion in power consumption. The blast wheel is built of heavy steel plate and instead of the spider usually employed for supporting the vanes, a steel plate cone is used. The apex of this cone is at the inlet of the fan so that the material to be exhausted, when entering the fan, strikes the cone, the direction of the material being gradually changed in this way without the loss of momentum due to sudden changes in direction. The cone offers no obstruction to the free passage of the material. The vanes are securely riveted to the cone and also to a heavy steel plate flange at the side opposite the inlet. This flange is extended beyond the tip of the vanes, preventing any material, thrown from the vanes, from coming in contact with a dead surface and retarding the progress. The fan is overhung on a shaft running in long journal bearings of the double ring oiling type. These bearings are supported on heavy cast iron pedestals in such a manner that the alignment of the fan is constantly maintained. The housing is built of heavy steel plate, securely bolted to a steel frame. It is adjustable to any angle of discharge on either side. All the necessary adjustments are quickly made on the outside of the housing. To change the direction of the discharge the bolts in the ring of each pedestal are loosened, and then the housing is revolved to the desired position.

These exhausters are applicable to various purposes, such as the removal of shavings, sawdust, refuse from wood-working machines and from buff and emery wheels, and from other abrasive processes. They can, of course, also be used for the exhaust of gases, acid fumes, etc.

WILMARTH & MORMAN SURFACE GRINDER

In order to meet the demand for a small convenient surface grinding machine of moderate capacity at a reasonable price, the Wilmarth & Morman Co., 580 Canal St., Grand Rapids, Mich., has placed on the market the machine shown in the engraving, known as the company's No. 1 surface grinder. This



Small Size Surface Grinder, manufactured by the Wilmarth & Morman Co., Grand Rapids, Mich.

machine has been built with a view of producing a machine equal in accuracy to larger machines, but limited to smaller work. The working surface of the table is 6 inches wide by 12 inches long, and sufficient movement is provided so that the grinding wheel can clear the working surface perfectly at both sides and at both ends. The transverse and vertical feed screws are provided with graduated dials with graduations reading in thousandths of an inch. These graduations are sufficiently coarse, so that even smaller sub-divisions can be readily obtained when such a degree of accuracy is required. The table is supported by the well-known knee and saddle construction used in milling machines, ample bearings being provided so as obtain the required rigidity. The vertical adjustment is obtained by a screw, as shown.

The machine is regularly provided with a grinding wheel of 12 inches diameter by 1 inch face, this wheel being intended to run at a speed of 1,400 revolutions per minute. The spindle bearings are cast in one piece with the column of the machine, which provides for rigidity and strength impossible to obtain when the spindle is carried by removable bearings. There is practically no overhang of the spindle at the end where the wheel is carried, thus increasing the capacity of the grinder for heavy cuts. On the opposite end of the spindle an additional grinding wheel is provided and the machine can be furnished either with or without the drill grinding attachment shown. Regularly it is furnished with this attachment which is of the well-known "New Yankee" type, which does not require any preliminary adjustments for bringing the drill in the proper position for grinding. The capacity of the attachment can be varied to suit the requirements of any individual shop.

NEW MACHINERY AND TOOLS NOTES

Four-Spindle Drill: American Watch Tool Co., Waltham, Mass. This machine consists of four independent sensitive bench drills mounted on a cast iron base-plate and adjustable to any position along the base. The spindles are operated by a foot treadle on the floor. The base-plates can be furnshed in lengths varying from 10 to 23 inches.

Quick Adjusting Micrometer: H. O. Costello, 87 Oakland Ave., Providence, R. I. This tool is an improvement on the quick adjustment micrometer mentioned in a brief note in the November, 1908, issue of Machinery. By means of a ratchet arrangement the barrel is adjusted rapidly for position without making use of the micrometer screw for the full length of the adjustment.

Bolt Pointing Machine: Webster & Perks Tool Co., Springfield, O. This machine is intended for pointing the ends of rods from 1/4 to 1/2 inch in diameter. The operation is very simple: The operator places the piece to be pointed in a vise against a stop and presses a foot lever; this grips the work and brings the cutter head forward. In this way, bolts can be pointed as rapidly as the operator can handle them.

Sixty-Degree Drafting Board: Emmert Mfg. Co., Waynesboro, Pa. This drawing board, known as the Noyes board, slides at a 60-degree angle, its weight being balanced so that it moves easily up or down. The frame is placed on any flat top table, and is usually provided with a board or leaf in addition to the inclined one, which is nearly horizontal and which can be used for calculations and reference drawings.

Saw Sharpening Machine: Hunter Saw & Machine Co., 59th and Butler Sts., Pittsburg, Pa. This machine has been designed for sharpening circular milling saws, and sharpens not only the faces and the tops of the teeth, but also bevels the cutting points in such a way as to materially add to the life of the saw and at the same time make it consume less power when in operation. Saws from 6 to 54 inches can be sharpened on the machine.

Breast Drill: North Brothers Mfg. Co., Philadelphia, Pa. With this drill two speeds are available, either of which can be obtained instantly, even when the drill is in motion. The tool is also so designed that it can be used either as a regular breast drill or as a right- and left-hand ratchet brace. These and other special features introduced in this drill, which differs considerably from the ordinary type, make it a very convenient tool for a great many different purposes.

Electric Hoist: Gustav Rasmus, 514 West 57th St., New York City. This hoist, while having a capacity of 5 tons, requires only 35 3/4 inches head-room, and weighs only 500 pounds. This is due to the fact that the motor is placed inside of the hoist drum, which constitutes the motor frame. The drive from the armature shaft is through a worm and worm-wheel, so that load and speed brakes are not required, as the gears are locked in position by the worm when the motor is at rest.

Large Drop Hammer: Erie Foundry Co., Erie, Pa. This machine is of very large dimensions, it being a 3,500-pound hammer, with an anvil block weighing 70,000 pounds. The entire weight of the hammer is 98,000 pounds. The hammer is provided with a piston stop placed at the top of the cylinder, which protects the cylinder head against damage due to carelessness or to the breaking of the rods or pulling loose of the cross-head. Adjusting screws are provided for cross movement of the anvil for lining up the dies quickly.

Precision Bench Lathe: American Watch Tool Co., Waltham, Mass. This machine is of the usual bench lathe type but some improvements have been introduced, particularly as regards the bearings for the spindle in the head-stock. The front end of the head-cone is also provided with graduations corresponding to the index holes at the back of the cone, mak-

ing it unnecessary for the operator to move from his position in order to set the index. The machine has a bed 36 inches long with a swing of 8½ inches and a chuck capacity of ⅝ inch.

Bench Profiling Machine: American Watch Tool Co., Waltham, Mass. This miniature profiling machine is designed along the same lines as the ordinary profiling machine with a vertical spindle and a guide located beside it. The vertical movement of the spindle is 1 inch and the cross movement 1⅞ inch. The slide or table below the spindle is capable of a 4-inch movement. By a simple arrangement the same handle operates both the vertical movement of the spindle and the side movement along the cross-rail of the slide carrying the spindle bearings.

Disk Grinder: Ransom Mfg. Co., Oshkosh, Wis. This grinder, designed especially to meet the requirements of the automobile trade, is furnished with disks either 23 or 27 inches in diameter; one grinding disk is provded at each end of the frame or column, the driving pulley being placed in the center between the spindle bearings. The work-tables at each end of the machine have independent lever feed, so that two operators can work simultaneously. Both tables can be tilted to an angle of 45 degrees with the face of the disk, and can be raised or lowered as desired.

Armor Plate Slitting Shear: Buffalo Forge Co., Buffalo, N. Y. This machine is not intended for cutting armor plate, as the name would imply, but the frame of the shear is made from armor plate which is a particularly touch and tenacious material and possesses a high elastic limit, especially suited for a machine of this character, subjected as it is to sudden and severe strains. The shear will cut metal of any width up to ¼ inch in thickness, and while possessing the requisite strength, it is, owing to the material from which it is constructed, lighter than any shear of similar capacity.

Milling Attachment for the Drill Press: E. C. Bliss Mfg Co., 91 Sabin St., Providence, R. I. This attachment is intended to be placed on the regular drill press table and is provided with slides in two directions so that milling operations can be performed by an end milling cutter placed in the drill press spindle. The working surface of the table is 8¾ by 21¼ inches, having a longitudinal movement of 9 11/16 inches and a cross movement of 5¾ inches. No swivel is provided, as the drill press table can be swung around when required. The adjusting screws have graduated collars reading to 0.001 inch. The weight of the device is 110 pounds.

Improved Lifting Magnet: Cutler-Hammer Clutch Co., Milwaukee, Wis. An improvement of this company's lifting magnet, shown in the September, 1907, issue of Machinery, has recently been made. The new magnet is of a smaller size and lighter than those previously described, but its lifting capacity is nearly as great. In the design, attention has been given to the conditions under which a device of this kind is operated, and the magnet can be used out-of-doors in any kind of weather without damage. Pig iron has been unloaded from gondola cars by means of it at the rate of 100 tons per hour and at a cost of ½ cent per ton, as against 5 or 8 cents per ton for manual labor.

Universal Monitor Lathe: Dreses Machine Tool Co., 227-239 West McMicken Ave., Cincinnati, O. This machine, as the name indicates, is provided with a turret and turret slide, the latter being provided with set-over and swivel. The top slide has combined lever and screw feed, and all slides have taper adjusting gibs. The turret is locked by a gibbed square key. The head and bed of the machine are cast in one piece, with entirely enclosed friction back-gearing. The entire operating mechanism of the friction in the head can be put in place and removed without taking out the spindle. A taper attachment is provided, placed separately on the bed below the V's, having knurled screws for fine adjustment.

New Line of Upright Drills: Cincinnati-Bickford Tool Co., Cincinnati, O. This company has redesigned its line of upright drills, including the 20-inch sensitive drill, the 21-inch drill with stationary head and the 21-inch drill with sliding head. Among the improvements included in the 20-inch drill are graduations on the spindle sleeve and an automatic stop for tripping when the required depth of hole has been drilled. In addition, ample guards have been provided for all gearing. The 21-inch machine has been provided with a new tapping attachment. This machine is back-geared, the back-gears being operated by a lever-controlled clutch. Power feed is provided by means of cone pulleys and worm and bevel gearing. In the sliding head machine, the head has a movement of 17½ inches, the table a movement of 16¾ inches and the spindle a traverse of 9 inches, giving the machine a large range. Improvements in the design of the full line of upright drills from 24 to 42 inches have been made, to make the machines capable of using high-speed drills to their full capacity.

"Most of the books on trigonometry are elaborate enough for a surveyor or an astronomer. A machinist doesn't want so much. For him to learn it all is too much like scraping something true to a surface-plate where it only fits against thin air."—*Extract from a letter.*

CHICAGO DUPLEX FEATHER KEYSEATING MACHINE

In the August, 1909, issue of Machinery a description of the Chicago duplex hand milling machine was published. The accompanying half-tone engravings, Figs. 1 and 2, show this machine in operation with both the vertical and horizontal spindles in use simultaneously. When thus arranged, the machine is intended in particular for the quick handling of feather keyseating work. The horizontal spindle is fitted with an arbor having a No. 9 Brown & Sharpe taper shank, the shank being held in place by a draw bar. On this arbor is mounted the required cutter for cutting the desired width of the feather keyseat. In the vertical spindle is placed an end mill of the required size, which is held in place by a draw-in collet.

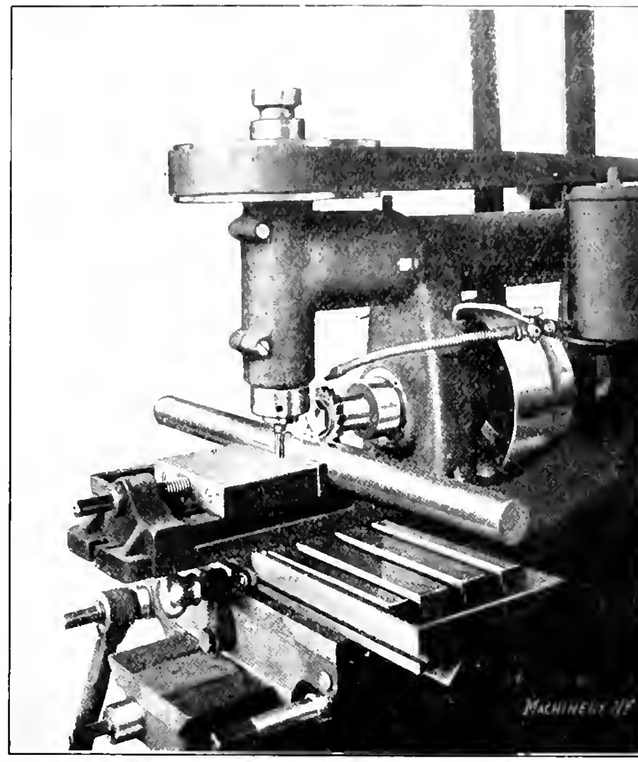

Fig. 1. First Operation in milling a Feather Keyseat on the Chicago Duplex Milling Machine

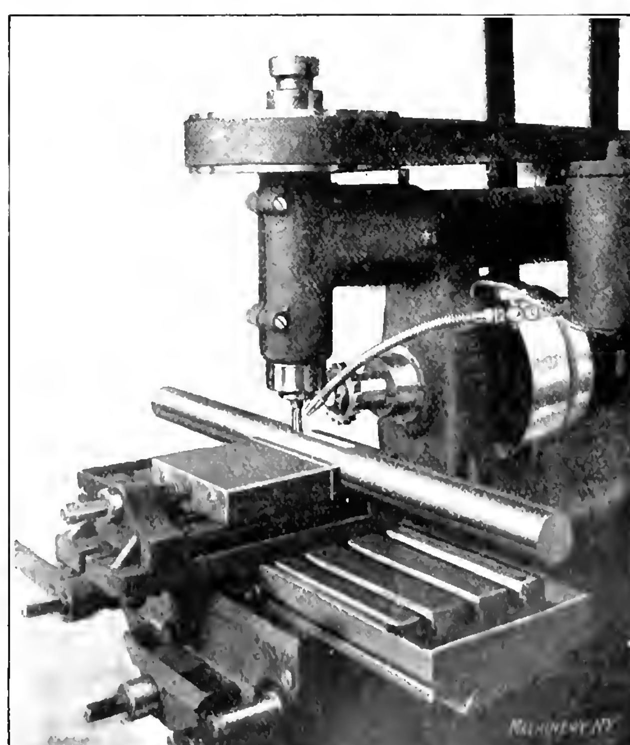

Fig. 2. Second Operation in milling the Feather Keyseat

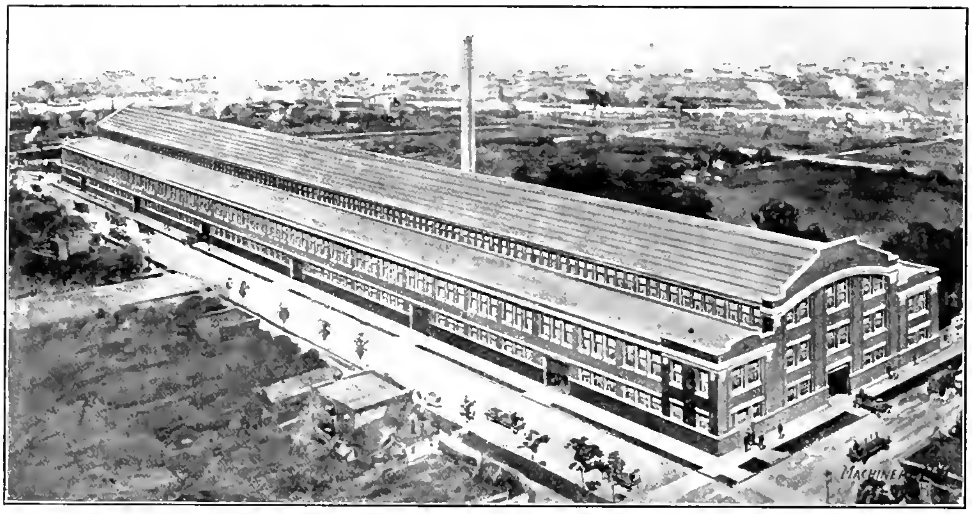
In Fig. 1, the machine is shown performing the first part of the operation of cutting a feather keyseat. The shaft in which

the keyseat is cut is held in a vise, and the side milling cutter shown mills out the keyseat excepting the finishing of the ends. This part of the operation is performed by the end mill in the vertical spindle, as shown in Fig. 2, where the table carrying the vise and shaft has been brought directly beneath the end mill. This makes a very handy arrangement for milling feather keyseats, as the two complete operations necessary for the milling can on this machine be made without resetting the work or even stopping the machine; thus, in reality, it may be considered as a continuous operation. The machine is equipped with six changes of power feed as well as crank and lever feeds, thus having a sufficient range to cover all ordinary work. The hand-lever feed is brought into service when the table is quickly returned after a cut has been taken. An adjustable automatic stop to the table feed is also provided which can be set for the length of keyseat desired. Hill, Clarke & Co., Inc., 125 North Canal St., Chicago, Ill., are the selling agents for this machine.

* * *

CHICAGO MACHINERY EXHIBITION WAREHOUSE

The illustration shows a new machinery exhibition warehouse just completed in Chicago that is 100 feet wide and 400 feet long and absolutely fireproof, being built of reinforced concrete throughout. It is located at 37th St. and Ashland Ave., on the Chicago Junction Railway, connecting with all railroads and boat landings. It was built by the Pfannmueller Engineering Co. to plans supplied by architect A. S. Alschuler, and was erected by general contractors J. P. & J. W. O'Connor.



Reinforced Concrete Machinery Warehouse just completed in Chicago at 37th Street and Ashland Avenue

The building is three stories high in front, two stories on the sides and one story in the center. The offices are on the three floors in the front of the building and run across the entire width of the building, giving office space on the second story 20 by 100 feet and on the third story 20 by 50 feet. The space in the center of the building, 50 feet wide by 40 feet high, runs the entire length of the building and is absolutely unobstructed. It is spanned by a 50-foot 25-ton Alliance traveling crane having a 6-ton auxiliary. The balconies on the sides are supported by massive concrete columns 20 feet apart, and these also support the crane runway. The spaces on the ground floor beneath the balconies are 20 x 25 feet, and may be partitioned off when so desired and thus make individual exhibition and storage rooms. In order that heavy machinery may be handled readily on the first floor, eye-bolts are set every ten feet in the brick wall to provide a means of attaching block and tackle to be used in connection with the crane for pulling heavy machinery into and out of these spaces. The balcony floors extend into the middle space 5 feet under the crane and are equipped with removable rails, thus providing a passageway and means by which the crane can serve the balcony. The building will be finished with all modern conveniences, including electricity, steam heat, ample toilet arrangements, shower baths, telephone switch-board with several trunk lines, etc.

Fig. 1. Ratchet Wrench for Tightening Tie-rod Nuts on Pipe laid in a Trench

In the rear of the structure there is a paved yard, fenced in, 100 feet wide and 160 feet long which will be used for rough machinery and metal products that do not necessarily have to be kept under cover. This space provides for the extension of the building. A private switch from the Chicago Junction Railway enters the building at the rear.

The building is located in the center of the manufacturing district and in the geographical center of Chicago. It is accessible by numerous car lines, and in view of the unsatisfactory conditions generally existing in Chicago affecting salesrooms and warehouses, it is believed that the new venture will fill a long-felt want. The fact that the equipment will handle heavy machinery at a minimum cost and that there will be no switching charges on carload shipments either incoming or outgoing, makes possible a big saving of charges now borne by the machinery warehouses not located so advantageously or provided with modern handling equipment.

RATCHET WRENCH FOR TRENCH WORK

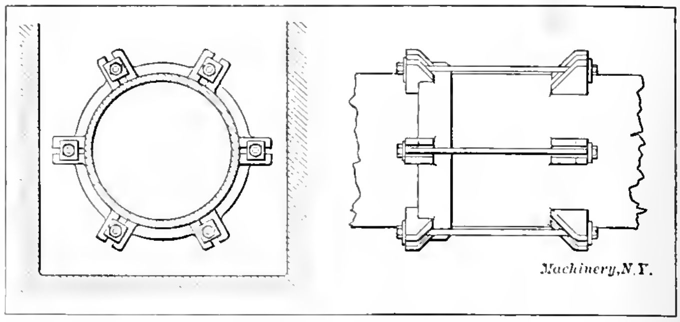

Fig. 2. Illustration showing the Work for which the Wrench shown in Fig. 1 was designed

The Philadelphia Gear Works was called upon recently to design some form of wrench for tightening 1¼-inch hexagon nuts at the bottom of a trench 3 feet wide and 10 feet deep. These nuts were on the tie-rods of a 20-inch cast-iron pipe line (see Fig. 2) where there was very little room in which to work, and some special arrangement was necessary for tightening them. To enlarge the trench was not advisable as excavating was done at so much per cubic yard, and as there were fifteen miles of pipe being laid, the idea of widening the trench at each joint to permit of the use of an ordinary wrench, was abandoned. The device shown in Fig. 1 was designed and does the work admirably. This wrench is simple in its construction as it consists of nothing more than a hexagon cup to fit the nut, a pair of miter gears mounted on a light frame, and a reversible ratchet and lever. As will be understood, the miter gears are to bring the ratchet shaft at an angle of 90 degrees with the axis of the wrench proper, so that the wrench lever is in line with the trench, thus giving plenty of room for its operation. With this device one man can tighten the two bottom nuts with less profanity and

time than is required to set up the four more accessible nuts with an ordinary ratchet wrench.

* * *

SPARKS AS INDICATIONS OF DIFFERENT KINDS OF STEEL*

The sparks given off when grinding iron and steel, by means of emery wheels, present a different appearance according to the kind of material ground. In the following, a review is made of the appearance of the sparks of different materials, and explanation is given of the causes of the differences, and the practical applications of this method of steel testing are pointed out.

The path of the spark from its origin to its extinction forms a line of light which may be called the spark-ray. This spark-ray consists of a line of light the end of which branches out in every direction, having an explosion-like appearance. It is this end of the rays that, in particular, varies for different classes of steel, and which in the following will be called the spark-picture. Some of these spark-pictures contain only a very few lines, while others contain a great many, some of them presenting secondary explosions and projections. The rays extending from the drop formation in the spark-picture have a strikingly higher speed than the particles in the spark-rays, and it appears as if they were suddenly thrown out in various directions by an internal force.

With a carbon content of from 0.07 to 0.08 per cent, the number of the lines in the spark-picture is from two to three. With an increase of the percentage of carbon the number of the branching lines also increases. At low carbon contents the lines appear to start from different points of the drop formation at the end of the ray, but when the carbon content is as much as 0.25 to 0.27 per cent the lines spring from a common point of the drop formation. The larger the carbon content the greater is the crowding of the lines projecting from the end of the ray. (See Fig. 1.)

The spark-picture of steel containing manganese (see Fig. 2) shows at the end of the individual branching lines a secondary explosion-like phenomenon, shorter lines collecting like leaves around a common central point. The number of the primary branching lines in this case also is in proportion to the carbon percentage in the steel; the extent and shape of the spreading ends of the primary branching lines appear to be in a certain relation to the percentage of manganese contained by the material.

In the case of tool steel, the spark-picture resembles the branch of a blossom, and the individual branching lines have a lilac-like form.

The spark-rays of steel containing wolfram are dark red lines, the ends of which show no spark-picture if the emery wheel is not sufficiently sharp and the pressure between the wheel and steel is small. Only the very end of the ray has a broader and more brightly glowing appearance, indicating the beginning of a spark picture. If the steel is pressed more firmly against the wheel, branching lines spring out in an explosion-like manner. These lines, however, take the form of small shining pin-head-like balls.

The spark-sheave (the combination of spark-rays and spark-pictures) of chrome-wolfram high-speed steel is distinct from that of the wolfram steel by the fact that two kinds of rays appear, some very thin dark red, and some thicker bright red ones, which are absent in the regular wolfram steel. The spark-pictures consist solely of short curved drop forms.

The spark-picture of nickel steel, containing less than three per cent nickel, is identical with that of carbon steel with a corresponding percentage of carbon. In case of larger percentages of nickel, however, the nickel steel can readily be recognized by the aid of the spark test, because the spark-pictures show themselves in a sporadic manner whereas in the case of carbon steel they occur in close proximity and in close succession to one another.

Dark gray cast iron is characterized by fine dark red spark-rays, spark-pictures here and there, and lines collecting around the drop formation like a net. The net-like lines disappear more and more with the increase of assimilated carbon, and with light gray cast iron they disappear altogether.

Fig. 1. Spark-picture indicating High-carbon Steel Fig. 2. Spark-picture of a Tool-steel containing Considerable Manganese Fig. 3. Spark-picture of Steel containing Wolfram Fig. 4. Spark-picture of Molybdenum High-speed Steel

Theory of Spark Formations

The spark emitted when grinding is of course a particle of the metal being ground, heated to a high temperature by the friction between the emery wheel and the material. This particle of metal is thrown out in a tangential direction. At a certain point of its line of flight, the red hot spark assumes a red heat; it changes to white heat, and then transforms itself in an explosion-like manner into a spark-picture. At the moment of the explosion-like transformation the spark is in a fluid state. The latter statement can be proved by introducing a plate of glass at right angles to the line of flight and microscopically examining the glass. It is apparent that the sparks must be in a fluid condition, as they either splash asunder when striking the glass or form crystals of different shapes.

The increase of heat of the spark is caused by an internal source of heat represented, partly, by the combustion heat of the carbon, which suddenly burns. The heat of oxidation of

* Abstract from a paper by Mr. Max Bermann read before the Copenhagen Congress of the International Association for Testing Materials.

the exterior surface of the mass of sparks prevents too rapid cooling of the spark. The heat of cumbustion of the carbon provides the quantity of heat necessary for melting the metal. As a matter of fact, however, this heat is not sufficient to melt the whole mass, because the amount of carbon is too small, and only the mass of the unoxidized core within the oxidized iron crust is melted by the quantity of heat available. The combustion gases of the carbon burst the outer crust of the spark mass and throw out the fluid contents in the direction of the primary branching lines. The silicon and phosphorus contained also burn at the melting heat of the iron, and raise the temperature of the fluid mass. This theory explains why the size of the spark picture increases with the percentage of carbon.

Practical Applications of the Spark Test

The most important practical applications of the spark test may be stated as follows: Different kinds of iron may be classified according to their carbon percentage and the metals principally alloyed with them; ends of rods which may have been wrongly arranged on the storing racks may be placed against the revolving emery wheel and thus identified. It is stated that the spark test is so sensitive that differences of 0.01 per cent of carbon may be perceived. In the inspection of received material the method is valuable for making a rapid test to make sure that the material complies with the requirements. The spark test also supplies a sensitive means of ascertaining differences in chemical composition at different places of the same bar or piece of material, it being possible to apply this test to both steel and cast iron. In the hardening room the spark test may also be of value in order to make sure before hardening what grade and class of steel has been used for making the various tools, so that the proper hardening process may be applied. In the forge shop the method may be of value for determining with certainty good malleable wrought iron.

PERSONAL

G. W. Hoffman has been appointed sales engineer in charge of the Chicago office of the Hill Clutch Co., Cleveland, Ohio.

R. K. Loofbourrow is the newly appointed purchasing agent of the Electric Welding Products Co., Cleveland, Ohio.

H. O. Connelly, recently assumed the management of the New York office of the Cleveland Pneumatic Tool Co., Cleveland, Ohio.

B. L. Waters, of Aurora, Ill., is establishing an Eastern Branch of the Lyon Metallic Mfg. Co., in New York, with headquarters at 1365 Hudson Terminal Building.

Richard B. Sheridan has been promoted from chief sales engineer to assistant general manager of the Brown Hoisting Machinery Co., Cleveland, Ohio.

Charles F. Baehr, for twelve years with the Northern Electric Mfg. Co., has taken the position of superintendent of the Globe Machine & Stamping Co., Cleveland, Ohio.

Ernest L. Smith, lately eastern representative of the Standard Roller Bearing Co., Philadelphia, is now sales manager of the Grant-Lees Machine Co., Cleveland, Ohio.

Albert Bayton, formerly tool-room foreman for the Reed Mfg. Co., Erie, Pa., is now superintendent, succeeding F. Hubbard, deceased.

George W. Johnson, for the past four years superintendent of the Chapman Valve Mfg. Co., Springfield, Mass., has resigned his position.

H. L. Hunter has been transferred from Edgemont, South Dakota, to Alliance, Neb., to take charge of the machine shops of the C. B. & Q. R. R.

W. M. Corse, secretary and treasurer of the American Brass Founders' Association, has been made works manager of the Lumen Bearing Co., Buffalo, N. Y.

William Perrine has been appointed master mechanic of the New Jersey Central and Lehigh and Susquehanna divisions of the Central Railroad of New Jersey.

George W. Fuller, for forty-seven years master mechanic of the Estey Organ Co., Brattleboro, Vt., has resigned his position and will spend the remainder of his life on "easy street."

Frank Davis, superintendent of the Haydenville Co.'s brass works, Haydenville, Mass., has resigned, and Fred Noble, assistant superintendent, has been made superintendent.

William Spire, formerly superintendent of the Marine Gas Engine Co. of New Jersey, has taken the position of mechanical engineer of the Electric Welding Products Co., Cleveland, Ohio.

A. N. Frecker, who has been for some years in the electric drill and grinder business at 95 Liberty St., New York, has been made general sales manager of the Van Dorn Electric & Mfg. Co., Cleveland, Ohio.

W. S. Howe, formerly advertising manager in charge of the small tools sales department of the Canadian-Fairbanks Co., Ltd., Montreal, has become associated with the S. A. Woods Machine Co., wood planer specialists, Boston, Mass.

Eugene Childs, formerly connected with the Trimont Mfg. Co., Roxbury, Mass., has been made president and general manager of the Springfield Drop Forge Co., Springfield, Mass, recently acquired by the Lakeside Forge & Wrench Co., Springfield, Mass.

W. S. Giel, lately superintendent of the Stoever Foundry & Mfg. Co., Myerstown, Pa., has severed his connection with that concern. Mr. Giel will devote his time to special work. His address is 3 Hamilton Park, New Brighton, Staten Island, New York.

Dr. W. H. Tolman, director of the Museum of Safety and Sanitation, 29 W. 39th St., New York, delivered an illustrated lecture before the National Machine Tool Builders' Association, Hotel Astor, October 13; also the same before the Liability Insurance Association at the Hotel Astor, October 20.

Howard Terhune, author of the article "Board Drop Hammer Design," published in this number, engineering edition, has resigned from the employment of Billings & Spencer Co., Hartford, Conn., and has taken a position with the E. W. Bliss Co., Brooklyn, N. Y.

Augustus M. Kelly, has resigned his position of foreman of the machine molding department of the Chapman Valve Mfg. Co.'s foundry, Springfield, Mass., to take the position of superintendent of the American Blower Co.'s foundry, Detroit, Mich., and has assumed his new duties.

H. A. Elliott, formerly with Alfred Schütte of Cologne, Paris and New York, has taken the position of American agent of Usines G. Derihon of Loucin, Belgium, specialist in the manufacture of automobile forgings. Mr. Elliott's headquarters are at 7502 Carnegie Ave., Cleveland, Ohio.

The personal note published in the April number stating that James W. Ogden, formerly superintendent of the Bridgeport Foundry & Machine Co., Bridgeport, Conn., had been made superintendent of the Wolverine Motors Works, Bridgeport, was erroneous. Mr. B. A. Yarrington is the superintendent.

H. J. Brandes, formerly connected with the Bullard Machine Tool Co., Bridgeport, Conn., in the capacity of superintendent, has severed his connection and has taken up the active management of the Springfield Mfg. Co., Bridgeport, Conn., maker of special grinders and emery wheels. Mr. Brandes purchased the business from Mr. George Jackman, who has retired.

Dr. William H. Tolman, director of the Museum of Safety and Sanitation, 29 West 39th St., New York, has completed arrangements for a lecture tour dating from October, 1909, to March, 1910, the itinerary of which includes the principal cities and towns in the New England, Middle and Middle Western States north of the Ohio and east of the Mississippi River, and a few cities west of the Mississippi, comprising St. Louis, Cedar Rapids, Davenport, Des Moines, and Burlington.

Aguste Isaac, president of the Chamber of Commerce, Lyons, France, visited America in October to study industrial conditions with special reference to the apprenticeship training of young men for the machinist's and other trades. He found a striking similarity between labor conditions in France and America as regards difficulty of holding boys to the terms of their indentures. They have the bad habit in France of working a year or two and then leaving and hiring out to other manufacturers as journeymen. The consequence, of course, is that there are many "half-baked" French machinists.

* * *

OBITUARIES

Edward T. Coe, treasurer of the Coe Brass Co., Torrington, Conn., died at his home in New Haven, Conn., October 5.

Carl Wilcox, of Wilcox & Gibbs, New York, a sewing machine inventor, died at his home in Westport, Conn., aged sixty-five years.

L. L. Heller, president of the Sterling Motor Car Co., Binghamton, N. Y., was killed October 6 by being struck by a Lehigh Valley R. R. train, near Waverly, N. Y.

Albert J. Perks, partner of the Webster & Perks Tool Co., Springfield, Ohio, died at his home in Springfield, October 4, aged fifty-eight. Mr. Perks was born in Birmingham, England, and came to America with his parents when a child. His parents located at Dayton, Ohio, where Mr. Perks spent his boyhood. He moved to Springfield when about eighteen, and since then has been actively engaged in manufacturing enterprises. For a number of years he was superintendent of the bar and knife department of the old Whiteley Machine Co., located where the Foos Gas Engine Co. now is. In October, 1891, he severed his connection with the Whiteley interests and entered into partnership with John F. Webster to manufacture machine tools under the firm name of Webster & Perks

Lewis C. Grover

Tool Co. Mr. Webster died in December, 1893, and Mr. Perks carried on the business alone until 1898, when Mr. Herman Voges, Jr., became associated as a partner in the business, which arrangement was carried on up to the time of Mr. Perks' death. Mr. Perks was an expert mechanic and machine designer, and an inventor of a number of valuable appliances. He is survived by his widow and two sons, George W. and Bert W.

LEWIS C. GROVER

Lewis C. Grover, chairman of the board of directors of Colts Patent Fire Arms Mfg. Co., Hartford, Conn., and for several years president of the company, died at his home in Hartford, September 30, following an illness of about three years. Mr. Grover was born, 1849, in Springfield, Mass., and was educated in the public schools. He served an apprenticeship to the machinists' trade in the Norwalk Iron Works, South Norwalk, Conn., and such was his aptitude for mechanical work that he was made foreman on the completion of his apprenticeship term. When only twenty-eight he accepted the position of general manager of the Whitney Arms Co., at New Haven, which position he held six years. In 1886 he was made assistant superintendent of the Colts Patent Fire Arms Mfg. Co., and soon became superintendent, and then general manager. In 1902 he was elected president and a director of the company to succeed John H. Hall. He was also elected president of the Colts Arms Co., of New York. He resigned the office of president of both companies last January because of poor health, but was elected chairman of the board of directors of each company. Mr. Grover was a man highly esteemed by his friends and employes. He was an indefatigable worker, and, although a broad-minded manager who understood how to delegate authority to subordinates and hold them responsible for results, no detail of the large manufacturing business which he managed was too trifling to receive his attention.

* * *

COMING EVENTS

November 9.—Monthly meeting of the American Society of Mechanical Engineers, Engineering Societies Building, 29 West 39th St., New York. Two papers will be presented; one by Prof. Gaetano Lanza and Lawrence S. Smith of the Massachusetts Institute of Technology on reinforced concrete beams, and the other by Prof. Walter Rautenstrauch of Columbia University on stresses in curved machine members. The paper on reinforced concrete beams compares the results of tests upon full size beams made at the Massachusetts Institute of Technology and the University of Illinois with three different theories of beams of this type. The paper on stresses of curved machine members outlines the method of procedure for the design of principal sections of hooks, punch and shear frames and other curved machine parts. Experimental results will be submitted in support of the theory presented. Calvin W. Rice, secretary, 29 West 39th St., New York.

November 18 19.—Annual meeting of the Society of Naval Architects and Engineers, Engineering Societies Building, 29 West 39th St., New York. W. H. Baxter, secretary, 29 West 39th St., New York.

November 19-20.—Annual meeting of the Ohio Society of Mechanical Electrical and Steam Engineers, Lima, Ohio. David Gaehr, secretary, Schofield Building, Cleveland, Ohio.

December 1-3.—Annual convention of the National Society for the Promotion of Industrial Education. An exhibition of school work from all over the United States will be one of the features. J. C. Monaghan, secretary, 20 West 44th St., New York.

December 7-10.—Annual meeting of the American Society of Mechanical Engineers in the Engineering Societies' Building, New York. Mr. Calvin W. Rice, secretary, 29 West 39th St., New York.

January 1-8.—Tenth international exhibit of automobiles and automobile appliances, Grand Central Palace, New York, under the auspices of the American Motor Car Manufacturing Association. R. E. Olds, chairman, 505 Fifth Ave., New York.

January 8-15.—Association of Licensed Automobile Manufacturers tenth annual exhibition of automobiles and automobile appliances, Madison Square Garden, New York. M. L. Downs, secretary, 7 East 42d St., New York.

April 1-June 30, 1910.—American Exposition in Berlin to stimulate trade relations with Germany and American export business generally. The exposition will be held in the Exposition Palace, having 110,000 square feet floor space. Max Vieweger, American manager, 50 Church St., New York.

NEW BOOKS AND PAMPHLETS

Annual Report of State Geologist of New Jersey for 1908. 159 pages, 6 x 9 inches. Published for the State by Mr. Henry B. Kümmel, State geologist, Trenton, N. J.

Transactions of the National Association of Cotton Manufacturers: No. 86. 556 pages, $6\frac{1}{2} \times 9\frac{3}{4}$ inches. Secretary and Treasurer C. J. H. Woodbury. Room 501, 15 Milk St., Boston, Mass.

Manual of Steam Engineering. By W. H. Wakeman. 411 pages, $3 \times 5\frac{1}{2}$ inches. Published by New York Belting & Packing Co., Ltd., for distribution.

This manual will be found valuable by those concerned with the common problems coming up in the power plant. It treats of boilers, boiler feeders and steam engines. Many tables and rules are given that should be appreciated by the stationary engineer and others. Description for setting the valves of duplex pumps and calculating the horsepower of engines are examples.

Manual for Engineers. By Chas. E. Ferris. 165 pages, $3 \times 5\frac{1}{2}$ inches. Published by University of Tennessee, Knoxville, Tenn. Price, 50 cents.

This manual, which is a revised edition, contains in convenient form many valuable tables and other data for engineers and business men. Some of the most important tables in the book are as follows: Areas and circumferences of circles; square and cube roots; natural sines, tangents and secants; steam tables dealing with capacity of turbines; extensive tables for electric wiring; interest tables, etc.

Mechanical World Pocket Diary and Year Book for 1910. 391 pages (including advertising), $3\frac{3}{4} \times 6$ inches. Published by Emmott & Co., Ltd., Manchester, England. Price, 6 pence.

This publication has become quite well known in the United States, this being the twenty-third year of publication. It treats of steam and steam engines, including compound and triple expansion types, details of construction, condensers and condensing plants and condenser details; steam turbines, boilers and boiler construction, chimneys, super-heating, feed water, fuels, gas and oil engines, gas producers, centrifugal pumps, beams and girders, shafting, gearing, ball bearings, belting, rope drives, wire ropes, bolts and nuts, screw threads, screw cutting, miscellaneous mathematical tables, etc.

Metal Spinning. By Fred D. Crawshaw. 74 pages, $4\frac{3}{4} \times 6\frac{3}{4}$ inches. 33 illustrations. Published by Popular Mechanics Co., Chicago, Ill. Bound in cloth. Price, 25 cents.

Metal spinning, while once of considerable importance, is an art that is going into decline and, strange to say, it is one on which it is claimed no book had been published until the appearance of this work. The present practice is to employ drawing and forming press tools to produce the work that was formerly made on the spinning lathe. The work recognizes this fact and was written largely for the instruction of amateurs, trade schools, and the crafts which produce art work in limited amount. The tools, chucks and samples of work produced are illustrated and described. The book will be found of considerable general interest because of the fact that no other work on the subject has been published and also because of the interesting character of the operations and tools employed.

Efficiency as a Basis for Operation and Wages. By Harrington Emerson. 171 pages, 5 x 7 inches. Published by the *Engineering Magazine*, New York. Price, $2.

This work is based on the articles published under the same title in the *Engineering Magazine* from July, 1908, to March, 1909, revised, rearranged and expanded by the author. Mr. Emerson is a well-known works management engineer who has given years of scientific study to the problem of efficiently employing labor and securing the highest efficiency by intelligent direction of effort. The philosophy of works management is slowly taking shape, and Mr. Emerson's treatment will be found exceedingly interesting by those concerned with it either in theory or in stern practice of everyday life. The contents by chapters are: Typical Inefficiencies and their Significance; National Efficiencies—Their Tendencies and Influence; The Strength and Weakness of Existing Systems or Organization; Line and Staff Organization in Industrial Concerns; Standards—Their Relations to Organization and to Results; The Realization of Standards in Practice; The Modern Theory of Cost Accounting; The Location and Elimination of Wastes; The Efficiency System in Operation; Standard Times and Bonus; What the Efficiency System may Accomplish; The Gospel of Efficiency.

Notes on Practical Mechanical Drawing. By Victor F. Wilson and Carlos L. McMaster. 186 pages, 6 x 9 inches. 86 illustrations. Published by Wilson & McMaster, East Lansing, Mich. Price, $1.50.

This book which treats of lettering, orthographic projection, isometric and oblique drawing, use of instruments, working drawings, geometrical drawing, machine sketching, etc., has been revised, rearranged and enlarged by 25 pages for the third edition. The chapter on lettering describes the various types of lettering commonly used on mechanical drawings, and illustrates a number of examples. Considerable attention has been given to orthographic projection, examples being given from which the student can get a clear idea of the relation of the three common views used in the ordinary mechanical drawing. The sketches in phantom perspective are well executed and give the work an attractive appearance. Practical instructions are given for making working drawings that agree very well with the common usage of draftsmen in manufacturing establishments. The book is one that can be recommended to industrial schools and all students who wish to study mechanical drawing at home or to others who wish to obtain a knowledge of the common relations of views and methods of making drawings without going to the trouble of learning to draw.

Power, Heating and Ventilation. By Charles L. Hubbard. 647 pages, 6 by 9 inches, 412 illustrations. Published by the Technical Press, Brattleboro, Vt. Price, $5.

This book is intended for designing and constructing engineers, architects, etc. The subject of power is treated especially from the steam side, but sufficient information bearing on electrical matters is given to enable the intelligent arrangement of the steam plant with reference to the requirements of electric lighting and the distribution of electrical power. The subject of boilers is quite fully treated, and much valuable information is given on the construction of various types, the design of tubular boilers, boiler accessories, care and management, etc. The theory of the steam engine is taken up and descriptions of different types given, including the steam turbine. The subject of condensers is also treated, and the use and construction of cooling towers explained. A chapter devoted to steam and feed piping contains many valuable tables and formulas and also considerable information of practical value to the engineer. The problem of heating and ventilation as applied to all classes of buildings, from a small furnace-heated dwelling to buildings with central plants of the largest size, is fully treated. The various chapters dealing with this subject are as follows: Systems of Warming; Ventilation; Heat Loss from Buildings; Furnace Heating; Direct Steam Heating; Indirect Steam Heat

ing; Direct Hot Water Heating; Indirect Hot Water Heating; Forced Hot Water Circulation; Fans; Forced Blast Heating and Ventilation; Exhaust Steam Heating; Electric Heating; Special Devices; Heating and Ventilating Different Types of Buildings; Care and Management of Heating and Ventilating Plants.

ELEMENTS OF MACHINE DESIGN. By Dexter S. Kimball and John H. Barr. 446 pages, 6 x 9 inches, 196 illustrations. Published by John Wiley & Sons, New York. Price, $3.

We have often been impressed by the fact that there is no American book on machine design that gives all of the many common subjects of machine design on which the designer is likely to require specific information. Reference usually must be made to a number of the available works before a satisfactory treatment of a given subject is found. The authors of the present work evidently having noted the shortcomings of previous writers have presented, we believe, a book on machine design that is more complete than anything of a similar nature put on the market by American publishers. The work is the outgrowth of the experience of the authors in teaching machine design to engineering students in Sibley College, Cornell University. The treatment of friction, lubrication and efficiency are sufficiently comprehensive for a work of this kind, as is also the work on springs, riveted fastenings, screws and screw fastenings, keys and cotters. The theory of stresses produced by force fits and the calculation of allowances is satisfactory, but an improvement is suggested in the shape of a table giving the results of practice in making shrink and force fits. So many factors enter into the problem that the result of practice on various classes of work would be exceedingly helpful to the designer who has not had the benefit of much experience. The treatment of tubes, pipe, cylinders, flues and tin plates was written with the advantage of the knowledge gained from the experiments made by the University of Illinois Engineering Experiment Station and the paper by Prof. Reid T. Stewart presented before the American Society of Mechanical Engineers, and, of course, is much more satisfactory than previous treatments available in other works on machine design. Journal bearings, pivots and roller bearings, are not treated in as comprehensive a manner as one who is especially interested in these subjects could wish, but probably as much space is given to these important subjects as the general plan of the work and the course of instruction for which it was prepared would permit. A portion of the book is devoted to axles, shafts and shaft couplings, belt, rope and chain transmission, application of friction including friction reels, friction brakes, friction clutches and pulleys. The treatment of tooth gearing is fairly satisfactory, there being forty-two pages devoted to the theory and practice of spur, bevel and helical gearing. Of course, the treatment of helical and spur gearing is brief and leaves a great deal unsaid. Following this chapter are chapters on fly-wheels and pulleys and machine frames and attachments. The work is one that we can heartily recommend to machine designers and others concerned with the problem of machine design, but it is not quite the comprehensive treatment that should be presented by some author. Whether a comprehensive treatment is practical is a matter for the publishers to decide, but the need for a good all-around work is evident to those who frequently refer to the present available books on machine design.

CATALOGUES AND CIRCULARS

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4698 of luminous arc head-lights.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4691 illustrating and describing small polyphase motors.

VALLEY BOAT & ENGINE CO., Baldwinsville, N. Y. Catalogue of marine engine castings and finished machine parts.

GISHOLT MACHINE CO., Madison, Wis. Leaflet illustrating the Gisholt 30-inch motor driven vertical boring mill.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4692 describing the General Electric No. 210 Railway Motor.

BICKFORD & WASHBURN, INC., Greenfield, Mass. Blotter illustrating the Bickford & Washburn pipe tap thread milling machine.

PRENTISS TOOL & SUPPLY CO., 115 Liberty St., New York. Circular of the 20-inch universal drilling lathe built by Fay & Scott, Dexter, Me.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4099 superseding Bulletin No. 4444 on motor-driven air compressors, geared type.

SPICER UNIVERSAL JOINT MFG. CO., Plainfield, N. J. Catalogue of Spicer dust-proof and oil-tight universal joints for motor cars, motor boats and other machinery.

ARGUTO OILLESS BEARING CO., Wayne Junction, Philadelphia, Pa. Folder advertising the Arguto oilless bearings which save oil and prevent ruined journals.

W. S. CALDWELL CO., Louisville, Ky. Catalogue of Caldwell wooden tanks for manufacturing plants and other users requiring large and small tanks for the storing of water, etc.

CLEVELAND TWIST DRILL CO., Cleveland, Ohio. Folder entitled "The Paragon Way" illustrating the new "Paragon" flat taper shank high-speed twist drill lately brought out by the company.

W. S. ROCKWELL CO., 50 Church St., New York. Circular illustrating the Rockwell furnaces, and fuel oil or gas-burning appliances. A new catalogue is in preparation and will be issued shortly.

GEORGE W. SOUTHWICK CO., 35 Warren St., New York. Circular illustrating the Hammond wire belt lacing tool for making a wire hinged joint for machine belting. The cost of the outfit is $7.50.

HARBISON-WALKER REFRACTORIES CO., Pittsburg, Pa. Catalogue of silica, nickel, chrome, and fire-clay brick used by steel mills, brass foundries, and other concerns employing furnaces for melting metals.

J. S. OSGOOD, 131-138 Erie County Bank Building, Buffalo, N. Y. Blotter illustrating the Osgood indestructible file and tool handle which was recently specified by the United States Government for the Rock Island Arsenal.

CUTLER-HAMMER MFG. CO., Milwaukee, Wis. Circular of the Cutler-Hammer pressure controlled speed regulator for use with motor-driven boiler draft fans, boiler feed pumps, gas pressure exhaust, etc. For description see MACHINERY, September, 1909.

ARTHUR D. LITTLE LABORATORY, Boston, Mass. Pamphlet by Harry S. Mork, engineering chemist, entitled "Selective Economy in Raw Materials," being a paper presented at the annual meeting of the American Chemical Society at the New Haven meeting, July 3, 1908.

MANVILLE BROS. CO., Waterbury, Conn. Circular of the "Yankee" power bench press, designed to take the place of the ordinary foot and screw press. It is made in three sizes with or without table. The stroke is 1, 1½ and 2 inches respectively.

PLANET ENGINEERING CO., 5 Beekman St., New York. Circular illustrating the constructive features of the Planet roller bearings for motor boats, thrust bearings, electric motors, centrifugal pumps, etc. This bearing is composed of rollers with the periphery a section of a spherical surface.

GEM MFG. CO., 3253 Spruce St., Pittsburg, Pa. Catalogue of "Gem" specialties, comprising steel and brass oilers, torches, oil carriers, tallow pots, flue scrapers, foundry chaplets, flexible shafts, rope-driven or motor-driven portable grinders and drills, electric polishing machines, universal joints, etc.

H. BRACHARACH, 720 Lewis Block, Pittsburg, Pa. Advance sheets of 1910 catalogue illustrating a German recording gage which measures and records pressure, draft, and velocity of gases. These gages are used in boiler plants, mine ventilating systems, gas producer plants, regenerative furnaces, etc.

THE GRAHAM MFG. CO., Providence, R. I. Blotter illustrating a Universal jig vise, which is made in three sizes with jaws 6, 9 and 12 inches long. This jig vise can be used as a plain drilling vise or for the drilling of interchangeable parts. It is a cheap substitute for expensive jigs on a large class of work.

GARDNER MACHINE CO., Beloit, Wis. Circular illustrating the Gardner grinder in use on intake manifolds, universal joints, pump cases, exhaust connections, jacket plates, and cylinder covers, all being examples of automobile work for machining which the disk grinder has been found to be a valuable tool.

BOGERT GAS POWER ENGINE CO., 1116 Chamber of Commerce, Buffalo, N. Y. Folder illustrating the Bogert tandem gas engine built in sizes from 50 to 500 horse-power; also Bogert tandem gas engines with no cross-head built in sizes from 50 to 150 horse-power and single cylinder gas or gasoline engines in sizes from 20 to 100 horse-power.

B. F. STURTEVANT CO., Hyde Park, Mass. General catalogue No. 165 illustrating the company's complete line of fans, blowers, dust collectors and conveyors, fuel economizers motors, engines, turbines, generating sets, forges, hot blast apparatus, etc. Principal dimensions and other information regarding the apparatus illustrated is given briefly.

FRANK MCHALE, 302 Havemeyer Building, New York City. Catalogue of books relating to engineering subjects, including chemistry, mining, mechanical, electrical and steam engineering, construction, hydraulics, etc. Books will be furnished at the lowest market prices and forwarded prepaid to any part of the world on receipt of advertised price.

BRUCE-MACBETH ENGINE CO., Cleveland, Ohio. Catalogue of Meriam vertical gas engines for electric lighting, pumping, and general power purposes. The catalogue illustrates the four cylinder engine built in sizes from 75 to 300 horse-power, and shows the details of construction. The two-cylinder type is also illustrated, and the four-cylinder engine with a gas producer plant.

NORTHERN MACHINE & REPAIR WORKS, Wausau, Wis. Circular of the "Little Giant" cutting-off machine for cutting tool steel, mild steel, cast iron, brass and other metals. The machine is of simple construction, being designed for use in shops that do not require an elaborate equipment and where a cutting-off machine with hand feeds answers all practical requirements

H. W. CALDWELL & SON CO., Western Ave., 17th-18th St., Chicago, Ill. General catalogue No. 34, of hoisting, elevating, conveying and power transmitting machinery for flour mills, grain elevators, cotton-seed oil mills, starch works, breweries, distilleries, malt houses, sugar refineries, cement works, phosphate works, tanneries, etc. The catalogue contains 847 pages, 6 x 9 inches.

OSCAR E. PERRIGO, 6 Beacon St., Boston, Mass. Circular outlining systematic methods in shop management and cost accounting, which Mr. Perrigo is prepared to install. He is a consulting and systematizing engineer who has given a great deal of attention to manufacturing methods and systems, and invites correspondence from officials having troubles with shop or office management.

DIAMOND MACHINE CO., Providence, R. I. Catalogue of grinding and polishing machinery, comprising floor grinding machines, motor-driven grinders, wet tool grinders, automatic face grinders, locomotive guide bar grinders, roll grinders, surface grinders, gun barrel machinery, internal grinders, lathe grinder attachments, drill grinders, polishing and buffing machines, polishing wheels, emery wheels, strapping machines, etc.

ROCKWELL FURNACE CO., 26 Cortlandt St., New York. Catalogue of forging, heating and welding furnaces. The catalogue has a novel trade-mark on the cover showing an animal known as "Go-Sum" which is said to be a cross between a hippopotamus and a grasshopper. The catalogue illustrates a large number of furnaces adapted for practically all classes of work in which portable or stationary furnaces are employed.

WELLS BROS. CO., Greenfield, Mass. Catalogue and price list of die holders principally designed for use on screw machines. The holder is firmly clutched in its forward movement and when not cutting the die is held by friction, thus doing away with the noise ordinarily noticeable on screw machines. The holders are adapted for the "Little Giant" adjustable dies which are of the same quality as the regular dies supplied by the company.

ELECTRIC CONTROLLER & MFG. CO., Cleveland, Ohio. Catalogue of lifting magnets, giving a list of users and illustrating the uses to which lifting magnets are put in steel mills and other plants where sheet metal, steel rails, scrap and other metals are handled in large quantities. The possibilities of the lifting magnet are startling. One illustration, for example, shows a magnet lifting a locomotive cylinder, the magnet being applied to the planed surface at the juncture between the two cylinders.

D. O. JAMES MFG. CO., Chicago, Ill. Catalogue D of speed-reducing transmission gears (see MACHINERY, August, 1908, for description), for spur, bevel, miter, internal, spiral and worm gearing. The speed-reducing gears are designed to transmit the power of electric motors and other high-speed apparatus, reducing the speed to that required for machine tools, centrifugal pumps, elevators, etc. The catalogue contains valuable data on gearing, tables of natural trigonometrical functions, diagrams of circular pitch gears, etc.

SKINNER CHUCK CO., New Britain, Conn. Catalogue of independent universal and combination lathe chucks, drill chucks, planer chucks, face-plate jaws, drill press vises and reamer stands. The catalogue contains 48 pages, is made up with rounded corners, and is perforated for a loose leaf binder. The construction of the new Skinner gear pattern drill chuck is illustrated in sectional views, and a phantom view is shown of the Skinner positive drive drill chuck. The catalogue is one that will be found of general interest by users of machine tools and accessories.

NEW JERSEY FOUNDRY & MACHINE CO., 90 West St., New York. Catalogue of overhead carrying devices comprising trolleys, hoists, cranes, buckets, cars and tracking, etc. The Newhall patent steel frame I-beam trolley is illustrated in combination with a differential hoist. Various other combinations are shown and examples of installations. The company builds jib cranes suitable for foundry shops and other places where a jib crane is profitably used. The catalogue will be found of general interest by those concerned with the problem of hoisting and conveying materials either in the shop or in the field.

KEARNEY & TRECKER CO., Milwaukee, Wis. Catalogue No. 17 of Milwaukee milling machines. The catalogue illustrates the construction of the Milwaukee miller and two views are reproduced with reference numbers in red, each part being named below. Details of con-

struction are illustrated, including a vertical section showing the flooded lubrication system which has made Milwaukee millers famous. The company manufactures universal milling machines in three sizes, plain milling machines in three sizes, and manufacturing milling machines in two sizes. All styles have single pulley drive, all geared feeds, and flooded lubrication.

RELIANCE ELECTRIC & ENGINEERING CO., Cleveland, Ohio. Treatise on the crank shaper, describing the characteristics of the cone pulley drive, speed-box drive, and variable speed motor drive with particular reference to the Lincoln variable speed motor which gives an infinite number of running speeds throughout its range. The treatise which is sent free on request will be found of much general interest to designers and users of shapers. It gives valuable information not only regarding the power required to drive crank shapers under definite conditions of work, but also compares the productive efficiency of the belt-driven and motor-driven shaper.

DAVIS-BOURNONVILLE CO., 97 West St., New York. Pamphlet illustrating and describing the Davis-Bournonville oxy-acetylene apparatus which produces a flame having a temperature of about 6,300 degrees F. that can be used either for welding or for cutting metals. The oxy-acetylene torch is described as a "putting on tool," which it is in fact, it being not only possible to weld together iron, steel, cast iron, brass, copper, platinum and other metals and to unite dissimilar metals but also to build up defective castings and other pieces wherein metal is required. As a cutting-off tool, the torch works with rapidity and efficiency, being one of the most rapid and practical devices known for cutting off steel sheet piling, beams and other heavy structural work.

HENDEY MACHINE CO., Torrington, Conn. Catalogue of an improved line of Lincoln milling machines. The Lincoln type milling machine is the standard manufacturing miller for armories, pistol factories, and other establishments where interchangeable parts are milled on a large scale. The company has developed this useful type of machine so that it is now being used successfully on operations which heretofore have been considered suitable for a knee type milling machine only. The catalogue illustrates the No. 8 Lincoln miller equipped with special table and chip pan; the same machine with high legs; improved Lincoln miller No. 5 with single and double spindles; and Nos. 4 and 2½ machines. All sizes are equipped with gear box giving twelve feed changes.

WATERBURY-FARREL FOUNDRY & MACHINE CO., Waterbury, Conn. General catalogue descriptive of all the lines of machinery built by the company, being a general reference book which briefly reviews the most prominent types of machines constructed. The catalogue comprises, rivet, bolt, and nut machinery, butt and hinge machinery, cartridge machinery, drop presses and hammers, screw presses, machinery for tubes and rods, hydraulic machinery, knuckle-joint press, special lathes, single-acting open-back presses, single-acting pillar presses, double-acting presses, shears and slitters, finishing machinery for sheet metal, mufflers and furnaces, wire-drawing machinery, eyelet machinery, gang slitting machines, etc. This catalogue is compiled in an attractive and interesting manner, making it a valuable work of reference as well as a catalogue of machinery in the various lines represented.

MANUFACTURERS' NOTES.

VAN DORN ELECTRIC & MFG CO., Cleveland, Ohio, has made Mr. A. N. Frecker sales manager. Mr. Frecker was for several years in the electric drill and grinder business in New York.

CINCINNATI IRON & STEEL CO., Cincinnati, Ohio, states that, owing to the heavy demand for the "Nugent" clutch, its machinery department is working full force day and night.

GENERAL ELECTRIC CO., Schenectady, N. Y., was awarded a grand prize at the Alaska-Yukon-Pacific Exposition for its exhibit of electrical apparatus and a completely furnished model apartment.

ROBBINS & MYERS CO., manufacturer of circular and desk fans, dynamos, motors, etc., has changed the location of its Chicago office from 48 West Jackson Boulevard to 501-515 West Jackson Boulevard.

KEUFFEL & ESSER CO., Hoboken, N. J., maker of drawing, mathematical and surveying instruments, measuring tapes, etc., was awarded the grand prize for its exhibit at the Alaska-Yukon-Pacific Exposition at Seattle.

GENERAL ELECTRIC CO., Schenectady, N. Y., and J. A. Roebling Sons Co., Trenton, N. J., were awarded the grand prize at the Alaska-Yukon-Pacific Exposition for their exhibit of insulated wire and cable.

ROCKFORD LATHE & DRILL CO., Rockford, Ill., succeeds the Rockford Machine & Shuttle Co. A. Floburg is president; W. B. Johnson, vice-president and superintendent, and Charles Holmquist, secretary and treasurer.

HILL CLUTCH CO., Cleveland, Ohio, manufacturer of power transmission machinery, announces the appointment of Mr. G. W. Hoffman as sales engineer in charge of its Chicago office, located at 610 Marquette Building.

VARIABLE SPEED CLUTCH CO., Milwaukee, Wis., has opened a New York office at 50 Church St., Hudson Terminal Building, with Mr. W. L. Tenney, manager. Mr. Tenney was formerly with the Standard Heater Co., New York.

WARNER & SWASEY CO., Cleveland, Ohio, recently opened an office in Detroit, located in the new Ford Building. Mr. Thomas Farmer, who has for several years represented the Warner & Swasey Co. in the Detroit territory, will be manager of the new office.

SPRINGFIELD MFG. CO., Bridgeport, Conn., maker of special grinding machines and emery wheels, has been purchased by H. F. Brandes, former superintendent of the Bullard Machine Tool Co., Bridgeport, Conn. Mr. George W. Jackman, former owner, has retired.

LAKESIDE FORGE & WRENCH CO., Springfield, Mass., has acquired the plant of the Springfield Drop Forge Co., Springfield, which again began operations with a full force of men September 27. Mr. Eugene Childs, formerly connected with the Trimont Mfg. Co., Roxbury, Mass., is general manager and president of the company.

WARNER & SWASEY CO., Cleveland, Ohio, is building a large addition to its new plant which was partly completed before the late depression in business. The addition is a single story steel and concrete structure and is equipped with electric traveling cranes and other modern features. It will be completed about December 1.

JOSEPH T. RYERSON & SON, Chicago, Ill., are reported to be contemplating entering the field of machine tool manufacture, and negotiations have been made for a suitable location in Cincinnati on which to erect a large plant. The concern now is known as a manufacturer and distributer of boiler shop machinery and other iron-working tools.

LYON METALLIC MFG. CO., Aurora, Ill., has established an eastern branch with office at 1365 Hudson Terminal Building, New York. The concern manufactures a complete line of steel factory equipment, including lockers, racks, tables, etc., and its rapidly-growing business has made an eastern branch necessary. Mr. B. L. Waters, secretary of the company, is in charge of the eastern branch.

BAY STATE MACHINE CO., Erie, Pa., is the name of a concern newly organized to manufacture marine engines. The new company has bought the charter of the old company of the same name. The officers are John E. Waitz, president; Joseph Crawford, treasurer and manager; L. E. Safford, vice-president and sales manager; and Charles Boring, superintendent.

GENERAL ELECTRIC CO., Schenectady, N. Y., states that there is a large demand for its tantalum lamps, which because of their excellent life service and efficiency make a considerable economy in incandescent lighting possible. The life of a tantalum lamp will average about 600 hours. It can be used on an alternating current of 50 cycles or less.

LITHOPRINT CO., 41-43 Warren St., New York, is prepared to make black prints on white ground, absolutely true to scale, on any kind of paper including any drawing paper, bristol board or tracing cloth. The prints undergo neither water nor acid bath so are unchanged in scale. They are made as quickly as blue-prints, and are said to be superior to any blue-print in quality and finish.

SOCIÉTÉ FRANCAISE DES ROULEMENTS A BILLES, manufacturer of the RBF ball bearings, announces that Lavalette & Co. are no longer its representatives in the United States. The International Engineering Co., 1779 Broadway, is now the sole and exclusive agent for the sale of RBF ball bearings in America, and all inquiries should be addressed to it in the future.

S. A. WOODS MACHINE CO., Boston, Mass., manufacturer of wood planers, has taken Mr. W. S. Howe, formerly advertising manager in charge of the small tool sales department of the Canadian-Fairbanks Co., Ltd., Montreal, Canada, into its employ. The S. A. Woods Machine Co. has reduced its line of wood-working machinery to planers and molders, on which it now specializes.

B. F. STURTEVANT CO., Hyde Park, Mass., has established a savings bank life insurance agency at its works in charge of an instructor furnished by the savings insurance committee of the Boston Chamber of Commerce. This agency is established under the Massachusetts law which became operative November 1, 1907, permitting any savings bank to operate a department for issuing life insurance policies and old-age annuities.

DEPARTMENT OF COMMERCE AND LABOR, Bureau of the Census, Washington, D. C., has fixed on November 3 as the date for examining applicants for appointments as special agents for the collection of the 13th census of manufactures, mines and quarries. The circular lists the cities in the various States in which the examinations will be held and gives the requirements of the applicants and the rate of compensation for the work.

S. OBERMAYER CO., Cincinnati, Chicago, and Pittsburg, has placed a new foundry product on the market called "Bulldog" core wash. It is so called because of its adhesive qualities. Foundries using it have no troubles from the core wash burning or peeling off. The largest castings can be made with cores washed with the new preparation with no troubles from the iron sticking to the sand, and come out of the mold with clean, smooth surfaces.

SHEFFIELD GAS POWER CO., Kansas City, Mo., has acquired the entire assets, factory and good will of the Weber Gas Engine Co., at a bankruptcy sale. The factory has been in continuous operation throughout the receivership term and is being continued in full operation by the present owners. The management of the business is in entirely new hands; George M. Hawes is president; Freeman Field, vice-president and treasurer; and W. H. Spiller, assistant manager.

WARREN WEBSTER & CO., Camden, N. J., state that the patent decision in the case of Warren Webster & Co. *vs.* C. A. Dunham Co., mentioned in the October number, does not refer to about one hundred existing patents under which Warren Webster & Co. operate. The patent in this case expired over a year ago, and the suit merely involved a case of liability for damages on the part of the defendant. There are now pending in the Federal courts suits against users of the Dunham apparatus for infringement on patents which have not expired.

INTERNATIONAL ACHESON GRAPHITE CO., Niagara Falls, N. Y., is adding a substantial and commodious addition to its Niagara Falls, Ontario, works. The structure is to be 50 x 105 feet and the contract has been awarded to W. S. Homan, Niagara Falls, Ontario. The facilities afforded by this addition will make the Canadian works of the company quite complete and enable them to care for a rapidly growing Canadian trade. The building will contain a new grinding plant in which the lubricating, electrotyping and other grades of graphite will be prepared for the market.

MUSEUM OF SAFETY AND SANITATION, 29 West 39th St., New York, announces that a prize of 2,500 kronen ($612) was offered by Dr. Louis L. Seaman while at the XVI International Medical Congress, in Budapest, in September, for the best paper on the subject: "What should be the Status of the Medical Department of an Army in order that its Sanitation and Hygienic Conditions may be maintained at the Highest Efficiency so that in the Emergency of Battle its Units may best respond to the Call of its Commanders?" The award of the prize will be made by the executive committee of the XVII International Medical Congress.

DODGE MFG. CO., Mishawaka, Ind., lays claim to having the largest plant in the world for the manufacture of machinery for the mechanical transmission of power. Its buildings cover nearly 40 acres in a 60-acre plot on the Lake Shore & Michigan Southern Railway. In it there are annually worked up 2,000 tons of pig iron, 7,000,000 feet of lumber, 900 tons of steel and structural iron, 6,200 tons of steel shafting and 9,000 tons of coal. The resulting production is 250,000 "Independence" wood-split pulleys, 100,000 Dodge standard iron pulleys, 90,000 solid iron pulleys, 95,000 hangers, 150,000 bearings of all types, 4,000 friction clutches and over 2,000,000 pounds of bearing metal.

ROBERTSON DRILL & TOOL CO., Buffalo, N. Y., has moved from 1848 Niagara St., to its factory, corner of Grant and Letchworth Sts. The new building is of brick, two stories high with basement of concrete construction, the length being 150 feet and the width 50 feet. The basement is used for storage and a heating plant. The ground floor is the machine shop for the manufacture of its drill presses and power hack saws. The machinery is driven by a 30-horse-power electric motor, and the shop is equipped throughout with new tools. The office is at the east end of the factory, and the top floor is used for pattern making, etc. The foundry is adjacent to the new building to the north about 50 feet, and is equipped with modern foundry appliances including an electric crane. The anticipated output of the new plant is about twenty-five drills per day.

DAVIS-BOURNONVILLE CO., 97 West St., New York, has lately performed some interesting repairs with the oxy-acetylene apparatus. Among the repairs made are the following: A cracked kettle weighing two tons, thickness varying from 5 inches at the bottom to 3 inches at the rim was successfully welded. The crack was 18 or 19 inches long. A 15-ton gear wheel made in two sections was cracked through the rim which was about 22 inches wide. The rim was welded and one tooth 22 inches wide and 6 inches high was built up, machined to shape and made as serviceable as the original. The apparatus was used very successfully by a railroad company for cutting up old steam boilers. It is generally known that the cost of scrapping steam boilers is very heavy in comparison to the value of the scrap material. The apparatus did the work rapidly and at a comparatively low cost. Several other repairs were lately made,

CONTENTS FOR NOVEMBER

including welding steam dryer pipes, fly wheel spokes, broken hydraulic press platen, smoke-box heaters, cast steel water pipe tee 20 inches in diameter, etc. The cast steel tee was welded in the trench with about 4 inches of water flowing through it. It would have cost about $200 to repair the tee, beside shutting off the flow of water for a considerable time. The crack was about 9 inches long.

Supplement to MACHINERY, December, 1909

Operations for the Article in this number entitled "Machine Shop Practice—Jig and Die Work in the Bench Lathe—II"

SHOP OPERATION SHEET NO. 118.

Bench Lathe Practice—Turning

NOTE.—The method of turning the small pin *A* in the bench lathe will be outlined in the following. In the succeeding sheets the way in which this piece is milled and ground will be explained.

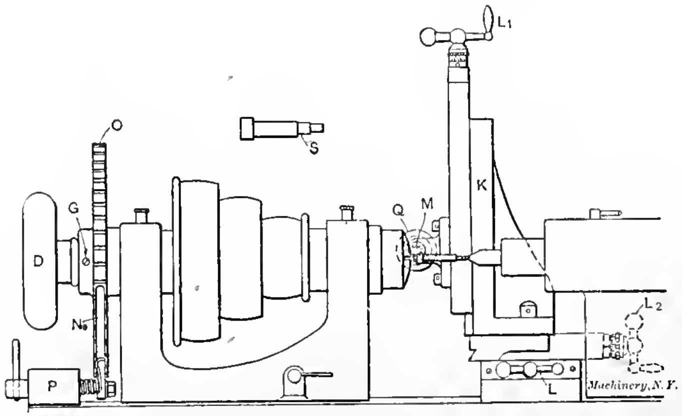
1. Saw off a piece of wire, No. 3 stub gage, to a length of 1½ inch. Insert a chuck into the spindle of lathe suitable for this size of wire. Examine the taper part of the spindle and chuck to see that they are perfectly clean. Insert the wire in the chuck so that it projects from the latter about ¼ inch, and tighten it by turning the handle *D*.

2. Unloosen the two screws *C* on the slide-rest and turn the latter around to an angle of 30 degrees. Move the carriage close to the spindle and clamp it to the lathe bed by a hand-nut underneath provided for this purpose. Fasten a diamond-pointed tool in the tool-post *E* of the slide-rest and set the tool so that its cutting edge is the same height as the axis of the work. This tool should be ground so that the point is sharp, as otherwise the work will tend to raise above its center and mount the tool. The end of the wire should now be turned to a point, as shown at *B* in the illustration.

3. Change the slide-rest back to the zero position and place an index plate *F* on the back end of the lathe spindle. In order to do this the handle *D* is first removed, after which the plate is put in place and secured by the set-screw *G*. After the handle *D* is replaced, the wire should be moved out so that it projects about 1¼ inch from the face of the chuck. Next move the tail-stock, which should be equipped with a small female center *H* in its spindle, up to the male center of the wire. Lubricate the center with a drop of oil, adjust it to the work so that it has a firm bearing. With the diamond-pointed tool, turn the whole length of wire to a diameter of 0.205 inch. Test the work with a micrometer to see if it is turned perfectly parallel; then continue the turning operation until the piece conforms to the dimensions given in the illustration, the shoulders being finished to length with a side tool, and 0.005 inch being allowed on the shoulders and diameters for grinding. Cut a groove just above the head of the pin, as shown at *J*. After hardening, the pin may be easily broken off at this point by holding it in the chuck by the head, close up to the groove.

SHOP OPERATION SHEET NO. 119.

A. L. Monrad. MACHINERY, December, 1909.



Bench Lathe Practice—Milling

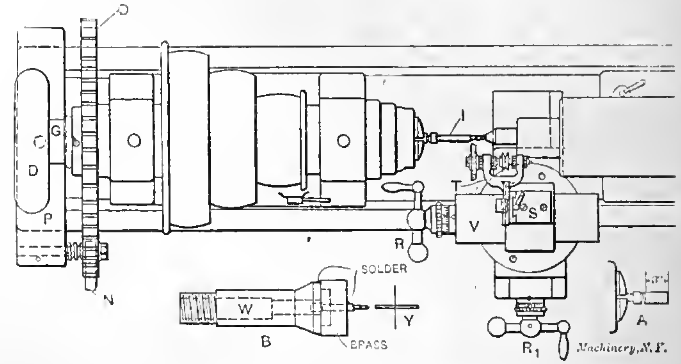
1. Without removing the work in the chuck, which is assumed to be in the lathe as in the previous operation, loosen the head- and tail-stocks and move them to the right to make room for the indexing block *P*. Replace the slide-rest, with a milling fixture *K*, and set this fixture so that the axis of the spindle is at right angles with the axis of the work. Place a 1/32-inch slotting cutter, 1/4 inch in diameter, in the milling fixture spindle. By means of the handles *L*, L_1, L_2, adjust the cutter *M* until its side just touches the side of the head on the pin shown. Move the thimble on the feed-screw *L* to zero, and then raise the cutter to clear the work. By the aid of this graduated thimble move the cutter inward an amount equal to half the diameter of the pin plus one-half the thickness of the cutter. Place the pawl *N* in the zero groove in the index plate *O* and mill a groove to a depth of 0.060 inch, by reading the graduation on the thimble of handle L_1 of the milling fixture. The spindle of the milling fixture is driven by a belt which passes over pulley *Q*.

2. As a second groove is to be milled in the opposite side of the work, turn the latter halfway around by placing pawl *N* in the 180 degree groove. The work will then be in position for milling the second groove.

3. Replace the slotting cutter by an end mill 0.150 inch in diameter. Place the pawl *N* in the zero groove of the index plate *O*. As the sides of the square *S* of the pin are to be 0.050 inch, or the same size as the cylindrical end, mill one side by feeding the cutter down by the handle L_1 until it is almost flush with this end, a slight amount of material being left for grinding. Raise the end mill so that the work will clear, and again feed it down after the work has been turned through 90 degrees by the aid of the index plate *O*. In this manner mill the four sides of the square. Remove the pin from the lathe by loosening the handle *D* which opens the chuck jaws. The pin is next hardened and drawn to a straw color, and polished all over with fine emery cloth preparatory to grinding.

SHOP OPERATION SHEET NO. 120.

A. L. Monrad. MACHINERY, December, 1909.



Bench Lathe Practice—Grinding

1. Insert a chuck in the spindle that will fit the body of the pin *I*, and place the work within it as shown at *A*. Set the slide rest *V* to zero for parallel grinding. Place the grinder equipped with a fine carborundum wheel, in the tool-post, set the spindle of the grinder in the same horizontal plane as the work, and grind the end *x* of the pin.

2. Obtain a chuck of a size corresponding to the end just ground, and place this end of the work in the chuck as shown in the illustration. Support the outer end of the pin by a female center and grind the three diameters of the work to the dimensions given, allowing 0.0002 for lapping. As the shoulders are to have perfectly square corners, they are ground with a diamond wheel charged to a sharp edge. In performing this operation the work should revolve very slowly.

3. The square, which was milled on the pin in the previous operation, as described, is next ground. Reverse the top slide *V* so that the handle *R* is on the left side as shown, to avoid the tail-stock. Mount a sliding angle-iron *S* on top of slide-rest *V* and clamp the grinder *T* in position, equipped with a charged diamond wheel. Place pawl *N* in the zero groove of plate *O*, and grind the top side of the square by moving the wheel across it by the handle R_1, and feeding it forward by handle *R*. When one side is finished flush with the cylindrical end, move the work 90 degrees by the aid of dividing plate *O*; then finish the next square, etc.

4. Grip the head of the pin in a chuck corresponding to its size, and break off the end *x*; then replace the lathe chuck with a brass soldering chuck *W*. Remove the indexing block *P* and place the head-stock in position for turning. Bore a hole in the brass chuck, and make it a push fit for the body of the pin. Remove the chuck and push the pin through it from the back, as shown at *B*. When chuck is replaced, move the handle *R* to the right side. With a grinding wheel *Y* in the position shown, face off the conical point of the pin to the proper dimension. With a side tool remove the solder; then withdraw the pin, and replace it in the chuck with the head out. Fasten the head with a little solder, and also grind it to the finish dimension.

CUTTING BEVEL GEAR TEETH—A NEW METHOD OF OBTAINING THE SET-OVER*

RALPH E. FLANDERS†

PERHAPS the most troublesome of the more common milling machine operations is that of cutting the teeth of bevel gears. Tables, explicit directions and formulas have been prepared for indexing, and for cutting spirals, cams, end-mill teeth, etc., but the shaping of a passably good bevel gear tooth has always been a matter of judgment and "cut-and-try." The writer, with the cooperation of the Brown & Sharpe Mfg. Co., herewith presents a method of setting the milling machine (or automatic gear cutting machine) for cutting the teeth of bevel gears, in which experimental trial cutting is nearly, if not quite, avoided, thus opening possibilities for a material saving in time, and improvement in the quality of the product. The method also enables much better results to be obtained in the hands of an operator unfamiliar with this rather difficult work. The whys and wherefores of the operation will be described from beginning to end, so as to give a clear understanding of the principles involved. First, however, the process itself will be described, so that the reader who does not care to go into the whys and wherefores will be able to use it.

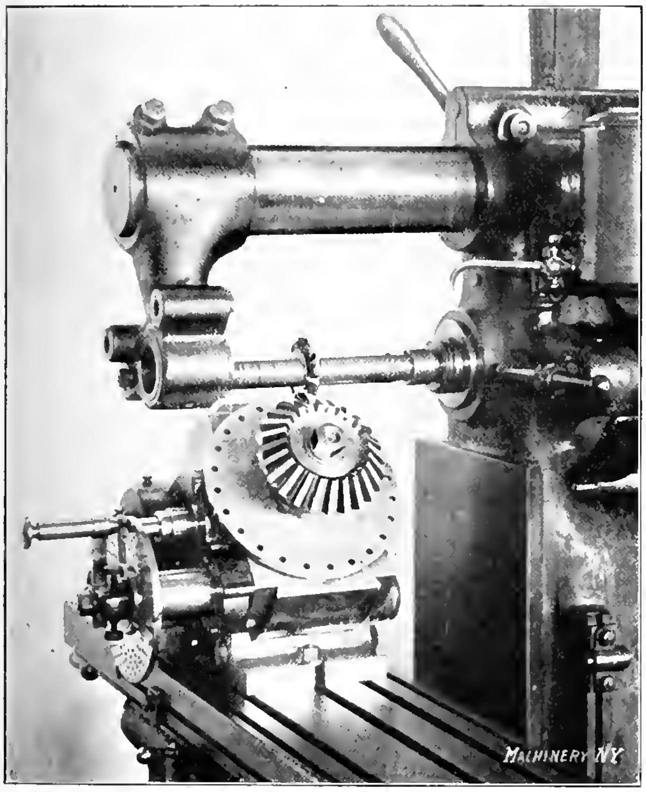

Fig. 1. Milling Machine set up for Cutting a Bevel Gear

Setting up the Machine

In cutting bevel gears by this process we are supposed to have given the number and pitch of the cutter we are to use, the diametral pitch of the teeth to be cut, the width of face of the gear (F in Fig. 2), the pitch cone radius of the gear (C in Fig. 2) and the thickness of the bevel gear cutter at the pitch line. The latter (which is variable) is best obtained by the Brown & Sharpe gear tooth caliper shown in use measuring a bevel gear tooth in Fig. 3. This should be set to measure the cutter at a depth $S + A$, in Fig. 2, which is the whole depth below the pitch line (this is given as $S + f$ in the tables in the Brown & Sharpe gear book for the different pitches, or may be found by dividing 1.157 by the diametral pitch). The thickness of the cutter at the pitch line as measured at this depth by the vernier tooth caliper is the dimension used in calculations.

It should be noted that when the table herewith presented is used for obtaining the set-over, the cutting angle must be determined as shown in Fig. 4. That is to say, the gears must be cut with a parallel clearance depth, in the way recommended by the Brown & Sharpe gear book as more closely approximating the true form than when the bottom of the tooth space is radial with the vertex of the pitch cone. This cutting angle is evidently found by subtracting the addendum angle θ from the pitch cone angle a. The milling machine is set up for cutting bevel gears in the usual manner with the work-spindle set at this angle, the cutter centered with the work and set for the full depth of tooth. If the gear is

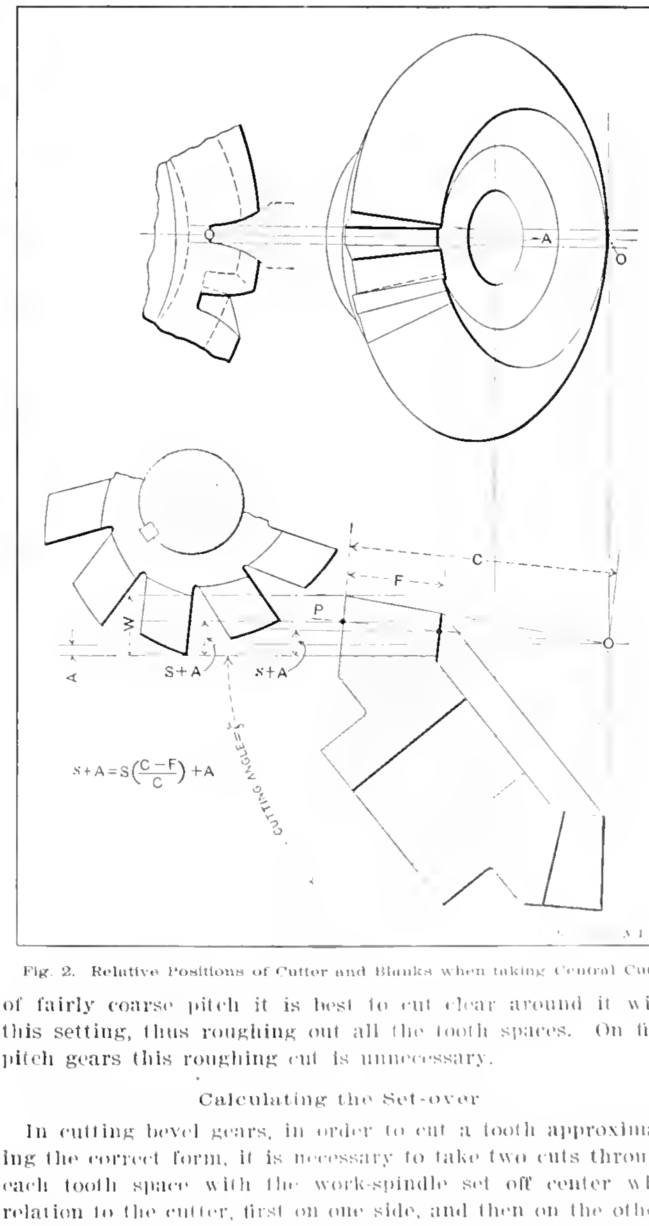

Fig. 2. Relative Positions of Cutter and Blanks when taking Central Cut

of fairly coarse pitch it is best to cut clear around it with this setting, thus roughing out all the tooth spaces. On fine pitch gears this roughing cut is unnecessary.

Calculating the Set-over

In cutting bevel gears, in order to cut a tooth approximating the correct form, it is necessary to take two cuts through each tooth space with the work-spindle set off center with relation to the cutter, first on one side, and then on the other, rolling the blank correspondingly to obtain the proper thickness of tooth at the large and small ends. It is proposed to

* For further information on this subject, see "Cutting Bevel Gears with a Rotary Cutter," October, 1907, and articles there referred to, and "Accurate Setting of the Bevel Gear Cutter," in this issue.
† Associate Editor of MACHINERY.

find the amount of this set-over from the accompanying table by the following formula:

$$\text{Set-over} = \frac{T_c}{2} - \frac{\text{factor from table}}{P} \quad \text{..........(1)}$$

Given as a rule, this would read: *Find the factor in the table corresponding to the number of the cutter used and to the ratio of pitch cone radius to width of face; divide this factor by the diametral pitch, and subtract the result from half of the thickness of the cutter at the pitch line.*

As an illustration of the use of this table in obtaining the set-over we will take the following example: A bevel gear of 24 teeth, 6 pitch, 30 degrees pitch cone angle and 1¼ face. These dimensions, by the ordinary calculations for bevel gears* which it is not necessary to go into here, call for a No. 4 cutter and a pitch cone radius of 4 inches.

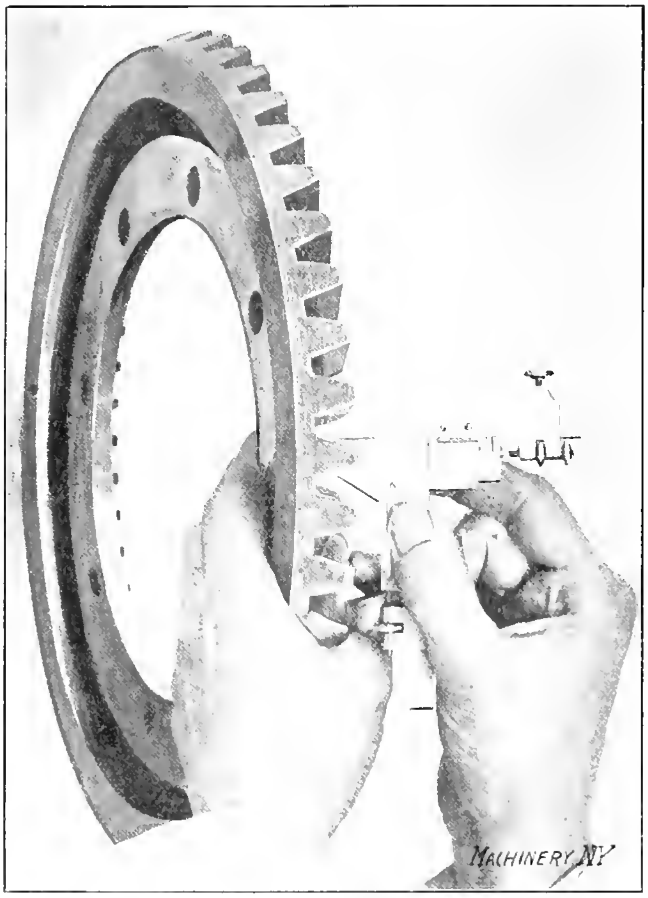

Fig. 3. Brown & Sharpe Gear-tooth Caliper in Use

In order to get our factor from the table, we have to know the ratio of pitch cone radius with length of face. This ratio is $\frac{4}{1.25} = \frac{3.2}{1}$ or about $\frac{3\frac{1}{4}}{1}$. The factor in the table for this ratio with a No. 4 cutter is 0.280. We next measure the cutter at the proper depth of $S + A$ for 6 pitch, which is found in the column marked "depth of space below pitch line" in a regular table of tooth parts, or by dividing 1.157 by the diametral pitch. This gives $S + A = 0.1928$ inch. We find, for instance, that the thickness of the cutter at this depth is 0.1745 inch. This dimension will vary with different cutters, and will vary in the same cutter as it is ground away, since formed bevel gear cutters are commonly provided with side relief. Substituting these values in Formula 1, we have

$$\text{Set-over} = \frac{0.1745}{2} - \frac{0.280}{6} = 0.0406 \text{ inch,}$$

which is the required dimension.

The work must now be set off center on one side of the cutter by this amount, taking the usual precautions to avoid errors from back-lash. In this position the cutter is run through the blank, the latter being indexed for each tooth space until it has been cut around. (If a central or roughing cut has been previously taken as suggested in an earlier paragraph, it will be necessary to line up this cut at the small end of the tooth with the cutter. This is done by rotating the tooth space back toward the cutter, either by moving the index crank as many holes in the dial-plate as are necessary, or by means of such other special provisions as may be made for doing this in the index head, independently of the dial-plate.)

Having thus cut one side of the tooth to proper dimensions, the work must be set-over by the same amount the other side of the position central with the cutter, taking the same precautions in relation to back-lash as before, and rotating the blank to again line up the cutter with the tooth space at the small end of the tooth. With this setting, take a trial cut. This will be found to leave the tooth whose side is trimmed in this operation a little too thick, if the cutter is thin enough, as it ought to be, to pass through the small end of the tooth space of the completed gear. This trial tooth should now be brought to the proper thickness by rotating the blank toward the cutter, moving the crank around the dial for the rough adjustment, and bringing it to accurate thickness by such means as may be provided in the head. In the Brown & Sharpe head, as shown in Fig. 1, this fine adjustment is effected by two thumb-screws near the hub of the index crank, which turn the index worm with relation to the crank.

Testing for Correctness of the Setting

With reference to the use of the table and formula, the Brown & Sharpe Mfg. Co., after trial in their gear cutting department, say: "We feel fairly confident it is within working limits of being satisfactory." While this sounds encouraging, it will evidently be wise to be sure we are right before going ahead, as the slight approximations involved in the derivation of the formula (to be explained later) may bring the setting not *quite* right, so that the thickness of the tooth at the large and the small ends is not what it ought to be. This point may be tested by measuring the tooth at both the large and the small ends with the vernier caliper as shown in Fig. 3, the caliper being set so that the addendum at the small end is in the proper proportion to the addendum at the large end—that is to say, that it is in the ratio $\frac{C - F}{C}$. In taking these measurements, if the thicknesses at both the large and the small ends, which should be in this same ratio, are too great, rotate the tooth toward the cutter and take another cut until the proper thickness at either the large or small end has been obtained. If the thickness is right at the large end and too thick at the small end, the set-over is too much. If it is right at the small end and too thick at the large end, the set-over is not enough, and should be changed accordingly, as is done by the regular "cut-and-try" process. The formula and table herewith given, however, ought to bring it near enough right the first time, and in the general run of work it can be safely relied on.

It may be said, in this connection, that nothing but a true running blank, with accurate angles and diameters, should be

TABLE FOR OBTAINING SET-OVER FOR CUTTING BEVEL GEARS

No. of Cutter	Ratio of Pitch Cone Radius to Width of Face $\left(\frac{C}{F}\right)$												
	3/1	3¼/1	3½/1	3¾/1	4/1	4¼/1	4½/1	4¾/1	5/1	5½/1	6/1	7/1	8/1

7	.289	.298	.308	.316	.324	.329	.334	.338	.343	.350	.360	.370	.376
8	.275	.286	.296	.309	.319	.331	.338	.344	.352	.361	.368	.380	.386

NOTE.—For obtaining set-over by above table, use this formula:

$$\text{Set-over} = \frac{T_c}{2} - \frac{\text{factor from table}}{P}$$

P = diametral pitch of gear to be cut.
T_c = thickness of cutter used, measured at pitch line

* Rules and formulas for bevel gear calculations will be found in MACHINERY's Data Sheet No. 69, May, 1907, and in Reference Series No. 37, "Bevel Gearing."

used in setting up the machine. If such a blank cannot be found in the lot of gears to be cut, it will be necessary to turn one up out of wood or other easily worked material. Otherwise the workman is inviting trouble, whatever his method of setting up.

Filing the Teeth

The method of cutting bevel gears just described requires the filing of the points of the teeth at the small end. This can be done "by the eye" very skillfully when the workman is used to it. The operation consists in filing off a triangular area extending from the point of the tooth at the large end to the point at the small end, thence down to the pitch line at the small end and back diagonally to the point at the large end again. This is shown in Fig. 5, by the shaded outline.

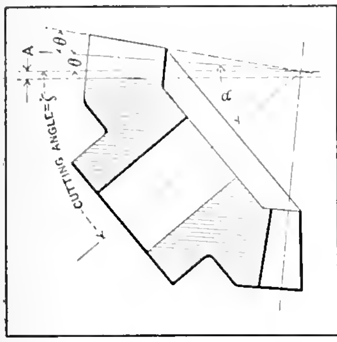

Fig. 4. Parallel Clearance, best adapted to shaping with Formed Cutter

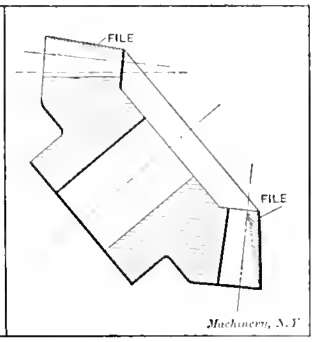

Fig. 5. Shaded Area shows Part of Tooth to be corrected by Filing

Enough is taken off at the small end of the tooth so that the edges of the teeth at the top appear to converge at vertex O in Figs. 2 and 6.

The bevel gears may be tested for the accuracy of the cutting and filing by mounting them in place in the machine and revolving them at high speed, or by mounting them in a testing machine made for the purpose. The marks of wear produced by running them together under pressure, with the back faces flush with each other, should extend the whole length of the tooth at the pitch line. If it does not, the amount of set-over allowed in cutting them was at fault, being too little if they bear heavily at the large ends, and too much if they bear heavily at the small ends. The bearing area should also be fairly evenly distributed over the sides of the teeth above the pitch line, from the large to the small end. If it is not, the filing is at fault. The marks of wear will not in any case extend far below the pitch line in a pinion of few teeth.

It is possible to get along without filing by decreasing the amount of set-over so as to make the teeth too thin at the pitch line at the small end, when they are of the right thickness at the large end. This does not give as good running gears, however, as when the method just described is followed.

Cutting Bevel Gears on the Automatic Gear-cutting Machine

The directions for cutting bevel gears on the milling machine apply in modified form to the automatic gear cutting machine as well. The set-over is determined in the same way, but instead of moving the work off center, the cutter spindle is adjusted axially by means provided for that purpose. Some machines are provided with dials for reading this movement. The cutter is first centered as in the milling machine, and then shifted—first to the right, and then to the left of this central position.

The rotating of the work to obtain the proper thickness of tooth is effected by unclamping the indexing worm from its shaft (means usually being provided for this purpose) and rotating the worm until the gear is brought to proper position. Otherwise the operations are the same as for the milling machine.

Derivation of Formula

The derivation of the formula and the method of calculating the table need not concern the workman who desires to use them, as he can employ them with no knowledge of mathematics other than that required for plain subtraction and division. For those, however, who desire to understand the origin of the table, the following explanation will be interesting.

Fig. 6 shows a section such as would be made by turning off the bevel gear blank down to the pitch cone—in other words, it is a section on the conical surface PO of Fig. 2. The same dimensions apply to both figures. We find, if we take a cut with the cutter set central, that the side of the tooth space will not pass through the vertex O, but through some point O' at one side. The distance between O' and O is X, which is the amount by which the cutter will have to be offset to bring the side of the tooth space at the pitch line radial with vertex O. A formula can be derived by simple proportion to obtain this offset, in terms of T_c, t_c, F and C. The formula is:

$$X = \frac{T_c}{2} - \left(\frac{T_c - t_c}{2} \times \frac{C}{F}\right) \qquad (2)$$

This determination of the set-over, of course, involves one or two approximations of minor importance, which will be readily perceived from an examination of the diagrams.

While this formula seems to furnish a means for obtaining by measurement and calculation the amount of set-over, it is rather clumsy. It remains therefore to put it in more usable form. From an examination of the formula, we note that while $\frac{T_c}{2}$ is a variable, depending on the thickness of the cutter, the quantity in parenthesis remains constant as the cutter grows thinner from being ground down. In fact, by taking the measurements T_c and t_c on a one diametral pitch cutter, and calling them T'_c and t'_c it would be possible to put this in the form:

$$X = \frac{T_c}{2} - \frac{1}{P}\left(\frac{T'_c - t'_c}{2} \times \frac{C}{F}\right) \qquad (3)$$

in which the quantity $\frac{T'_c - t'_c}{2} \times \frac{C}{F}$ would be constant for all cases of all pitches having the same ratio of $\frac{C}{F}$ and using the same number of cutter.

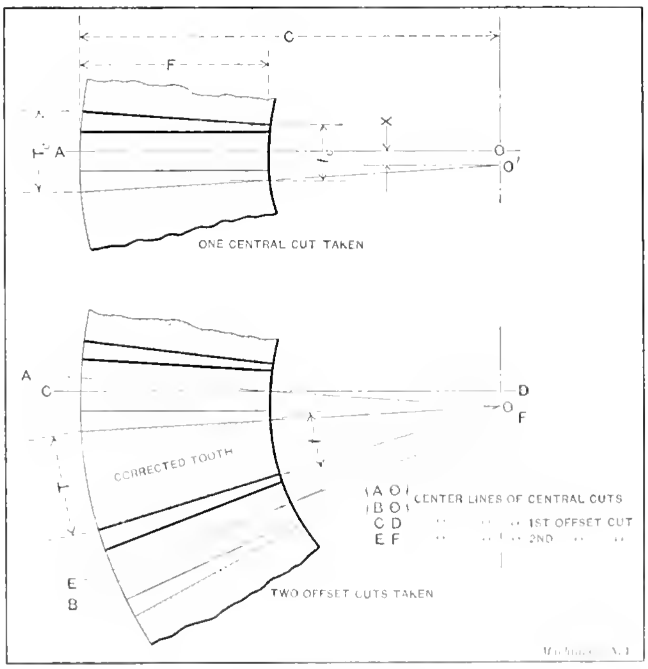

Fig. 6. Section on Pitch Cone Surface PO of Fig. 2, showing Central and Offset Cuts

Now it is possible to put this formula in still simpler form by tabulating the values of $\frac{T'_c - t'_c}{2} \times \frac{C}{F}$, as measured on a one pitch cutter, for different values of $\frac{C}{F}$. This has been done in the table for thirteen values of $\frac{C}{F}$, which cover the major part of the bevel gears cut by the formed tool process. Using the factor as given in the table, the formula reads:

$$X = \text{set-over} = \frac{T_c}{2} - \frac{\text{factor from table}}{P} \qquad (1)$$

as we have already given it.

The method of filling in the table will be easily understood. A one pitch cutter is measured with the Brown & Sharpe gear tooth caliper at depth $S + A$ for dimension T'_c and at depth $s + A$ for t'_c (see Fig. 2). Of course, $s + A$ and consequently t'_c will vary, as $\frac{C}{F}$ is taken $\frac{3}{1}$, $\frac{3\frac{1}{4}}{1}$, etc., respectively. Having found these dimensions, the quantities to fill in the table are evidently obtained by the formula:

$$\text{Factor from table} = \frac{T'_c - t'_c}{2} \times \frac{C}{F} \qquad (4)$$

Use of the Formula for Other Methods of Approximation

It would seem as though the form of table and formula here given would be suitable for recording for future use the amount of set-over obtained by the "cut-and-try" process for other methods of approximation than that here given. Transposing Formula 1 to solve for the factor, we have

$$\text{Factor from table} = P\left(\frac{T_c}{2} - \text{set-over}\right) \qquad (5)$$

in which the measurement as before is taken on the cutter used for the job. By recording the factors for all jobs done, and thus gradually filling in the tables from his own practice, the machinist would be able to put the data in usable form to apply to future jobs.

It is customary also among workmen expert in cutting bevel gears with formed cutters, to cut loose from rules and formulas for the selection of the cutters, and depend on their experience to get shapes which require somewhat less filing than would otherwise be necessary. Whenever this "cutting loose" requires, as it sometimes does, the use of a cutter of finer pitch than that of the teeth of the bevel gear at the large end, Formula 1 and the table are inapplicable. Formula No. 2 may then be used. This has been tried on several widely varying cases with good results. It requires, it will be seen, two measurements of the cutter in place of the single one required when the regular pitch of cutter is used.

Other Methods for Calculating the Set-over

At least two other attempts have been made to give values for the settings required in cutting bevel gears. The first of these was described by Mr. Jacques in the June 7, 1900, number of the *American Machinist*. The second was described by Prof. Forrest R. Jones in a paper at the December, 1896, meeting of the American Society of Mechanical Engineers. Of these methods the first, while aiming at the same results as obtained by the author, is impracticable, owing to the fact that it requires a peculiar design of machine for its successful use. The method here described may evidently be used in any machine in which the cutter can be adjusted axially, and in which the work can be rotated on its spindle. It may thus be used on the plain automatic gear cutting machine as well as on the milling machine. It may be even employed in the same identical way for a formed tool in the shaper, the same measurements being made and the set-over being read on the graduated dial of the table cross-feed screw.

Professor Jones' method was the result of long experiment and careful study. Its drawbacks are, first, the fact that it is designed for a method of approximation in which the tooth shape is obtained as nearly as possible from the cutter, without corrective filing; second (and principally) because it gives the setting in terms of rotation of the blank instead of the set-over of the cutter. There can be no question as to which of these dimensions is the deciding one in obtaining the proper tooth shape. It is the setting of the cutter off center which determines whether or not the side of the tooth at the pitch line shall be radial with the vertex of the pitch cone. The effect of the rolling or rotating of the blank is simply that of changing the thickness of the tooth, not of changing its shape. If the workman is directed to first roll the blank a certain amount and then shift the cutter sidewise to obtain the proper thickness, he has in mind the thickness and not the shape in making the last adjustment, and according to whether he makes the teeth thicker or thinner, so will the shape be changed; and for the same reason such a rule will give different shapes of teeth with similar cutters of varying thickness.

Practical Results from the Use of the Table

The methods obtained with the templet process and, above all, with the generating process, are so much superior to those obtained with the milling cutter that the use of the latter should be avoided wherever possible. It has a legitimate field, however, on gears too small to be cut on any commercial planing machine. In general, it is not considered advisable to plane gears having teeth finer than 10 to 12 diametral pitch. It is allowable, however, to mill gears of coarser pitch which are to run at slow speeds, or which are to be used only occasionally—such, for instance, as the bevel gears used for turning the elevating screws of a planer cross-rail, or those used in connection with other hand-operated mechanisms. Under ordinary conditions it is impracticable to mill bevel gears having teeth coarser than 3 diametral pitch, no matter what the service for which they are to be used.

Two of the approximations involved in this method may be mentioned. In Fig. 2, it will be noticed that the various dimensions W, $S + A$, etc., are taken perpendicular to the bottom of the tooth, instead of perpendicular to the pitch line as they should be. The setting of the cutter to depth by this usual method, therefore, involves an error, but it is so slight as to be negligible. The other approximation relates to the use of the uncorrected tooth thickness and addendum for measuring the cutters in preparing the table. The chordal tooth thickness might have been used, but at the cost of a considerable complication in the process. It was found by investigation that this refinement would not affect the final result enough to make it worth while.

The Brown & Sharpe Mfg. Co. has been trying this method of setting the milling machine and automatic gear cutter for the past four or five months, first in an experimental way, and later in regular practice. The workman can with confidence cut a trial tooth with the set-over given and expect to find it (in an 8-pitch gear, for instance) about as close to size as he would naturally measure, so far as thickness of the tooth at the large and small ends is concerned.

The writer's thanks are due to the Brown & Sharpe Mfg. Co. for the very kind attention given to this matter, both in the experimenting in the shop, and in the preparation of the table in the drafting-room.

* * *

The whitewashing of coal, says the *Railway and Engineering Review*, would seem to be a rather silly proposition; but it is not done for looks, nor to change the quality of the material. It is rather a simple detective scheme said to be effective. The purpose is to locate loss of coal from open cars by theft or otherwise, in transit. The top of the load is sprayed with lime water—an easy and cheap process. It is thus whitened as the water evaporates, and the appearance is that of a load of white coal. Any disturbance of this surface by removal of even a small quantity is readily noticeable. By observing this at division and junction points, the place of the disappearance can be approximately located. This plan has been tried on some western roads, but has been abandoned solely on account of the opposition of dealers who claim that their customers do not want coal so treated. As the quality of the coal is unaffected, there can be no reasonable objection to it. The real reason is believed to be that dealers prefer not to get the protected coal but prefer the opportunity of making claims for alleged losses in transit. If this is the fact, there is a condition into which railway commissions, state or national, might well look. It is to the best interest of shippers and carriers that there should be no losses in transit, and no bogus claims for alleged losses.

* * *

About one-third of an ounce of radium-chloride, equivalent to about one-thirtieth of an ounce of pure radium, was the total output of the Joachimsthal mines in Austria for eighteen months. The radium will be sold for about \$5,000 a grain.

DIES AND METHODS FOR MAKING WATCH CROWNS

GEO. J. MURDOCK*

The art of making watch crowns is one of the most interesting branches of precision mechanics, and of comparatively recent development, as watches, like clocks, were originally wound with a key. In the course of the refinement of the watch it was discovered that a watch key was a very elusive article, which, being small, was easily mislaid or lost.

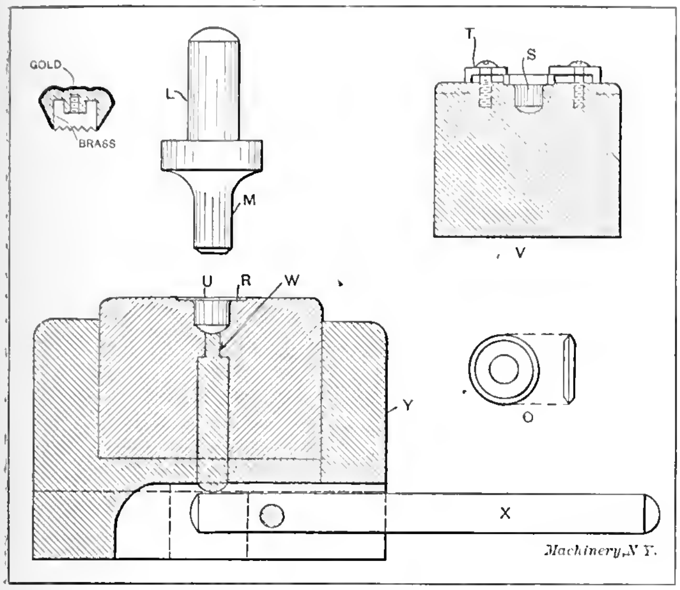

Fig. 1. Dies used in making Watch Crowns

The stem-winding, and finally the stem-setting watch was improved so as to render the key unnecessary, and with this improvement came the watch crown. In the beginning, it was globular, or nearly so in shape, but in recent years the style known as the antique crown has almost completely superseded the old form, particularly on American watches.

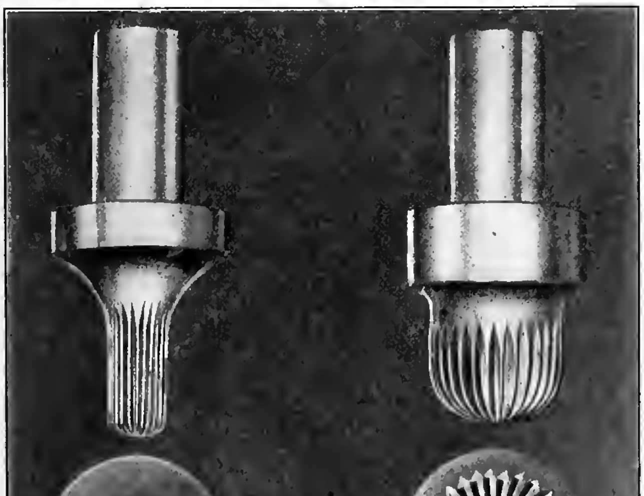

Fig. 2. Two Punches used for Forming the Gold-plated Outer Shell

There are numerous sizes made which are numbered from 0 to 24 or larger. The small sizes are used mainly on ladies' watches, while those for men seldom range above size 18.

Such a thing as a solid gold crown is unusual, the practice being to make a central hub or core of brass, over which is drawn a filled or solid gold shell, as shown in the sectional view in the upper left-hand corner of Fig. 1. Manufacturers at the present time seem to be unanimous in two particulars: First, the brass hub is made just as large and heavy as possible; and second, the shell over the brass is made just as thin as the trade will allow. The reasons for this are obvious. Thus it will be understood that when one has what he fondly imagines is a solid gold watch in his pocket, it is composed, in reality, mainly of brass and steel.

The machinery required in the making of tools for watch crowns, is a screw press, lathe, and a small universal milling machine. In making the dies, the punch for the gold shell is the first thing to make. A punch of hard tool steel such as is used for one of the final operations is shown in Fig. 1, and also at the left in Fig. 2. It has a shank *L*, and point *M* which is fluted on the milling machine with the correct number of divisions for its size. These divisions are standard for the different sizes, and must be very smoothly cut by a small V-shaped 60-degree milling cutter such as shown at *O*. The fluting of the punch necessitates not only a keen cutter, but such an exercise of skill on the part of the toolmaker as will produce a surface on the flute free from chatter marks or blemishes of any kind. The perfection of the punch in this respect should be followed by a die that is also perfect. After the flutes are cut in the punch both on the sides and

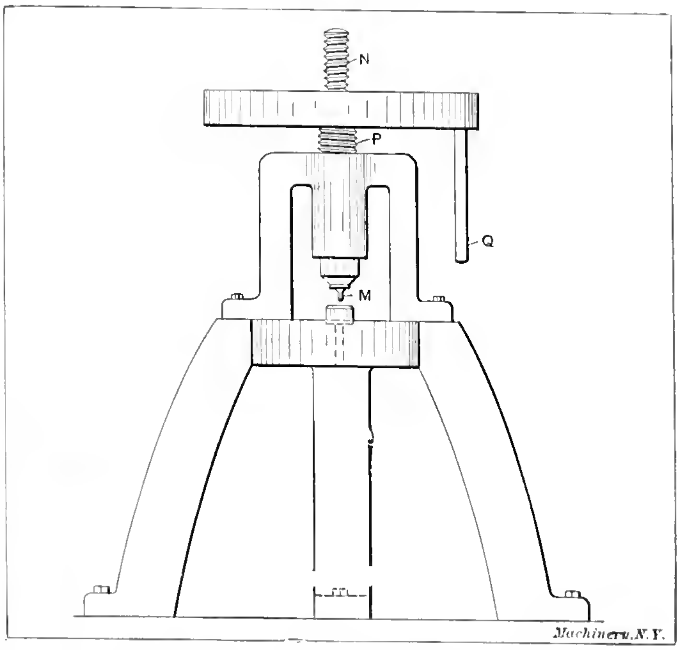

Fig 3 Screw Press in which Dies and Crowns are made

end to the center, the part that forms the crown top is turned (usually by hand) to a gage, as shown in the end view in Fig. 2. I will state here that the top of a watch crown is the small central hub on the top where the flutes end. The bottom or point of the punch is turned to this shape, as shown, and to the exact diameter that the body of the hub on the finished crown is to be.

The punches, when ready to be hardened, are packed in a cast iron box with a mixture of powdered charcoal and bone-dust. The cover is then luted with fire-clay so as to make it air tight, and the box with its contents is heated long enough to bring the punches to the right temperature for hardening. They are then taken out one by one, and dipped vertically in lukewarm water. Care is taken to keep those that are in the box covered with the charcoal, for an exposure to the air even for a few seconds will cause them to scale so as to render it impossible to get them of the necessary smoothness again. Before packing the punches they should be slightly warmed and dipped in the following solution: Boracic acid, 1½ ounce; aqua ammonia, 2 ounces; powdered borax, 1 ounce; potassium cyanide, ½ ounce. This solution is dissolved by boiling it in ½ gallon of rain water. It forms a protection to the finished surface of the punch, and assists in keeping it from scaling. If it is used, the punches will come out bright, and nearly as smooth as when put in the fire, which is a very essential thing to consider in work of this class. After hardening, the punches are scratch-brushed (not buffed), and then put into a muffler and drawn to a clear straw color all over. When cold, the

* Address: 33 Wallace Place, Newark, N. J.

point M is dipped in water, and with a gas blow-pipe, the shank L and the enlarged part of the punch is drawn to a dark blue, while the point as far as it is in the water will remain a straw color.

The die is usually about $2\frac{1}{2}$ inches in diameter by $1\frac{1}{2}$ inch thick, and the blank is turned all over so as to be round, and parallel on the top, and bottom. For the smaller sizes, the spot where the punch will strike in sinking, should be smoothly polished. The die is set in a recess on the bed of the screw-press, as indicated in Fig. 3, and the punch M is brought gently down on it. The screw-press is made with a compound screw N and P which, together with a heavy fly-wheel actuated by the handle Q, gives it great power. Before beginning the operation of sinking the die, the punch should be wet with the following mixture, which seems to have a softening effect on the steel of the die, causing it to give away with greater ease before the punch; in addition, the sunk surface will remain smooth in service longer than when oil is used: sulphuric ether, 6 drams; pulverized camphor, 2 ounces; enough oil of turpentine to fill a 6-ounce bottle.

In sinking the die, it should be held down in the recess in the bed-plate of the press with the right hand, while with the left the wheel is swung so as to move the plunger of the press with the punch up and down. Too much force must not be applied at first, but the blows should be struck gently, until the point of the punch has entered the die far enough so that the flutes on the sides of the punch are well supported by the wall of the die. The greatest danger of breaking the punch is when the operation of sinking is first started, but by observing the above precaution, breakage may be reduced to a minimum. The punch should be kept wet with the solution (which is applied with a small brush) and driven a little at a time down into the die. Care should be taken to prevent dirt, bristles from the brush or other foreign matter from getting into the pit as it is being sunk, and after every two or three blows the die should be turned around. In doing this, it should be lifted by the hand from the recess in the press bed, and placed on the punch, after which the press is carefully brought down, and the die located in the recess, when the sinking may be continued. As the punch travels down, the force of the blows may be increased with safety, until the required depth is nearly reached, when they should be again moderated, and at the finish the die should only be tapped gently. The reason for this is that a large number of gently delivered blows towards the finish will make a much more durable die, and one that is less liable to crack in hardening.

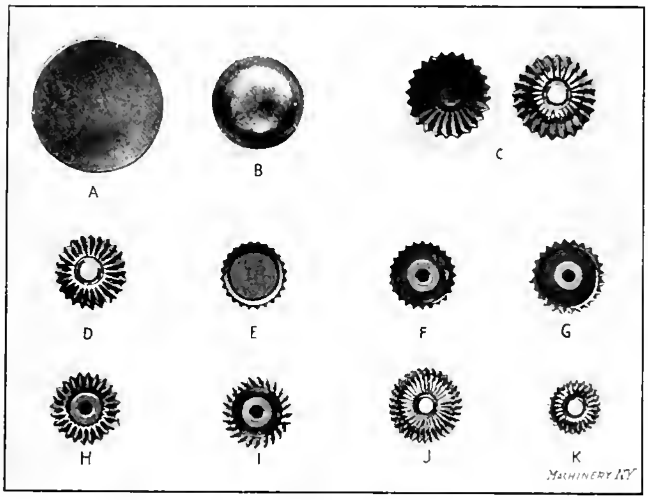

Fig 4. The Evolution of a Watch Crown

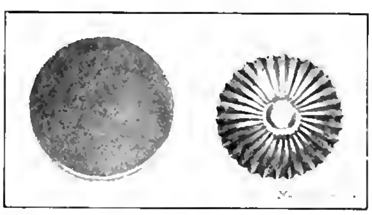

Fig. 5. Gold-filled Blank for 18-size Crown, and Shape after Second Operation

If by any means one of the flutes of the punch should break in the sinking (and it sometimes happens with the most careful management) see that no small pieces of the splinter are in the die, and then, by the method of turning heretofore described, it may still be saved, or if the splinter has injured it only slightly it may be used for a larger size. The old method of sinking, especially with the large sizes, was to heat the die red hot, and then bring the punch down on it, a proceeding that was almost sure to ruin the punch, and produce a die more or less rough and pitted. With the sinking fluid mentioned, however, dies of any size can be sunk cold with ease, and the hot method is no longer used by up-to-date toolmakers.

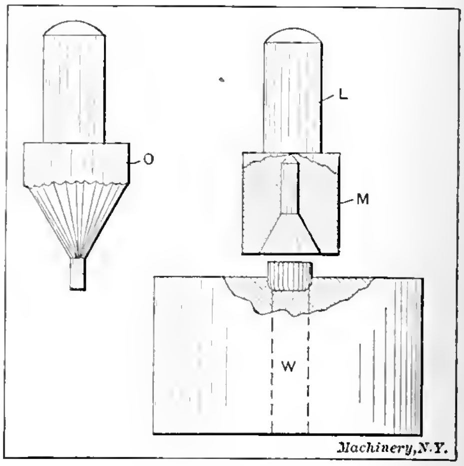

Fig. 6. Punch and Die for Closing Crowns as at H, Fig. 4

After the die is sunk, it is put on the face-plate of a lathe, and indicated until the pit in the die comes central, and then a recess R (Fig. 1) is turned concentric with the pit to receive the round blank A (Fig. 4) which is to form the shell of the crown. The stock from which the shells are made varies in thickness for different sizes, but for an 18 size it would be 0.012 of an inch thick for filled stock. In some cases instead of the recess R, a nest S is made to hold the blank. Holes are then drilled and tapped in the top of the die as shown, and the nest is held in place by the straps T. I regard these holes as objectionable, however, and always use the recess R in preference, where it is permissible. In turning out the recess, the sharp corner U of the pit in the die is slightly rounded and highly polished. If this is not done the gold will be scratched or even cut by the sharp corners of the flutes which are now, of course, exact duplicates of the flutes on the punch.

In making the larger sizes of crown dies it becomes necessary to turn out a pit in the top of the die, removing most of the metal in the way of the punch before beginning the operation of sinking so that the punch has only to draw up the flutes. This hole should be turned as smooth as possible, and polished. I have known a small ring made in the turning which was hardly discernible with the naked eye, to irretrievably ruin a die, for no matter to what extent the sinking was carried, that ring would still appear on the flutes, and of necessity on the finished crown. Filled gold plate consists of a very thin sheet of gold (10 or 12 carat) laid on a sheet of copper, and united by pressure alone, no solder or other adhesive being used. It will be seen, however, that all the work on a crown die using this stock must be perfect, for the slightest scratch through the thin gold will quickly show on the darker colored copper beneath, which will eventually turn a dark brown while the uninjured part of the gold will remain bright. A flute on the punch that has been slightly distorted in hardening, will sometimes draw the gold so that it will not cover the copper after the slight buffing the crowns receive as a finish, and a dark spot on the crown will soon develop in use.

Dies for small sizes of crowns are commonly made solid at the bottom of the pit, as in the die V, Fig. 1, but the larger sizes require some means of pushing the drawn shell out of the die. A rod W is used for this purpose which has a small end or shoulder as shown, which is of such a length that when the shoulder strikes the bottom of the counterbored hole in the die, and the shell is forced down into the die, the top of the crown is drawn into shape by the top end of the rod, instead of the bottom of the pit as in the small sizes. In making dies of this class, it should never be attempted to drill the central hole for the rod W after the die is sunk. It is my practice to drill the hole while the die is on the face-plate, and after the clearance hole is made for the punch. It should be a few drill sizes smaller than the correct finish size for the small end of the rod. The punch in sinking will fol-

low this hole very accurately if everything else is correct, and after the die is sunk, the hole may be enlarged to the proper size for lapping to an exact fit on the rod after hardening. In the smaller sizes, the shell will come out of the die on the punch from which it may be removed with the fingers, but in the large sizes a blow from a mallet on the lever *X* is often required to force the shell out of the die. This lever is fulcrumed in the shoe *Y* which is strapped to the bed of the press, and holds the die in position under the punch. A slight tap on the lever will, through the agency of the rod *W*, drive the shell out of the die after the punch has been withdrawn.

After the die has been completed, a second working punch for drawing the shells must be made. It is in all respects like the first or sinking punch in shape, but is made smaller in diameter by twice the thickness of the stock used. This applies to both the body, and the hub which forms the top of the crown. In addition to this, a small clearance must be allowed which varies from a fraction of a thousandth of an inch to one or more thousandths, according to the size of the crown to be made. This allowance is for distortions in hardening, and other small differences between the punch, die, and stock, although the latter is usually very uniform in thickness. The round blanks are found in the market, of the correct diameters for the various sizes, and are generally bought by the manufacturers ready for use, so that the toolmaker is chiefly concerned with the various drawing processes.

The first drawing operation is to make the round blank into a shallow cup as at *B*, Fig. 4, where a cup for a 16 size crown is shown. This is done in a die that is easily made, but must, of course, be correct in size and smooth. This die is made with its punch, in the same manner as described for the fluted ones, but a little more latitude may be allowed between the punch and die so as to treat the gold blank as gently as possible. Heating between the drawing processes is never necessary if the preliminary tools are made right, as the stock will harden but slightly, before the shell reaches the fluting stage.

The second operation, *C*, puts the primary flutes in, as well as the top in a rudimentary form. The blank for an 18 size and also its shape after the second operation, is shown in Fig. 5. The punch used in forming the blank to this shape is shown to the right in Fig. 2. The third operation, *D*, brings the sides up parallel or nearly so, and to the correct diameter of the finished crown. The punch for this operation is shown to the left in Fig. 2. In small work, operation number two is omitted, and the shell is drawn directly from a plain shallow cup to the shape shown at *D*.

After the third operation, the shell is ready to receive the hub in which is tapped the thread for the stem. This hub is made from a chunk of soft brass which is chopped off in almost any old way. It is thrown into a die that forms it as shown at *E*, with the same number of flutes as the shell. The top is smaller than the top of the shell, but exactly fills it. The making of the punch for sinking this die is the same as for the other fluted punches, but it is slightly smaller than the inside diameter of the shell so that the hub may be pushed into the shell without stretching it. After the die is finished, a second punch is made with a blunt end somewhat smaller than the inside of the die at the top. This outfit is used commonly on a foot-press that is operated with great spirit by one of the small jokers of the establishment, who turns the hubs out by the thousand at so much per.

After the hub is struck up, it is put into a spring chuck, counterbored, drilled, and tapped for the stem of the watch as at *F*. It is then pushed into the shell by the aforesaid small joker, as at *G*, and it is then ready to close in, which requires a special punch and die, as shown in Fig. 6. This die is made so that by changing the rod *W*, a number of different sizes may be closed by the same die. The punch as well as the die is sunk, which is done as follows: The shank *L* having been duly turned, the body *M* is bored out to the proper taper and a smaller straight hole is bored as shown. The sinking punch *O* has the same number of flutes in it, and is as carefully made as the shell punch so that the flutes in the taper will be absolutely smooth, and of a high polish. At its point it is provided with a pilot that fits the straight hole in the punch *M*. The punch *M* is placed in an inverted position in a special shoe on the screw-press, and the flutes sunk in it by the punch *O*, which is attached to the press plunger.

After both punch and die are finished, the shell of the crown containing the brass hub is placed top side down in the die, and the punch *M* is brought down on it until it strikes the die. This action draws the top together, as shown at *H* (Fig. 4), and brings the crown to the shape required for frazing, which consists essentially in counterboring the ragged edges where the brass hub and shell come together, to the correct size to fit the watch case. Samples of the completed crowns, antique style, are shown at *I*, *J* and *K*, the first two being number 16 in size and the last number 12.

After the dies are made, and are ready to be hardened, the pit is filled with a stiff paste of lampblack mixed with the non-scaling solution mentioned in this article. The die is now luted into a hardening box, and brought to a low red heat, and allowed to cool off over night. Unless this precaution is taken, the great molecular strain set up in the top of the die blank by the sinking, is liable to cause it to split in the hardening. When the die is finally ready to be hardened the pit is again filled with the lampblack mixture, and the die is packed in the same manner as heretofore described for hardening the punches, and then heated to the proper temperature to dip.

The hardening bath is sometimes of oil, but I prefer clean rain water which has been made lukewarm. The die is taken quickly from the box, and dipped face down into the cup *C* (Fig. 7) of the hardening tank. Holes are cored out in this cup so as to allow a free circulation of the water, and to permit the steam to escape readily. Water is let into the cup until it is about half full, and then the die is placed therein; the water which is supplied by a pump at about 15 pounds pressure, is then turned on full.

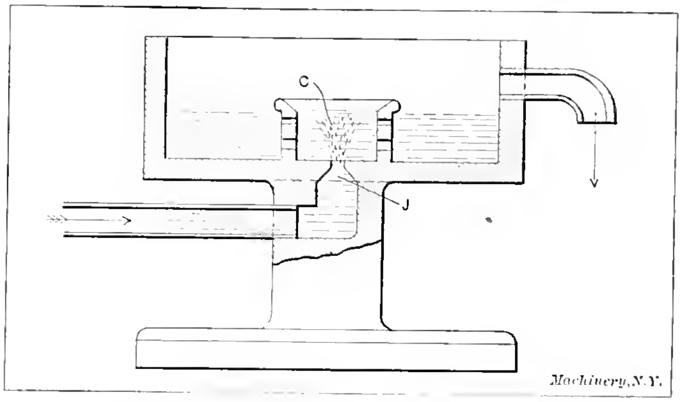

Fig. 7. Tank in which the Crown Dies are hardened

The jet *J* comes directly under the sunk pit in the die, and quickly washes out the lampblack, driving it with the steam through the holes in the side of the cup. If the dies are of the proper temperature, it will be found that the flutes and bottom of the pit that forms the top of the crown, are perfectly hardened, smooth, and almost as bright as when put in the hardening box.

Both the punches and dies for making watch crowns, should be so smooth and bright as to reflect any article brought near them like a mirror, and if in this condition they will turn out perfect work.

EXPLODED BOILER PROJECTED TO GREAT HEIGHT

A 400 H. P. vertical water-tube boiler of the type having water and steam drums connected by the water tubes, exploded in the Denver Gas & Electric Co.'s power plant in Denver, Col., last June. The bottom head of the lower drum ruptured at the rivet holes where connected to the shell, and the boiler "sky-rocketed" to a calculated height of over 1,600 feet; it fell into the engine room 175 feet from its starting point and demolished a Hamilton-Corliss engine and two large direct-connected generators. The explosion caused the immediate death of four persons and serious injuries to four others. The estimate of the damage to property ranged from $60,000 to $200,000. The explosion and calculations of the height to which the boiler projected itself were the subjects of an interesting article in the July number of the *Locomotive*.

ACCURATE SETTING OF THE BEVEL GEAR CUTTER*

WARREN E. THOMPSON†

This article deals exclusively with the formed bevel gear rotary cutter, and introduces a method of mathematically finding the correct setting of the bevel gear cutter in relation to the axis of the gear; also the amount of rotation of the gear blank required for the correct thickness of the teeth.

Bevel gear cutting with a formed cutter is but a compromise process, the teeth having to be shaped, to a certain extent, after cutting by filing or other means. The customary practice is to cut the large end of the tooth to the correct form as nearly as possible and then finish the small end addendum by rounding, either with a file or by running it in mesh with a hardened master gear. Another method is to cut the large end of the tooth slightly more rounding than necessary and the small end of the space deeper than regularly figured. The latter method saves considerable of the after finishing work and if the teeth are cut somewhat thin, an amount varying with the pitch, they may be run with no other labor on them, but will be noisy at high speed. These two methods of producing bevel gears with rotary cutters are the most economical of the many available, but the first produces the most nearly correct tooth form of any.

The following methods of obtaining settings are applicable to all methods of cutting with rotary cutters whether in the milling machine or gear cutter, but, of course, allowances must be made in the formulas for conditions other than those described:

The Choice of the Cutter

The choice of the cutter is perhaps the most important item of any, as the smoothness of the tooth action is entirely dependent upon the shape of the formed cutter. The best method for selection of the cutter, in the writer's opinion, is to figure or measure the back cone radius of the gear, and multiply it by twice the given diametral pitch. This gives the number of teeth of an equivalent spur gear having the correct tooth form. The position of the cutter in relation to the axis of the gear is variable with each case, and this is what makes the selection of the cutter a rather difficult proposition. Select a spur gear cutter for the calculated spur gear, and scribe the outline of the tooth form on a piece of blackened zinc or other sheet metal. Select a bevel gear cutter having the same or slightly less concave form. This method has been used by the writer and found more satisfactory than any other coming within his experience. [Of course the tooth faces of the spur cutter and bevel cutter must be ground exactly radial and parallel with the cutter axis, as they should properly be, in order to make the comparison effective.—EDITOR.]

The Setting of the Cutter

The setting of the cutter has been a matter of cut-and-try and a rather unsatisfactory operation as well as costly in high-grade labor. The following method overcomes these difficulties to a marked degree; it enables the draftsman to put the figures for the shop on the gear drawings the same as other shop data:

Fig. 1 represents the layout of the middle section of a gear tooth lying in the same plane as the axis of the gear. BT is the pitch radius; BP the front cone radius; and BR the back cone radius. AB and A_1B_1 are the addenda; BC and B_1C_1, the working depths; and BD and B_1D_1 the whole depths of space below the pitch line, called the $S + F$ and $s + F$ of the large and small ends of the tooth respectively. BB_1 is the length of the tooth, called the "face." B_1D_1, or the $s + F$ of the small end equals $\frac{PB_1}{PB} BC + F$. Clearance is constant.

By referring to Fig. 3, which is a section of a bevel gear cutter, it can readily be seen that every different $S + F$ or height from the bottom has its definite corresponding thickness, and the accompanying table of proportions comprises a series of measurements taken from large standard layouts. This table has correct figures for 1 diametral pitch

* For further information on this subject, see "Cutting Bevel Gears with a Rotary Cutter," October, 1907, and "Cutting Bevel Gear Teeth—A New Method of Obtaining the Set-over," in this issue.

† Address: 119 Washington St., Winchester, Mass.

cutter only, and starts at T_c or the pitch line of the cutter; hence the $S + F$ of the actual case must be multiplied by the stipulated diametral pitch before referring to the table. Under the number of the standard cutter chosen by the method just described the given $s + F$ will be found with its corresponding t, or loss in thickness. This number must be divided by the given diametral pitch to get the actual loss in thickness from the large to the small end of the actual tooth space on the cone pitch line PR.

Now a bevel gear cutter set central with the axis of the gear will cut some such lines as DE, Fig. 2, passing outside of the gear center. The finishing face of the cutter must be moved until it cuts cone pitch lines passing through the center as FO. The angle subtended by the pitch points of the

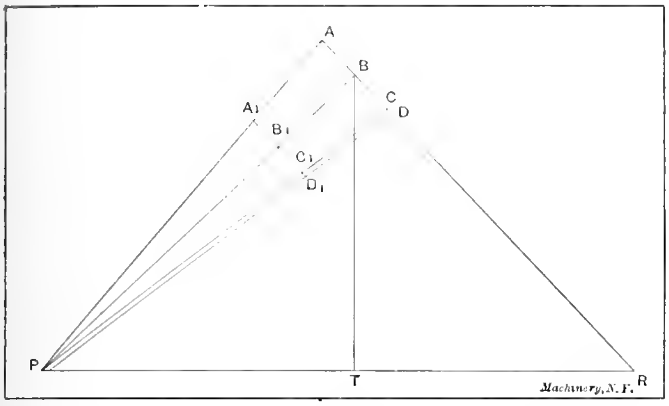

Fig. 1

cutter when it is set in its central position, measured from a line passing through the cone center parallel to the center line of the form of the cutter, is called the "cutter angle." The tangent of this angle equals $\dfrac{t}{2\text{ face}}$, or the t of the table divided by twice the length of face.

The front cone pitch line of the gear multiplied by the sine of the cutter angle equals the distance to set the pitch points of the finishing faces of cutter out of center. Call this distance D_c. To determine the required distance to move the cutter, after setting it central, the thickness of the cutter at

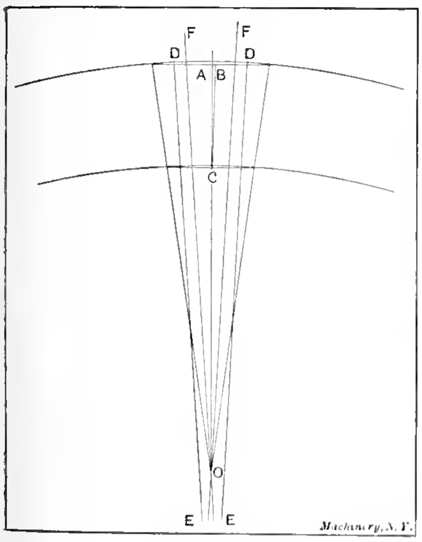

Fig. 2. Angle A C B is the "Cutter Angle"

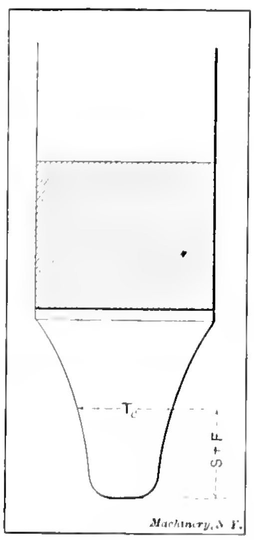

Fig. 3

the $S + F$ of the large end of space must be measured with the Brown & Sharpe vernier gear tooth caliper, because the cutters vary in practice. Call this thickness T_c. Subtract D_c from $\dfrac{T_c}{2}$, and move the finishing face of the cutter toward the center line of the blank an amount equal to the remainder, for cutting each side of the tooth.

The table gives, in the columns headed $s + F$, the depths to which the cutter is sunk below the pitch line of the gear at the small ends of the teeth, and begins with the $S + F$ at the large ends which is measured to the pitch line T_c, Fig. 3. These depths, of course, are proportional to the length of tooth face plus the constant clearance.

$$B_1D_1 = \frac{\text{cosec. center angle} \times \tfrac{1}{2}\text{ pitch diam.}-\text{face}}{\text{cosec. center angle} \times \tfrac{1}{2}\text{ pitch diam.}} S + F$$

The values in the columns t are the differences in width of the cutter at the respective $s + F$ points, corresponding to the depth of the cutter at the cone pitch line at small end of the tooth space and the width T_c on the normal pitch line. The table being for 1 diametral pitch, the values must be divided by the diametral pitch to obtain t for other pitches.

The various operations of finding the setting may be formulated thus:

1. Find $\left(\dfrac{\tfrac{1}{2}\text{ pitch diam.} \times \text{cosec. center angle}-\text{face}}{\tfrac{1}{2}\text{ pitch diam.} \times \text{cosec. center angle}} S+F\right)$ $\times$ diam. pitch. $F = 0.157 \div$ diam. pitch.

2. Refer to the table and find the corresponding t.

3. $\dfrac{t}{\text{diam. pitch} \times 2\text{ face}} =$ tangent of cutter angle.

4. Measure the thickness of the cutter at the $S + F$ of large end of tooth space to obtain T_c

5. $\dfrac{T_c}{2} -$ (cone pitch line $\times$ sine cutter angle) $=$ the required distance to set the cutter each side of the center.

The center angle is the angle included between the axis of the gear and the front cone pitch line.

These formulas are correct for both methods of cutting set forth in this article, but where the tooth is cut deeper at the small end, the $s + F$ must be figured accordingly, and this will give a small cutter angle, making the setting distance greater.

The Rotation of the Blank

The rotation of the blank may be figured by the following formula. This formula is not exact, but is very nearly so, and is used in preference to the actual true formula on account of the complications arising from the latter, making it impracticable. The vernier tooth caliper should be used to size the teeth and the blank revolved more than the formula calls for, if necessary. On small pitch gears no change from the figured rotation will be necessary unless the teeth are desired thin.

Subtract the product of twice the cone pitch line of the gear and the sine of the cutter angle from the width of the tooth space on the pitch line and divide the difference by the pitch radius to get the tangent of the angle of rotation, or,

6. $\dfrac{T_s - (2\text{ cone pitch line} \times \text{sine cutter angle})}{\text{pitch radius}} =$ tangent of angle of rotation.

Example from Practice

Bevel Gear:—16 pitch, 12 teeth, 0.75 inch pitch diameter, 0.25 inch face, 9 degrees 30 minutes, center angle, 2.272 inches cone pitch line, No. 6 cutter, $S + F = 0.069$ inch.

1. $\left(\dfrac{0.375 \times 6.0588 - 0.25}{0.375 \times 6.0588} 0.059 + 0.10\right) \times 16 = 1.0000$

2. t, from table $= 0.086$

3. $\dfrac{0.086}{16 \times 0.5} = 0.01075$ tan cutter angle; cutter angle $= 37$ minutes.

4. T_c measured $= 0.065$ inch.

5. $\dfrac{T_c}{2} - 2.272 \times 0.01076 = 0.0081$ inch.

Set the cutter central, then move the finishing face 0.0081 inch toward center. Cut once around and move cutter back 0.0162 inch for the opposite side of the tooth.

6. $\dfrac{0.098 - (2 \times 2.272 \times 0.01076)}{0.375} = 0.13066$ tangent.

Angle to revolve $= 7$ degrees 27 minutes.

If a dividing head having a 54-hole plate is used the blank would be given one-fortieth of a turn (one turn of the index handle) plus nine holes on the 54 circle as each hole on the circle equals 1/6 of one degree, or 10 minutes.

CLAMPING DEVICES*

LUCIEN L. HAAS†

If the reader will carefully go over the twenty illustrations of different clamping devices found in the accompanying Data Sheet, he will find that some of them are very similar; yet the mechanic will be able to cite many instances where one, and only one, of these types can be used to advantage. Of course, it will be understood that these illustrations are diagrammatical and are intended to indicate the principles of various clamping methods rather than the actual design and construction of the clamp itself. In order to make each illustration more complete, the work itself has been represented in each case by sections shown in solid black.

Figs. 1 and 2 represent the every-day method of clamping work to the table of a milling machine or to the face-plate of a lathe. The type of clamp shown in Fig. 3 is commonly used for holding work in a drill jig when one bolt or screw is sufficient, especially when it is desired to have an open end jig. Fig. 4 illustrates a scheme which is not often found in use. This type of clamp is adapted to box jigs; it has the advantage of being easily removed, which is accomplished by sliding it longitudinally. By glancing at the detailed view to the right, which shows the end of the clamping bar and its retaining grooves, the way in which it is held in place and removed will be clearly understood. Figs. 5 and 6 show clamps which are very much alike, but as a great many mechanics use the design shown in Fig. 5, I added that of Fig. 6, as it is both simpler and two-to-one quicker, when it comes to removal. It will be noted that when the clamp is slotted as shown in the plan view of Fig. 6, that fixed studs may be used instead of the swinging bolts. As there are a great many mechanics who prefer the cam as a means of clamping, the illustration Fig. 7 is presented as a reminder of the application of this principle. As is well known a cam can be used in possibly a hundred different ways. The type shown in Fig. 8 is often found in machine shops, on milling fixtures, drill jigs, lathe fixtures, etc. The clamp and bolts can be removed by loosening the nuts and pulling out the slip washers which allow the nuts to pass through the large holes. Fig. 9 illustrates a scheme which is commonly used on milling fixtures when light milling is to be done. The design of clamp shown in Fig. 10 is not frequently seen in use as it is a scheme which a mechanic will not use if he can see another way out of it; but at times it is found almost impossible to use a clamp of any other type. Fig. 11 shows the style of clamp that is used in connection with box drill jigs when it is desired to support a part to be drilled on two points. As will be seen, these two bearing points are self-adjusting. The design of Fig. 12 is generally used when it is desired to support the work in two places in an open-end drill jig. Figs. 13 and 14 show types which are quite similar, but, as before stated, there are many cases where one type can be used to advantage and not the other. For instance, the clamp, Fig. 13, is intended for box jigs and one would not think of using the type of Fig. 14 in such a jig, because the latter is altogether too slow. However, its advantages over Fig. 13, in case it is desired to have an open end jig, are apparent. The relation of the first cost of a jig to the quantity of work to be done, is a factor which sometimes makes a jig which is not perfect from a purely mechanical standpoint, more desirable than one which represents better design but greatly increased cost. Fig. 15 shows the old hook-bolt scheme, a clamp which is found in use almost as often as that of Fig. 1. The type shown in Fig. 16 answers practically the same purpose as that of Fig. 11, and it is used on, I dare say, one-third of the drill jigs now in use. A style of clamp that is somewhat similar to the one illustrated in Fig. 4, is shown in Fig. 17. In this case, however, two clamping bolts are used and the clamp is removed from the end of the jig. This is a good, as well as a quick method, of clamping work in open-end drill jigs. Fig. 18 illustrates the use of bolts only, for holding down work. The illustration is self-explanatory. Fig. 19 shows a good design of clamp for holding work in a milling fixture. It binds the work both horizontally and vertically and "has it all over" any other type when it can be used. The last but not the least of the clamping devices is shown in Fig. 20, which illustrates the wedge method. This is found in use in about every machine shop in the world, and its application is familiar to all mechanics.

HELICAL TIMING GEARS FOR AUTOMOBILE MOTORS

ERNEST L. SMITH*

It is a fact, becoming better known each succeeding year, that correctly cut helical gearing will run with less noise than equally well cut spur gearing. That this knowledge is not wider spread, or in fact universal at present, is due naturally to the fact that the high development of hobbing machinery and the hobbing process is comparatively recent, as it is only by this process that perfect helical teeth can be machined at low cost.

The reason that the helical tooth is quieter in action than that of the spur gear is that the angle at which this tooth is cut permits only of its gradual engagement, and as this angle is usually great enough to permit the following tooth to enter contact before the first has quite passed out of mesh, we derive what may be characterized as practically a continuous contact.

The field in which these gears have been found especially desirable is that of the timing gears for a gasoline motor, *i. e.*, the gears that drive the cam-shaft and the magneto. The service of these gears is not arduous but it is imperative that they be quiet in action at either high or low speeds, and this quality the helical tooth possesses as does no other.

Regarding the specific points to be taken care of in adopting helical gears for motor timing, the Grant-Lees Machine Co., Cleveland, Ohio, suggests as an ideal outfit the following: Crank-shaft gear, of 20-point carbon steel, with no recessing; magneto gear, carbon steel, with no hubs; idler gear, of cast iron, with no hubs; cam-shaft gear of cast iron or 20-point carbon steel.

It is suggested that no recessing be done in the steel gears, because, while lightening the motor is of undoubted importance, the amount of lightening possible here is really negligible, but the increase in cost for such recessing is not. Hubs should be avoided where possible, for the same reason of cost, as they prevent ganging the gears for cutting.

An important point, then, that should be held in mind by the engineer when designing helical gears is to produce blanks that can either be made automatically from the bar or, in case the blanks are of cast iron, a simplicity in construction should be carried out so as to allow ganging of gears and the smallest number of settings of the machine for hobbing and facing them.

Cast iron is recommended in place of the once customary bronze as it is cheaper than bronze, and for this service in no way inferior. In fact, it has this one advantage, which is of higher value than at first might appear. If a bronze gear is dropped or struck accidentally, it is liable to be harmed to an extent not noticeable on inspection, but will show up later in action. If a cast iron gear is not broken by a similar accident, it will be found as good as before.

Almost any angle of the teeth from 12 to 20 degrees will give satisfaction, as the end thrust resulting from an angle within these limits will for this service (timing gears) be slight enough to be negligible. A diametral pitch from 9 to 12 is usually employed, and approximately a one-inch face on the gear.

Although the use of helical timing gears was practically unknown four years ago, the designers of automobiles have already come to regard them highly as is shown by the fact that the Grant-Lees Machine Company will in 1909-10 cut timing gears of this type for something over 20 per cent of the American automobile manufacturers, this percentage practically covering the field.

ELECTRIC DRIVE OF TURBINE PUMPS*

It is becoming a well-recognized fact that the electrical engineer, in order to successfully solve the problems of his particular science, must give earnest study and work to many other branches of engineering. The peculiarities of electrical rotating machinery make it desirable, and often essential, to obtain a thorough knowledge of the mode of operation, variation of load, and nature of product, of the mechanical apparatus that it will be applied to. The point of view of the electrical engineer is in this study so different from that of the mechanical engineer in designing his part of the combination that it should cause no surprise if the investigations of the former must run along entirely original lines. Such has most prominently been the case in introducing the electric motor in steel, cotton and paper mills, or when applying gas engines to the driving of electric generators. The turbine pump, to which this paper will be devoted, has been comparatively neglected, and yet the erratic conditions found in many pump installations show the unquestionable necessity for a better understanding of the problem involved in electric drive of turbine pumps.

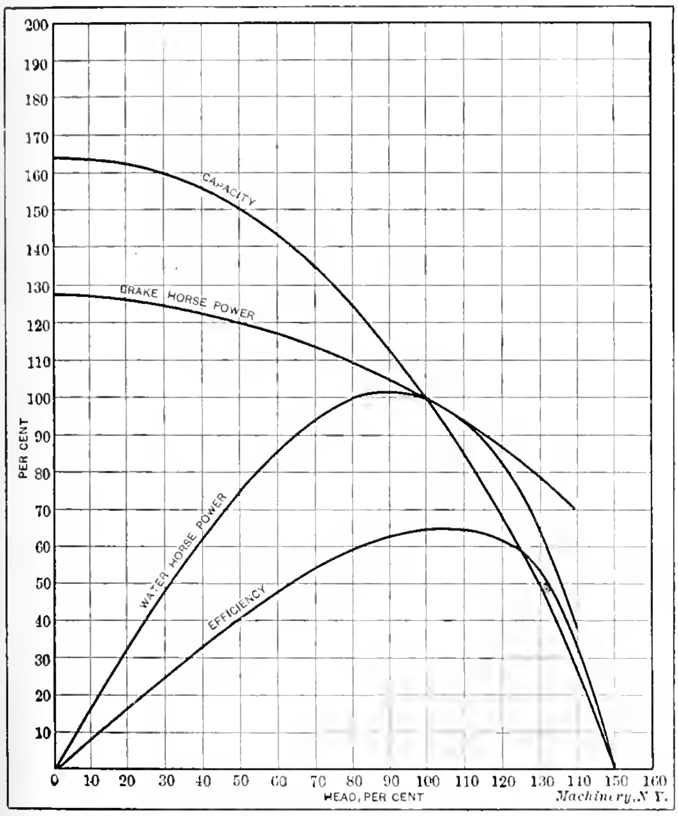

Diagram showing the Relation between Capacity, Brake Horse-power, Water Horse-power, and Efficiency of Centrifugal Pumps running at Constant Speed

The troubles experienced indicate that there are two principal questions, the correct solution of which insure successful electrical operation of turbine pumps. First, the selection of the proper size of motor to take care of varying load conditions; second, the selection of the proper type of motor to meet different starting requirements.

Taking these questions in the order just mentioned, it first becomes necessary to investigate how the load on a turbine pump running at constant speed or nearly so, varies with varying capacity and head. The variation of the load with different speeds is less important and less involved. It is less important, because at each speed that may be desired our reasoning for constant speed is applicable. It is less involved, because the behavior of the turbine pump in this respect is well known, and all necessary information is voluntarily and fairly accurately supplied by the pump manufacturer. The self-evident necessity of allowing margin in the motor for different speeds has caused this condition to be well taken care of. The most frequent speed variation desired is one speed for so-called domestic service pressure and another for fire service pressure. In the case of multipolar alternating current motors, this variation is generally accomplished by using a different number of poles for the two speeds.

* Abstract of a paper by Mr. J. E. Fries, read before the American Society of Swedish Engineers, at Brooklyn, N. Y., October 16, 1909.

At each constant speed, however, it will be found that most pump manufacturers are by no means certain as to how the load on any particular pump varies with varying head. Neither do they seem to think accurate information in this respect of special value. A glance at the accompanying diagram, which shows a typical relation between head, capacity, efficiency and brake horse-power in ordinary commercial turbine pumps demonstrates the great importance to the electrical engineer of obtaining a similar diagram or equivalent information wherever he undertakes to prescribe the size of the motor. In this diagram an efficiency of 65 per cent is assumed, but the relations given will be approximately correct for all efficiencies between 50 and 80 per cent.

The pump ought to be adapted for an average head corresponding to its maximum efficiency. This head, however, will nearly always vary considerably; the water level will, for instance, rise and fall in the source of supply and in the tank or reservoir into which the water is pumped, or if the water is forced directly into a distribution system, the varying demand will frequently cause the discharge pressure to vary over a wide range. The emptying of dry-docks through turbine pumps presents a particularly interesting problem of this nature. In such cases it will be found that when the *head falls off*, the capacity generally increases, and as the efficiency at the same time goes down rapidly, *the load* in most turbine pumps *increases*. It becomes imperative, therefore, that the electrical engineer should know what this overload amounts to, within the range of abnormally low head liable to occur, and the duration of such overloads.

It is true that the pump manufacturers are beginning to realize that this characteristic of the turbine pump makes it unsuitable for electric motor drive, and that they, therefore, have endeavored, and partially succeeded, in "flattening" the capacity curve over a considerable range, thereby making the horse-power required fairly constant between the same limits; but the electrical engineer will as yet seldom meet this condition, and in any case it is safe to remember that the size of the motor is governed by capacity at low rather than at high head. Where no information in this respect is obtainable, it is safe to assume the relations shown in the diagram. On account of the efficiency in all motors, and the power factor in induction motors, being lower at lighter loads, electrical engineers should use every opportunity to impress upon pump builders the desirability of designing pumps with a horse-power curve as flat as possible.

Official test records of pumps recently furnished the U. S. Government for dry-dock purposes will soon be published, and will show that the desired constancy in load has been reached almost to perfection. In these pumps the vanes of the impellers act themselves as automatic throttles, so to speak, restricting the capacity with decreasing head so that the energy consumed is kept constant.

It is often left to the electrical engineer to determine the horse-power required by a certain pump from the capacity in gallons per minute, total head in feet or pounds pressure per square inch, and the efficiency of the pump. Frequently, however, the head given in the specifications does not include friction in the water pipes. It is necessary, of course, to make allowance for this factor when calculating the horse-power of the motor. For the convenience of the electrical engineer who meets this problem, the accompanying table is here given, showing the friction head in feet per hundred feet commercial pipe sizes and for different capacities. The number of U. S. gallons delivered per minute multiplied by 8.3 gives the pounds of water handled per minute. This product multiplied by the sum of the total vertical head and total friction head taken from the table gives foot-pounds work done per minute. If the head is stated as composed of suction lift and pounds of pressure delivered by the pump, it is only necessary to remember that each pound corresponds to 2.3 feet static head. As one horse-power is equivalent to raising 33,000 pounds one foot in one minute against the force of gravity, we obtain the work done in the pump expressed in horse-power by dividing the foot-pounds just calculated by 33,000. This

result is often called "water horse-power." A final division by the efficiency of the pump gives effective horse-power required from the motor. The suction lift and the friction head in the suction pipe added together must, of course, be kept as far below the theoretical limit of 32 feet as possible.

The second consideration that must be given serious thought when attempting electric drive of turbine pumps is that of starting. The direct-current motors possess such remarkable qualities in this respect that little difficulties are to be anticipated in their application to turbine pumps, provided they have the proper capacity to handle the load under all other conditions. The great majority of electrically-driven centrifugal pumps are, however, supplied with alternating current. An induction motor of sufficient capacity to handle the expected load will also start the pump successfully, provided the current rush is tolerated. A synchronous motor, on the other hand, may or may not start the pump, the torque of the motor, especially with certain designs, being very small until synchronism is reached, while the torque required by the pump grows with the square of the velocity. Just before synchronism, therefore, is the critical point in starting turbine pumps. The best remedy for this trouble, as well as for excessive starting currents, is to start the pump empty and prime it after full speed has been reached. Where water is not delivered to the pump under pressure, this may be accomplished either by an auxiliary pump of the rotary type, or an ejector where steam is available, in both cases forcing the supply of water up the suction pipe into the pump.

The electrical engineer is often told that although the pump is filled with water, it will start under very light load, because a check valve will be closed either in the suction or in the discharge pipe, and the writer has seen similar statements in specifications issued by consulting engineers of very good standing. The truth is, however, that neither of these expedients improve starting conditions at all. With the valve closed in the suction line, the pump supports the ordinary water column just the same, and with the valve closed in the discharge line, the pump creates a pressure behind the valve, so that in either case the load is practically normal, and the energy consumed is transformed into heat, which soon makes the water boiling hot. The only way to partially relieve the load from a primed pump is to close a valve in the discharge pipe and open an outlet between this valve and the pump, thus discharging close to the pump and letting the water go to waste during the period of starting. In the case of a single-stage pump, however, the capacity is much greater at the lower head, and the load may even be more than normal, as pointed out before, but with multi-stage pumps the water passages through the pump do not allow such great increase of water flow as would correspond to the extremely low head, and although it might be thought that the excess energy would be converted into heat, practice shows that the load on the motor is in this way partly relieved.

It is evident from the foregoing that the synchronous motor of ordinary design when applied to turbine pumps may fail to pull into synchronism. As the starting torque in a synchronous motor is due to eddy currents and hysteresis, and more to the former than to the latter, it follows that every means to increase the eddy currents improve the possibility of starting a turbine pump. Thus solid steel poles are far superior to laminated ones. Some manufacturers provide copper rings around the pole tips for the same purpose. A radical, although expensive, method of improving the laminated pole motor, is to provide it with a squirrel-cage winding in the pole faces, thus approximating induction motor starting characteristics. Owing to the big air gap and consequent leakage and also to the uneven distribution of this secondary winding, the torque is far from that of an induction motor.

It seems that where synchronous motors are desired the best solution is to prime after starting. It would also seem, however, that where high starting currents are not objectionable, sufficient starting torque may be obtained in synchronous motors with inherent low starting torque, without the highly expensive squirrel-cage winding, by supplying a starting compensator capable of producing about 25 per cent excess voltage. As the torque increases with the square of the voltage, this means should in most cases prove sufficient. Precautions must be taken, however, to make the change from one voltage to another gradual and not sudden, so as not to overstrain the windings.

METHODS AND TOOLS USED IN METAL SPINNING

C. TUELLS

Metal spinning, that process of sheet metal goods manufacturing which deals with the forming of sheet metal into circular shapes of great variety by means of the lathe, forms and hand-tools, is full of kinks and schemes peculiar to itself. It is the purpose of this article to give a description of spinning in general, and to outline some of the methods and tools used in spinning for rapid production.

The products of metal spinning are used in a great many lines of manufacture. Examples of this work are chandelier parts, cooking utensils, silver and brittania hollow-ware, automobile lamps, cane-heads and many other sheet metal specialties. Brass, copper, zinc, aluminum, iron, soft steel, and, in fact nearly all metals yield readily to the spinner's skill. At best spinning is physically hard work, and the softer the stock, the easier and quicker the spinner can transform it into the required product.

There are but two practical ways of forming pieces of sheet metal into hollow circular articles: by dies and by spinning. By far the cheapest and best method of producing quantities of this class of work is by the use of dies, but there are many cases where it is impractical or impossible to follow this course. Dies are expensive and there is constant danger of breakage, whereas spinning forms are easily and cheaply made and are almost never damaged by use beyond a reasonable amount of wear. Thus it will be seen that when the production is small, it does not pay to make costly dies. Again, the styles or designs of many articles that are spun are constantly being changed; if made by dies each change would necessitate a new die, while in spinning merely a new wooden form is required—and sometimes the old form can be altered, costing practically nothing. Still other advantages of spinning are that in working soft steel, a much cheaper grade may be spun than can be drawn with dies; beads may be rolled at the edges of shells at little expense; experimental pieces may be made quickly, and, added to these features, comes the fact that very difficult work that cannot possibly be made with dies can be spun with comparative ease. It must not be construed from the above that spinning is to be preferred to die work in all or even in the majority of cases, because, on the contrary, die work is a more economical method of manufacture, and should always be used when possible on production work. The cases already cited are merely given to point out some of the instances in which, for economical reasons, spinning is to be preferred to die work.

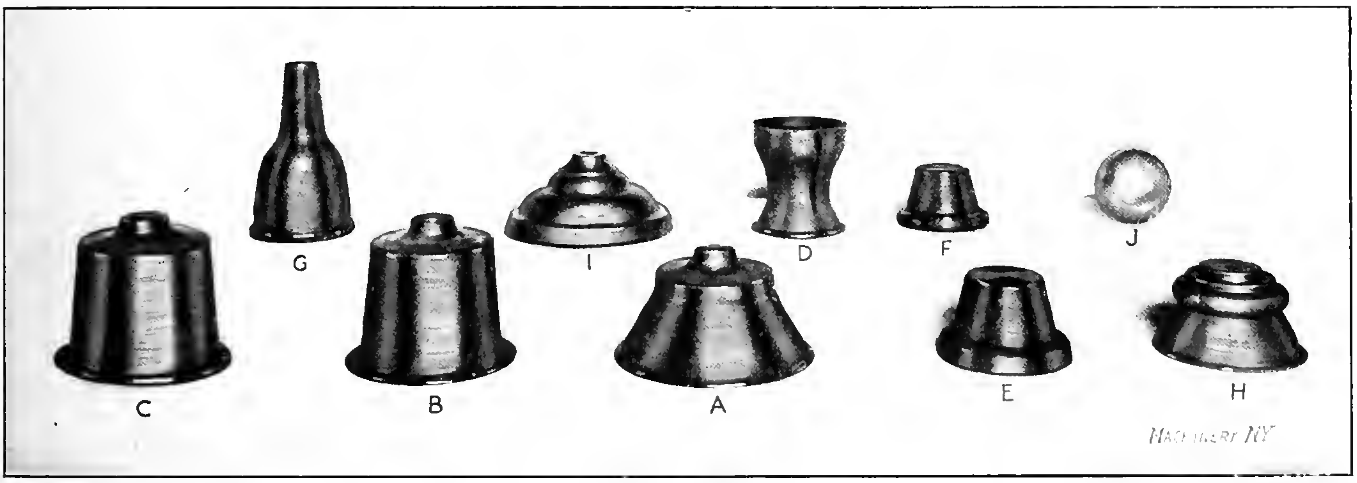

Fig. 1. Specimens of Metal Spinning

The Spinning Lathe

The principal tool used in the operation of spinning is the spinning lathe, shown in Fig. 2. While in many respects this machine is similar to any other lathe, it is built without back-gears, carriage or lead-screw, is very rigid in construction, and, on the whole, very much resembles a speed lathe. Like other lathes, the spinning lathe is fitted with a cone pulley (preferably of wood, because of its lightness and gripping qualities), allowing the use of four or five different speeds. Speed is an important factor in spinning. Arbitrary rules for spinning speeds cannot be given, as the thicker the stock the slower must be the speed; thus while 1/32-inch iron can be readily spun at 600 revolutions, 1/16-inch iron would necessitate reducing the speed to 400 revolutions per minute. Zinc spins best at from 1,000 to 1,400 revolutions; copper works well at 800 to 1,000; brass and aluminum require practically the same speed, from 800 to 1,200; while the comparatively slow speed of 300 to 600 revolutions is effective on iron and soft steel. Brittania and silver spin best at speeds from 800 to 1,000 revolutions.

One of the essential parts of the spinning lathe is the T-rest. The base of this rest is movable on the ways of the lathe, and it has at the side nearest the operator, a stud about four inches in diameter and six inches high, through which is swiveled the T-rest proper. As the illustration shows, provision is made for raising and lowering the rest, and the entire rest may be clamped in any desired position by means of the hand-wheel shown beneath the ways. The rest proper consists of an arm, 12 to 15 inches long, similar to a wood turner's rest, and through the face of this arm are from twelve to sixteen closely spaced $\frac{3}{8}$-inch holes. These holes are to receive the pin against which the hand tools are held while spinning. The pin is three inches long and of $\frac{3}{4}$-inch steel, turned down on one end to loosely fit the holes in the rest.

Another important part of the spinning lathe is the tail-center. This center is sometimes the ordinary dead center that is in general machine shop use, but nearly all spinners use the revolving center, shown in Fig. 3. The revolving center is $\frac{3}{4}$ inch diameter (without taper) and about six inches long, and is fitted into the socket in which it runs; this socket is, in turn, fitted to the taper hole in the tailstock. At the bottom of the hole in the socket are two steel buttons, hardened and ground convex on their faces. These buttons act as ball bearings and reduce friction to a minimum.

Forms and Chucks for Spinning

The shape of a shell made by spinning is dependent on the form or chuck upon which the metal is spun. Forms are used for plain spinning where the shape of the shell will permit of its being readily taken from the form after the spinning has been completed; but when the shape of the shell is such that it will not "draw," as the molders say, it becomes necessary to employ sectional chucks, similar to the one shown in Fig. 5. Generally speaking, spinning forms are made of kiln dried maple. After being bored and threaded to fit the lathe spindle, the spinner turns the maple block to agree with a templet shaped in outline to the sample shell. When no sample is furnished, the templet must be laid out from the sketch or drawing; in either case proper allowance is made for the thickness of the stock. When large quantities of shells are to be spun, all alike, the form is sometimes made of lignum vitae. Another method is to turn the maple form small enough so that one shell may be spun and cemented to it and then this metal-cased form is used to spin the balance of the shells

For continuous spinning, forms are made of cast iron or steel, which of course makes a most satisfactory surface to spin on and gives indefinite service.

A sectional or "split" chuck, as it is sometimes called, is, as the name implies, a spinning chuck or form which may be taken apart in sections after the shell has been spun over it. As before stated, this class of spinning chuck is only used when the finished shell could not be removed from an ordinary form after spinning. After a shell has been spun over a sectional chuck, the shell and the sections of the chuck are together pulled lengthwise from the core of the chuck. Then, starting with the key section, it is an easy matter to remove each section from the inside of the shell. As the sections are removed, they are replaced upon the core, slipped under the

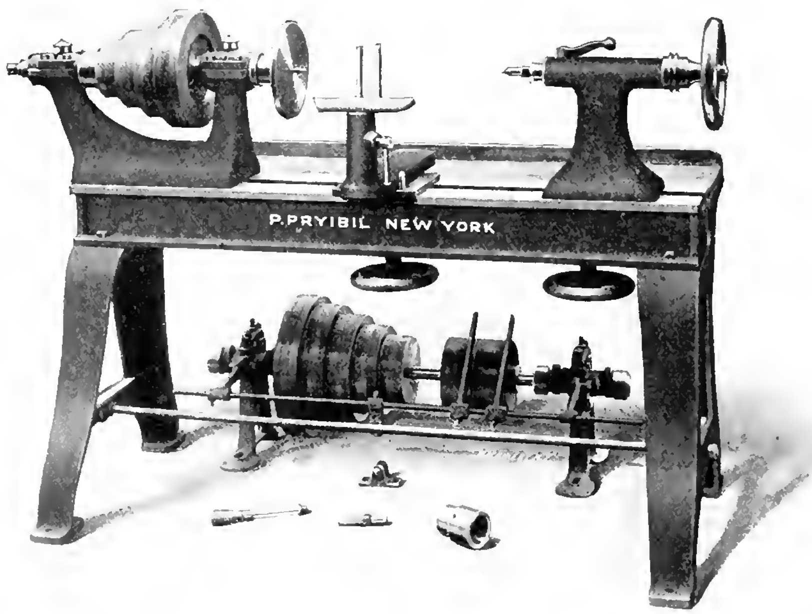

Fig. 2. Spinning Lathe

retaining flange and the chuck is ready for spinning a new shell. The whole operation of removing and replacing the sections of a chuck takes less time than it does to tell it, and, as the sections are of different sizes, it is easy to replace them in the proper order. Like other forms, sectional chucks are made of wood or metal, according to the requirements of the job. The core and retaining ring are first made from one piece and then the sections are turned in a continuous ring and split with a fine saw. In some cases it is necessary to add a small piece to the last section to make up for the stock lost in splitting the sections.

Another kind of sectional chuck, known to the trade as a "plug" (shown in Fig. 7) is used extensively in some shops in cases where the shell must have projections or shoulders at both ends, and no bottom to the shell is required. In making the plug, which is always in two parts, the first half is turned to take the shell from one end to the center of the smallest diameter. Into the end of this part is bored a hole to which is fitted the end of the second part, which is afterwards turned to fit the shell. Over this two-part plug the shell is spun; then the bottom of the shell is cut out and the first half of the plug removed thus allowing the shell to be withdrawn. The first part is then replaced and the plug is ready for use again. Fig. 6 shows a method of spinning difficult shells that ordinarily would require a sectional chuck. The shell shown at the left of Fig. 6 is first spun as far as the bulged part on an ordinary form that ends at this point. Then after annealing, it is replaced on the form and while another operator holds the wooden arm, supported with a pin in the T-rest, the spinner forms the metal around the bulge-shaped end of the arm. The arm, being stationary on the inside of the shell, acts as a continuation of the spinning form, and by this method as good a shell is obtained as could be spun with a sectional chuck.

For spinning operations upon tubing or press-drawn tubes, steel arbors are generally used. Tubing may be readily spun upon an arbor and it can be reduced or expanded to comply with the shape of shell required much more quickly than the shell could be spun from the blank.

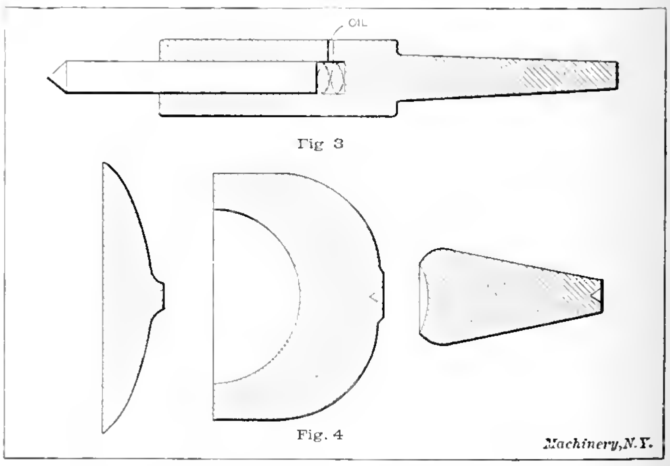
Followers

For holding the sheet metal blank to the spinning form, a block of wood known as the follower, is used (see Fig. 4). Followers are made to suit the shape of the work with which they are to be employed, always being made with the largest possible bearing on the work; thus a shell with a flat bottom twelve inches in diameter would be turned with the aid of a follower having an 11¾-inch face; while a shell with a 4-inch face would take a follower with a 3⅞-inch face. All shells do not have flat bottoms, consequently, in spinning such as do not, it becomes necessary to employ hollow followers. Hollow followers have their bearing surfaces turned out to fit the ends of the forms with which they are to be used. In practice, the blank is held against the end of the spherical form with a small flat follower until enough of the shell has been spun to admit of the hollow follower being used. All followers are made with a large center hole in one end to receive the revolving tail-center.

In starting to spin a difficult shell it sometimes happens that the necessarily small follower will not hold the blank. To prevent this slipping, the face of the follower is covered with emery cloth. Often, however, on rough work, the spinner will not stop to face the follower, but will make a large shallow dent at the center of the blank; the extra pressure required to force the metal against the form will usually overcome the slipping tendency.

Hand Tools

Hand tools, in great variety, form the principal asset of the spinner's kit. Spinning tools are made of tool steel forged to the required shapes, and are hardened and polished on the "business" end. The round steel from which they are made varies from ½ inch to 1½ inch in diameter, according to the class of work upon which they are to be used. The length of a spinning tool is about 2 feet, and it is fitted into a wooden handle 2 inches diameter and 18 inches long, making the total length of the handled tool about 3 feet, as shown in Fig. 8. As the spinner holds this handle under the right armpit, he



Figs. 3 and 4. Revolving Center and Three Types of Followers

secures a great leverage upon the work and is better able to supply the physical power required to bring the metal to the desired shape.

The commonest and by far the most useful of the spinning tools is the combination "point and ball" which together with a number of other tools, is shown in Fig. 10. This tool is used in doing the bulk of the spinning operations—for starting the work and bringing it approximately to the shape of the form. Its range of usefulness is large on account of the many differ-

ent shapes that may be utilized by merely turning the tool in a different direction. Next in importance comes the flat or smoothing tool which, as the name implies, is for smoothing the shell and finishing any rough surfaces left by the point and ball tool. The fishtail tool, so named from its shape, is used principally in flaring the end of a shell from the inside, "spinning on air" as it is sometimes termed. This tool is used to good advantage in any place where it is necessary to stretch the metal to any extent, and its thin rounding edge proves useful in setting the metal into corners and narrow grooves. Other tools are the ball tool which is adapted to finishing curves; the hook tool, used on inside work; and the beading tool which is needed in rolling over a bead at the edge of a shell when extra strength or a better finish is desired.

When much beading of one kind is being done, a large heavy pair of round-nose pliers (Fig. 11) with the jaws bent around

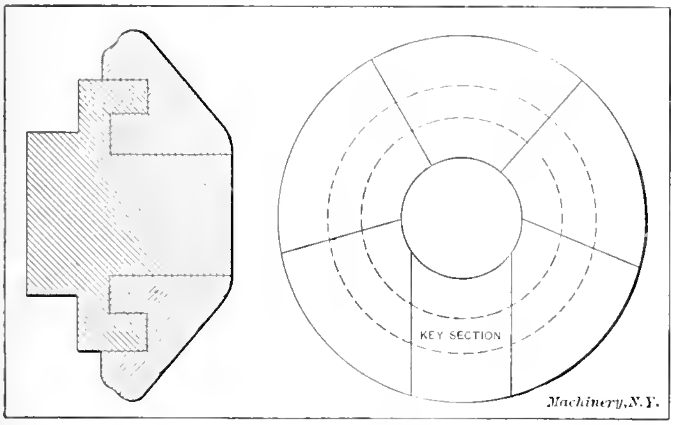


Fig. 5. Sectional Spinning Chuck

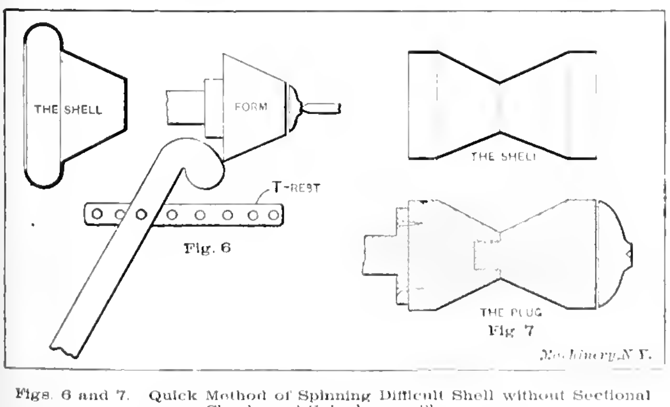
in a curve and sprung apart enough to allow for the thickness of the metal proves to be a handy tool. After the edge of the shell has been flared out to start the bead, the pliers are opened enough to admit the metal and then closed and the stock guided around to form the bead as far as possible. In this way the larger part of a bead is rapidly formed; one jaw of the plier acting as a spinning tool and the other corresponding to the back-stick. During this operation, the pliers are, of course, supported by being held against the T-rest.

Closely allied with these spinning tools are two other tools (also shown in Fig. 10) known as the diamond point and the skimmer. The diamond point is for trimming the edges of the shell during the spinning operation and for cutting out centers or other parts of the work. The skimmer is for cleaning up the surface of a shell, removing a small amount of metal in doing so, the amount depending upon the skill the spinner used in the spinning proper.

When the bottoms are to be cut from a large number of shells and it is necessary that they be cut exactly alike, a tool



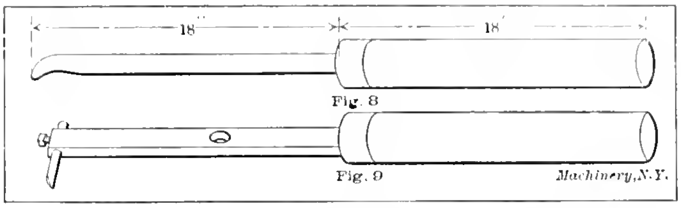
Figs. 6 and 7. Quick Method of Spinning Difficult Shell without Sectional Chuck, and Spinning on Plugs

known as a swivel cutter is used. This tool (see Fig. 9) is simply an iron bar with a cutter on one end, which swivels near the center around a pin in the T-rest; thus by a slight movement of the arm the cutter is brought up to the work, cutting a piece from the shell of exactly the same size each time.

The Spinning Operation

In order to make clear the successive steps in spinning, let us briefly consider the making of a copper head-light reflector, and the way the work is handled when a few hundred pieces are to be made.

By trial spinning, the size of the blank required for one of the reflectors is determined, and with the square shears the



Figs. 8 and 9. Handled Spinning Tool and Swivel Cutter

copper sheets are cut into pieces an eighth of an inch larger each way. These squares are then taken to the circular shears and cut to round shapes ready for the spinning lathe. The spinning form, of kiln dried maple, is screwed to the spindle and the belt thrown to that step of the cone pulley which will bring the speed nearest to 1,200 revolutions. From the stock room a follower is selected whose face will nearly cover the bottom of the form. It is now "up to" the spinner. Holding a blank and also the follower against the end of the form, he runs the tail-center up to the center in the follower just hard enough to hold the blank in place. Then, starting the lathe, he centers the blank by lightly pressing against its edge a hard wood stick. As soon as it "lines up" he runs the center up a little harder and clamps it in place. Some spinners will "hop in" a blank with the lathe running, but this is dangerous

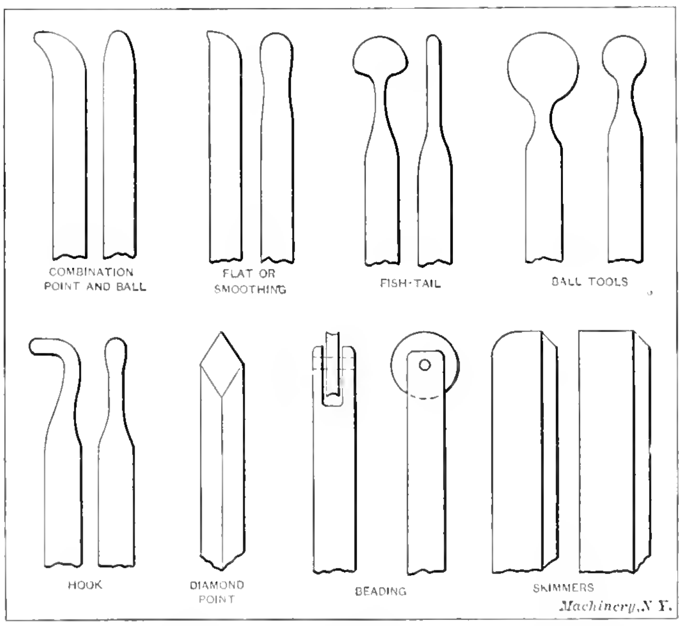


Fig. 10. Hand Tools of Various Forms used in Spinning

practice and sometimes the blank will go sailing across the room. Often this happens in truing up the blank and for this reason it is considered advisable to have a wire grating at the further side of the lathe to prevent serious accidents; for a sheet metal blank is a dangerous missile traveling at the high rate of speed which is imparted to it by the lathe.

With a piece of beeswax (soap is sometimes used for economical reasons) the spinner lightly rubs the rapidly revolving blank and then adjusts the pin in the T-rest to a point near enough to the blank to obtain a good leverage with the spinning tool. Holding the handle of his point and ball tool under his right armpit and using the tool as a lever and the pin on the rest as a fulcrum, he slowly forces the metal disk back in the direction of the body of the form; never allowing the tool to rest in one spot, but constantly working it in and out, applying the pressure on the way out to the edge of the disk and letting up as he comes back for a new stroke. In the meantime his left hand is busy holding a short piece of hard wood (called the back-stick), firmly against the reverse

side of the metal at a constantly changing point opposite the tool. The object of the back-stick is to keep the stock from wrinkling as it is stretched toward the edge of the disk. Wrinkles cause the metal to crack at the edges and for this reason they must be kept from the stock as much as possible.

After a few strokes of the spinning tool have been taken, the shell will appear about as shown at *B*, Fig. 12, and at this point, it is necessary to trim the shell at the edges with the diamond-point tool. Trimming is required because spinning stretches the stock and the resulting uneven edge will cause splits in the metal if it is not trimmed occasionally. As a carpenter is known by his chips, so a spinner is known by the way his work stretches. While the even pressure of a good spinner will stretch the stock very little, the uneven pressure of the inexperienced man will lead him into all sorts of trouble

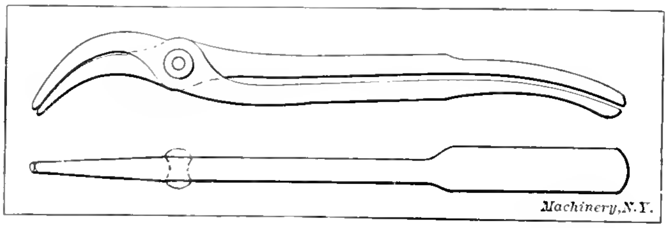

Fig. 11. Spinner's Pliers

on account of the way the stock will go. In either case the metal always stretches least in the direction in which the sheet stock was originally rolled, consequently giving the edge a slight oval shape. In trimming zinc, the spinner holds a "swab" of cloth just above the diamond point, to prevent the chips from flying into his face and eyes—or those of his neighbors. With other metals the swab is unnecessary.

The reflector is now taking shape. With each successive stroke the spinner sets a little more of the metal against the form. Not only does spinning stretch the metal, but it hardens it as well; therefore, at the stage *C* it becomes necessary to anneal the partially completed reflector, which is done by heating it to a low red in a gas furnace. In running through a lot of shells, the common practice is to spin them all as far as possible without annealing and after annealing the whole lot, to complete the spinning.

After replacing the shell upon the form, it is trimmed and worked further along the form, gradually assuming the ap-

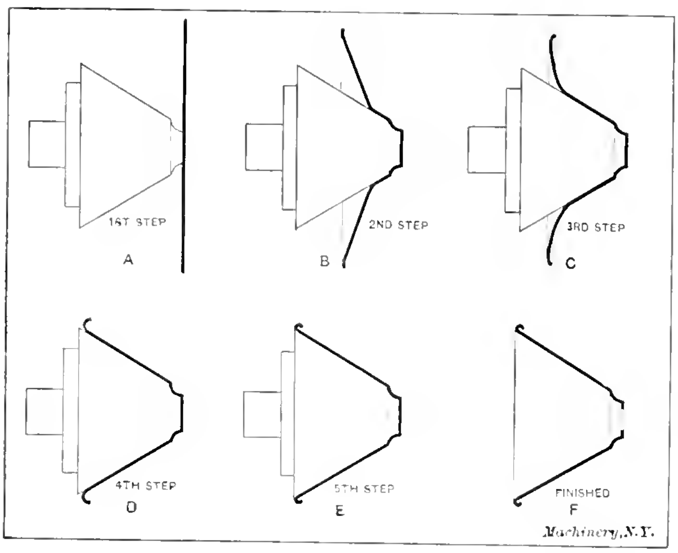

Fig. 12. Successive Steps in Spinning a Reflector

pearance shown at *D*. At this time, the spinner goes back to the small radius at the front end of the shell and with a ball tool he closes the annealed metal hard down against the form, for the spinning has tended to pull the stock slightly from the form at this point. The body of the reflector is now practically completed and the spinner directs his attention to rolling the bead at the outside edge. Slowly he begins to roll the edge of the shell back, using his hook tool to complete the bead as far as possible and exercising care to keep the back-stick firmly against the metal so as to keep the wrinkles out.

Now, with the diamond point, he gives the edges a final trim and with the beading tool closes down the bead snugly against the rest of the shell, as shown at *E*. Lastly, the swivel cutter is placed in the proper hole of the T-rest and a turn of the tool cuts out the center to the exact size, and the reflector is completed. If any burrs or rough places remain they are easily removed at this time with the skimmer or diamond point and a little emery cloth gives the shell a finished appearance.

Referring to the illustration Fig. 1, *A*, *B* and *C* represent the three most important stages of spinning a shell like that shown at *C*. Annealing is necessary between steps *A* and *B*. *D* is a shell spun upon a form of the plug variety, and *E* and *F* are two views of a shell spun after the method shown in Fig. 6, *F* being the completed shell. *G* illustrates a very difficult shell to spin, on account of the small follower that must be used; the length of the small diameter also adds to the difficulty. *H* shows a shell that must be spun upon a sectional chuck, while *I* is a plain easy job of ornamental spinning. The ball shown at *J* was spun from one piece of aluminum and it is more of a curiosity than a specimen of practical spinning. It was first spun over a form that would leave one-half of the ball complete and the stock for the other half straight out like a short tube. Next a wooden split chuck was made, hollowed out to receive the finished end of the ball and the open end was gradually spun down and in until the ball was complete with but a 1/16-inch hole at the finish. This hole was plugged and the hollow ball was done.

While the operation of spinning is a comparatively simple one to describe, it is not easily learned, and to-day good all-around spinners are hard to find. The limits of accuracy are not as closely defined as in straight machine work, but there are times when good fits are absolutely necessary, as in cases where two shells must slip snugly together. In this article we have taken up only the plain every-day kind of spinning, and were we to follow its work in the gold and silversmith's trade, we would see it evolve into a fine art. In order to insure really good work coming from the spinning lathe, there is a wide range of knowledge that the spinner must have. That knowledge may be brought together and summed up by a single word—*judgment*.

* * *

A STEAM BOILER INCIDENT

Seventeen years ago an enterprising farmer living near Boston purchased a portable steam pump to water his farm. Every summer he has had one of the young men in the neighborhood run it, under the supervision of Mike, the foreman, whose word was law. This summer the boiler leaked so badly that the facts came to my attention. The boiler tubes became so overheated and loosened that there was not a single one which was tight. In former years when they leaked badly, Mike, with a hammer and chisel, would calk them until they were fairly tight. Several years ago the steam gage was stolen, and since that time the "engineer" estimated the pressure by the rate the pump worked with the throttle wide open. How he estimated it when the pump was not working was not made clear to me. The water used in the boiler was the same as that used in the pump, and it came from a dirty frog pond. Small fish and eel grass were continually thrown out of the discharge nozzle of the pump and the natural inference was that they were just as frequently thrown into the boiler. The water glass was so dirty that even if there had been any water in it it could not have been seen; as Mike explained, "It was so stuck up with mud that you couldn't ever depend on it."

Once (long ago) Mike opened a hand hole to clean out the boiler, but as he said, "there was such a mess in there that it would have taken a whole day to clean it out, and what was the use, since it was running all right as it was"—and the mud stayed in there. In all these seventeen years no repairs have been made to the boiler, it has never been inspected, the inside has never been cleaned, its safety valve and steam gage (when it had one) have never been tested, and it has never had anyone with a license to run it. In spite of all this, the owner refuses to have any repairs made, saying that "It isn't worth it, and as long as it will pump water, let it alone and don't fool with it." E. M. S.

MANUFACTURING AUTOMOBILE EQUALIZING GEARS*

A TYPICAL EXAMPLE OF GOOD DESIGN AND SHOP PRACTICE

RALPH E. FLANDERS†

There is always some question in the mind of the editor as to the interest of his readers in descriptions of typical shop operations. There are occasional operations of particular interest owing to the accuracy required, the novel principles employed, or unusual difficulties to be overcome; about such material there is no doubt. This present article, on the other hand, deals with operations which do not present these unusual or spectacular features, yet the writer feels that they have a value derived from the fact that they are closely related to the operations which produce the bulk of the product of the machine shops of the country; for that reason they should attract the attention of mechanics interested in accurate and economical work. In the particular case with which this article deals, we are able to describe and adequately illustrate the operations from beginning to end, for making a complete, compact machine unit—a differential or equalizing gear for automobile use. The completeness of the job gives it a suggestive value that would not be offered by a series of miscellaneous operations, however interesting. The value of this description, however, does not depend on its completeness

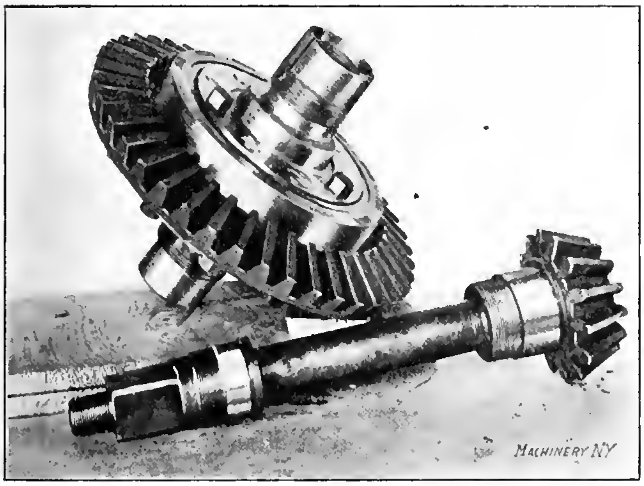

Fig. 1. The Equalizing Gear Complete, with Bevel Gear and Pinion, as used in the Stevens-Duryea Automobile

alone, as many of the specific shop operations give evidence of a high degree of manufacturing ability.

Description of the Equalizing Gear

Figs. 1, 2 and 3 show assembled, dismantled and detail views, respectively, of an equalizing or differential gear, designed by Mr. A. A. Fuller, of the Providence Engineering Works, Providence, R. I. The determining feature of this design is the necessity for getting a maximum of strength and effectiveness in a minimum of space—coupled, of course, with reasonable cost of manufacture. This problem was attacked by scientific analysis. It was possible, without great difficulty, to obtain reasonable strength in the casing which contains the equalizing gearing. The crucial point was in the design of the equalizing gears themselves. In determining the proportions of the gears, curves were drawn showing the strength of the teeth for lay-outs of varying pitch and number of teeth, arranged to be contained within a casing of a given diameter. The strength and bearing area of the pivots, and the strength of the pinions as limited by the thickness of the shell between the bottom of the tooth and the bore, had also to be reckoned with. The tooth shapes were not confined to standard forms, but various pressure angles and heights of addendum were investigated. By comparing the curves for various possible designs, a certain pitch, number of teeth and shape of tooth for the various gears were found for each diameter of casing, so proportioned that if any of the dimensions were changed, the mechanism became weaker instead of stronger. These proportions, worked into a design satisfactory in other particulars, have been adopted as standard, and the makers feel confident that it is impossible to enclose in the same space gears of greater strength than they are offering in the design illustrated herewith. As this confidence is based on mathematical calculations and has been further tested by many months of experience, it seems reasonable that they should hold to it.

Referring particularly to Fig. 3, the mechanism is contained within case *B* and covers *A* and *A'*. It revolves in the rear

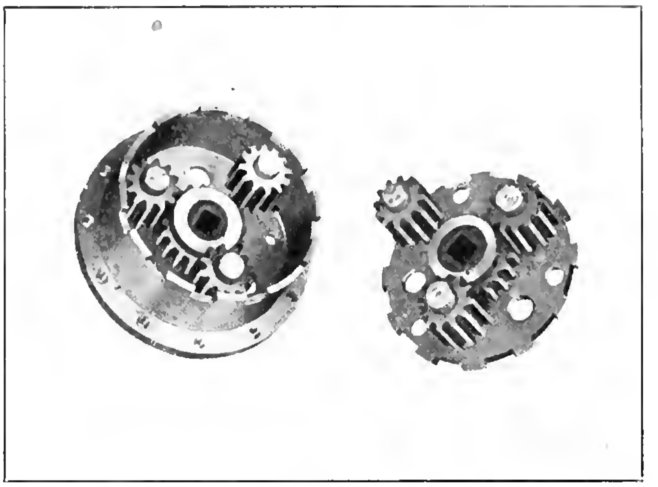

Fig. 2. A Small Size of Equalizing Gear Dismantled to show Construction

axle gear casing on ball bearings, mounted at the ends of casings *A* and *A'*, and the driving bevel gear is carried on the periphery of case *B*, to which it is clamped by hex-head screws *H*. The pivots *E* are riveted into the flanges of covers *A* and *A'*, three in one side and three in the other. These pivots carry pinions *F* and *F'* meshing with gears *C* and *C'*; the latter run in bronze bushings *D* and *D'* forced into the two covers, and are provided with broached square holes by which the floating wheel shafts are driven. As will be seen in Fig. 2 in connection with Fig. 3, gear *C* meshes with pinion *F'*, which also meshes with pinion *F*, the latter in turn engaging gear *C'*. Thus, when gear *C* is turned, gear *C'* is revolved in the opposite direction, and *vice versa*, thus forming a spur gear differential mechanism.

Attention may be called to some of the features which make for strength in this design. It will be seen, for instance, that

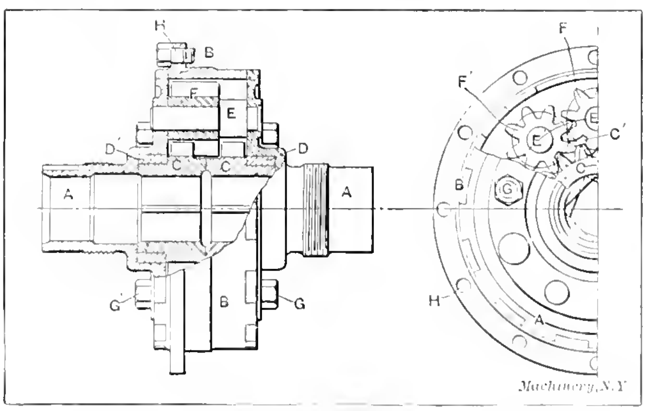

Fig 3 Details of Construction of the 7-inch Equalizing Gear

the gears have teeth of special shape and of very coarse pitch and few numbers of teeth. The pinions have eight teeth and the gears sixteen each. In designing the mechanism by analysis, as described, it was found that this construction was necessary for strength. Older designs of this kind, more commonly met with, in which the pinions are smaller in proportion to the gears, have repeatedly proved their weakness by breakage.

Mention should also be made of the solid way in which the parts composing the casing are fastened together. The casing *B* is provided with tongues locking into the grooves cut in covers *A*, so that the strain of transmission is taken on these interlocking members and does not depend on the bolts, dowel pins or similar parts. So far as this torsional strain is con-

* For further description of this type of differential gearing, see October number of MACHINERY, page 84, engineering edition.

† Associate Editor of MACHINERY.

cerned, the casing is as strong as if it were made of solid metal—an impossible construction, of course. Through bolts and nuts G and G' clamp the whole casing firmly together.

The proper meshing of the bevel gears can be controlled by shifting the whole casing axially in its bearings. Nuts are mounted, for this purpose, one on the threaded diameter of A and the other at the same point on A'. By loosening one and tightening the other the teeth of the gears can be brought more closely into contact, or *vice versa*.

The provisions for oiling should be noted. The casing in the rear axle is provided with a bath of oil in which the bevel gears run. Three holes cut in the exterior of B (not shown in Fig. 2, but visible in the detail views of the operations in Fig. 4, and at the right of Fig. 5, where these holes are being drilled) admit oil from this bath into the interior spur gears. Pivots E and pinions F are grooved, as are also gears C and C', permitting a flow of oil through the whole structure, kept in constant motion through the revolving of the parts.

In describing the manufacture of this device we will take up each part in turn. The manufacture of the bevel gears will not be described in detail, as their design is determined

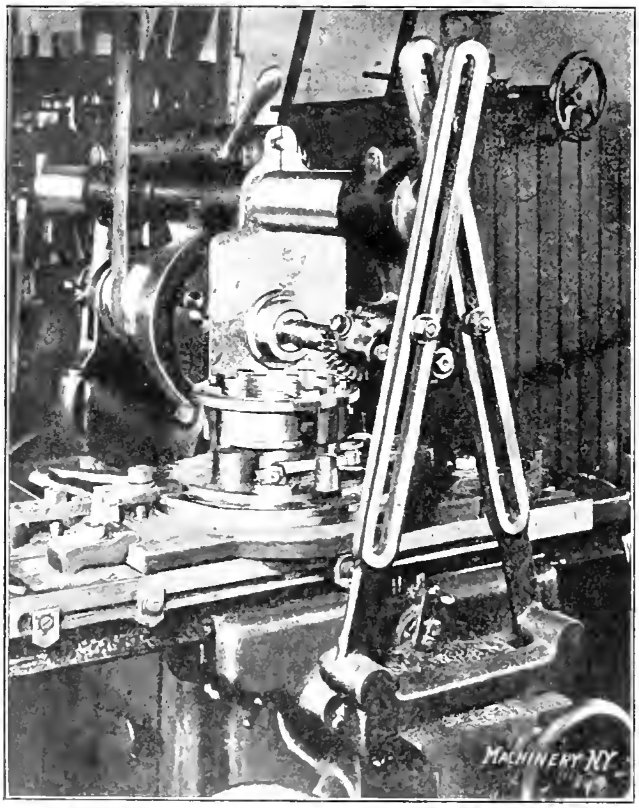

Fig. 4. Milling the Driving Tongues in the Gear Case—Second Operation

by the maker of the car in which the device is to be installed. The first part to be considered will be the gear case, shown at B in Fig. 3.

Operations in the Manufacture of the Gear Case

The case is made from a malleable iron casting on which the first operation, naturally, is that of snagging to remove fins, gates, etc. The second operation is performed in the Jones & Lamson flat turret lathe, of which large use is made in this shop. The casting is placed in the chuck of the machine with the flange outward. In this operation the hole is finished to size, the flange is turned, and the projecting end is faced. The regular equipment is used for this purpose, the only special tools being gages for the inside diameter of the hole and the outside diameter of the flange.

In the third operation, performed in the same machine, the part is grasped by the finished flange in special soft chuck jaws, which have been turned in place to fit the diameter they are to receive. This gives assurance that the work done in this operation will be true, within reasonable limits, with the cuts previously taken. Regular flat turret lathe equipment is used for this operation as well, suitable gages of simple construction being provided. The next operation, shown at the right of Fig. 5, is drilling the three holes which admit oil to the interior of the case. This jig is of the simplest possible construction, consisting of a knee with a turned seat on which the work is placed, and an overhanging lug carrying a drill bushing. A clamp provides for holding the work, and a plug, entering a suitably located hole in the seat, provides means for indexing the second and third holes drilled, from the one previously completed. The other operation shown in this engraving will be described later on.

The tongues which interlock with the grooves in covers A, A' (see Fig. 3) have next to be milled. The fixture for doing this is shown in use in Fig. 4. It consists of a base provided with an index plate and a revolving table, by means of which

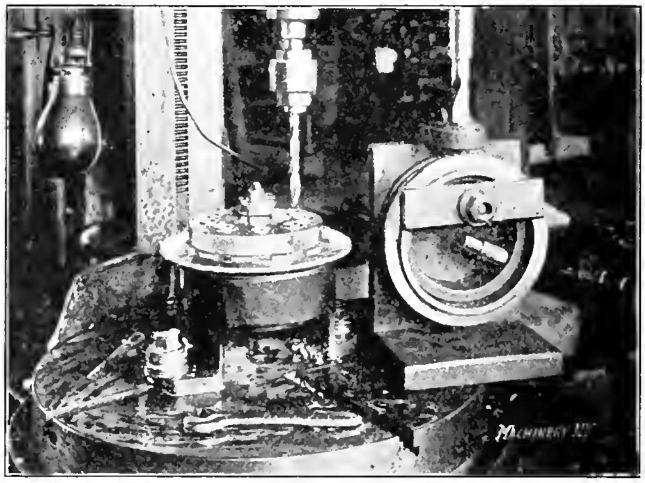

Fig. 5. Drilling the Three Oil Supply Holes in the Case (see Fixture at the Right), and Drilling the Bolt and Pivot Holes in the Cover

the work may be indexed step by step to cut the various tongues. These are shaped by straddle mills which form the opposite sides of the tongues parallel, so that they fit into corresponding grooves milled into the covers by a straight-sided cutter. In the operation illustrated, tongues have been cut on one side of the casing, which is located in its seat in the fixture by the interlocking of these tongues with grooves provided to receive them as shown. This assures alignment of the cuts on each edge of the case. In the first operation the uncut edge of the work is simply set down onto this seat. It is held down by three clamps, provided with noses which enter

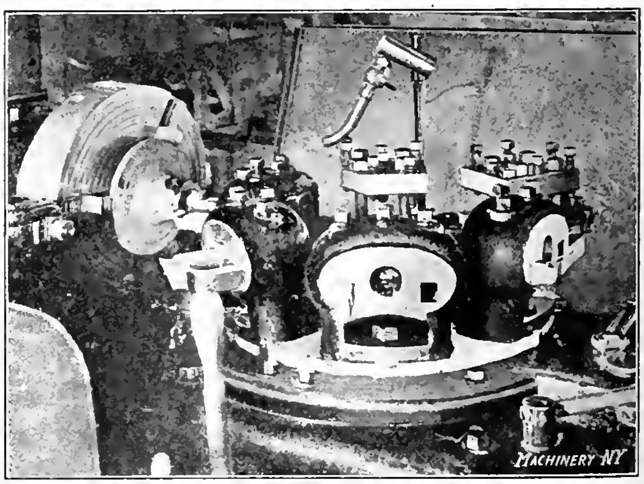

Fig. 6. The First Turret Lathe Operation in Finishing the Gear Case Covers

the three holes drilled to admit oil to the interior of the mechanism.

It is interesting to see the expertness with which the operator cuts out these tongues. The automatic feed is set at the highest point practicable when cutting the full depth. As this would be less than the maximum possible when the cutter is entering the work, he begins with a hand-feed at a considerably higher rate, throwing in the automatic feed when the cutter gets down to work. Although the machine is of modern construction, the workman was feeding it all the belt could handle, and was evidently then not satisfied with its performance, as he was engaged in tightening up both the countershaft and driving belts during the time of the writer's visit.

The gear casing is now complete except for certain operations performed on it in assembling, as described later.

Operations on the Gear Case Cover

The gear case covers are made from machine steel drop forgings. After the snagging, the first operation is the simple one of putting a 1½-inch hole through the center of the forgings. This is a drill press operation and is merely done to remove stock, it being, of course, impracticable to form the hole in the forging. It is next clamped by the rim with the hub projecting, in the chuck of the flat turret lathe. This first turret lathe operation is shown in Figs. 6 and 7, the latter diagram indicating the arrangement of the tools.

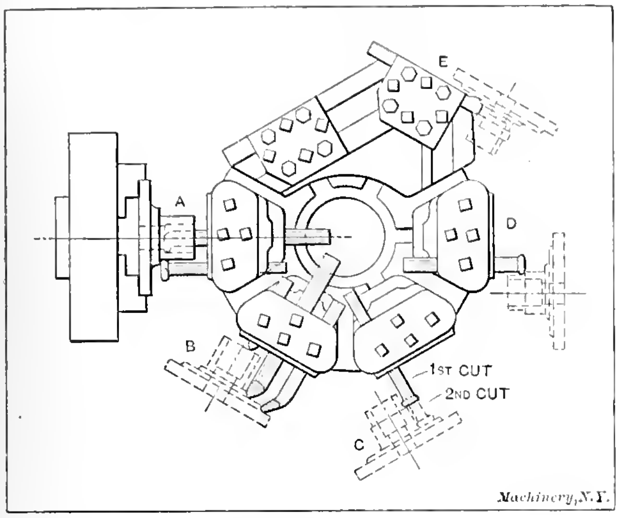

Fig. 7. Lay-out of Tools on the Flat Turret Lathe for the Operation shown in Fig. 6

The first cut is shown at *A*. An outside turning and boring tool, acting in conjunction, rough turns the hub and rough bores the hole. At the next station, *B*, three tools simultaneously face the end of the hub and the two surfaces of the flange. Two cuts are taken with these, one for roughing and one for finishing. A third cut is taken with the same tools fed axially against the work to form the two grooves in the face of the flange, as most plainly shown in Fig. 3. At the third station *C*, another turning tool removes the stock on two diameters of the hub, two cuts being taken. At *D* a finishing cut is taken over the smaller diameter, while at *E* a form tool shapes that portion of the hub extending from the threaded diameter to the flange. This operation is completed in about 18 minutes.

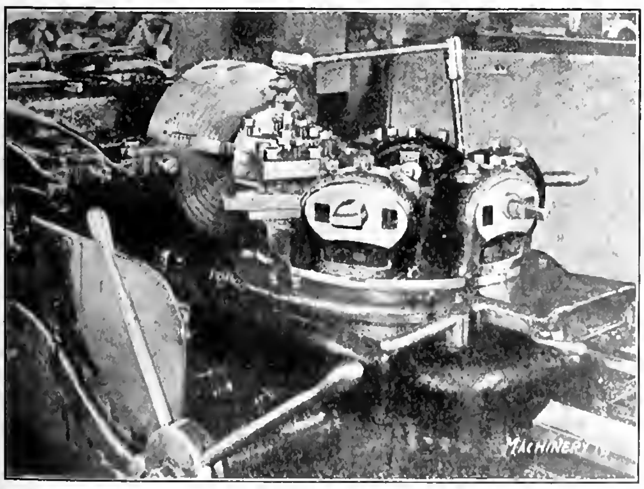

Fig. 8. Second Operation on the Flat Turret Lathe, using Special Jaws

In the second operation (see Figs. 8 and 9) the completed end of the piece is grasped in soft jaws turned to fit the surface they grasp, assuring true running of the surfaces made in the two operations. The tool at *A* bores out the large diameter of the hole, which is for clearance only. The reamer at *B* finishes the small diameter to size. The tool at *C* faces the flange, taking two cuts, one to rough out stock and the second to bring it to size. A flat-nosed tool at *D* finishes the flange. The tool at *E* roughs out the counterbore, while that at *F* finishes it. This latter tool is fed directly in, boring the diameter of the counterbore to size until the bottom is reached, when the sliding head is fed outward, so that the same tool faces the bottom of the counterbore. The finishing is thus done by turning cuts instead of forming cuts, giving a higher degree of accuracy. Work of this kind shows the flat turret lathe to very good advantage. In the lay-out of tools shown in Figs. 7 and 9, there were probably no special tools of any kind required, with the exception of the form tool *E*, the rest being stock turning tools of the kind which forms the regular equipment of the machine. It may, have been necessary in some cases to give the tool a knock of the hammer on the blacksmith's anvil to crook it in one direction or the other, but nothing more would be needed. The cross sliding head and the multiple stops come into play in such operations as those at *B* and *C* in Fig. 7, and *F* in Fig. 9, giving each separate tool a wide range of usefulness, especially when it is so made that it can be used for both turning and facing jobs.

Hand vs. Automatic Machines

Of course there are all sorts of opinions about such matters, but in the question of hand versus automatic machines, this company believes that the conditions favor the use of the hand turret lathe in its work. The simplicity of the tooling is an important factor on contract work. The management can never be sure of the long continuance of any job, so that anything approaching costliness or elaboration is prohibited. Furthermore, it is reasonably certain that one hand machine will turn out more work than one automatic, particularly when, as in this shop, there is an inducement, such as the premium system, for the workman to get the most possible out of his machine. He is constantly changing his feeds and speeds as the varying diameters, depths of the cut and condition of the tool require. He is thus able to take heavier cuts without injuring his cutting edges than would be possible without constant personal supervision. Probably three or four changes are made in each operation to one that would be made by an automatic machine. As another advantage, this greater production of the machine means a much less capital outlay per dollar of output.

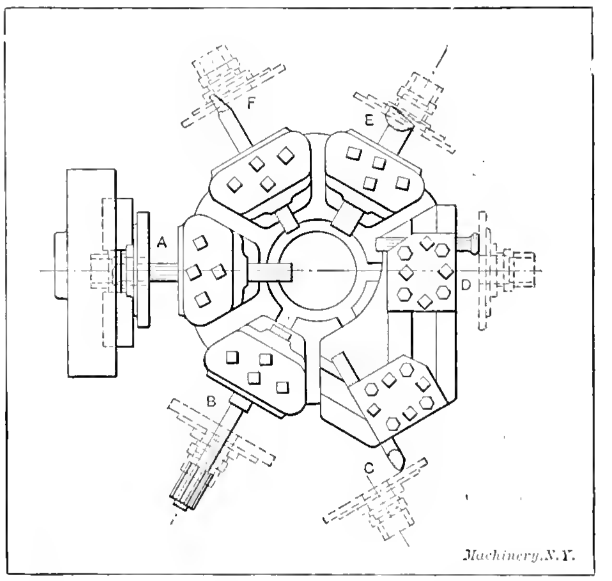

Fig. 9. Lay-out of Tools in the Operation shown in Fig. 8

It certainly does keep the operator busy to get the most out of one of these lathes. There is no possibility of his running more than one machine, on this particular work at least. Cuts are taken very rapidly and changes of feed and speed follow each other in constant succession. There is a line of demarkation at the point where the intensity of production on the part of the hand machine and the lower capital charge on machines, buildings, stock, etc., balance the higher output per man and the consequent lessened labor cost for the automatic machines. In accordance with their judgment, some shop managers will draw the line at one point and some at another. It is fortunate for the builders of both types that all men do not come to the same conclusion when reasoning from the same premises.

Gear Case Covers—Continued

In Fig. 10 the milling machine is shown rigged up to cut the driving slots in a pair of the gear case covers. The two are mounted together face to face on a special iron arbor, having a driving tail cast integrally with it in place of the usual separate dog. A formed cutter is used which shapes the bottom of the slot to the true radius of the inside diameter of the casing B (see Figs. 3 and 4) assuring a tight fit. This operation and that shown in Fig. 4 have to be done to close limits with good indexing plates, only 0.001 inch variation being allowed on the thickness of the slot and the tongue. This means that in order to make a good fit the dividing must be very accurate. In the cases the writer saw assembled, these parts drove together with a very little gentle urging from a lead hammer. Not much of anything else seemed to be required. In Fig. 11 is shown a jig for drilling the bolt and pivot holes in the gear covers. It is of simple construction, the cover being supported on four legs and located by a central spindle over which it is dropped and by which it is clamped, an open side collar and nut being used as shown. The bushing plate set over the work is located to bring the

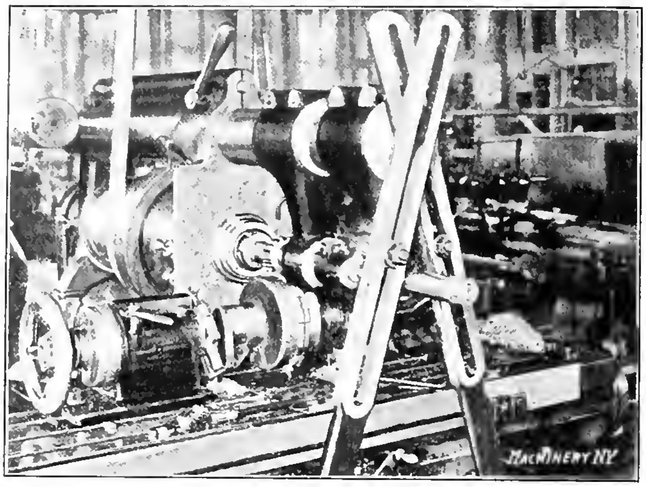

Fig 10. Milling the Driving Slots in a Pair of Gear Case Covers

holes in right relation with the slots, by a tongue entering the latter. In the next operation the covers are mounted on a special face-plate, as shown in Fig. 12. This face-plate is surfaced true in place and is provided with an expansion mandrel centered integrally with it. The gear case is slipped on over this mandrel and tightened in place by turning on a wedge screw. While thus held the countersink in the outer end of the hub, the seat for the ball bearing, and the threaded diameter are turned. The thread is also cut. This is done by the Rivett-Dock threading tool, shown in operation. These

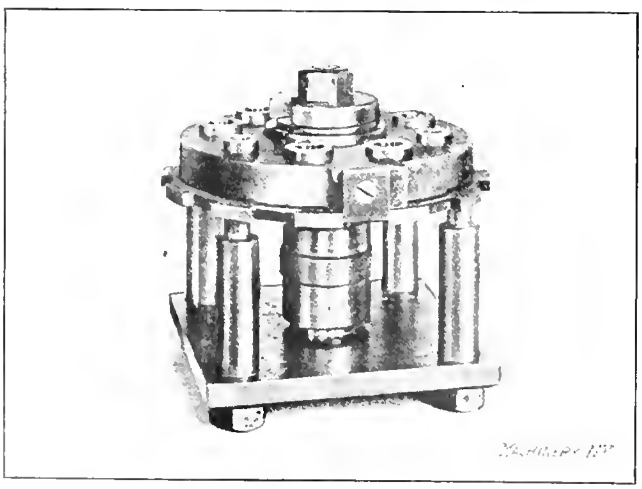

Fig 11. Jig for Drilling the Bolt and Pivot Holes in the Gear Case Covers. Another Jig for the Same Operation is shown at the Left of Fig 5

operations of countersinking, turning and threading, altogether, average about eight minutes time for each piece. When the turning was in progress, the writer timed the lathe and found it was making 250 revolutions per minute, which gives about 150 surface feet per minute for the cutting speed.

A fixture and mill of obvious construction are used for cutting the keyway by which the inner race of the ball bearing is made fast to the hub.

Equalizing Pinions, Studs and Gears

The studs E are made on the Gridley automatic turret lathe with the regular tools and equipment, the job being, of course, one of the everyday variety for this machine. Oil grooves are milled, and then the burrs are removed by hand. The

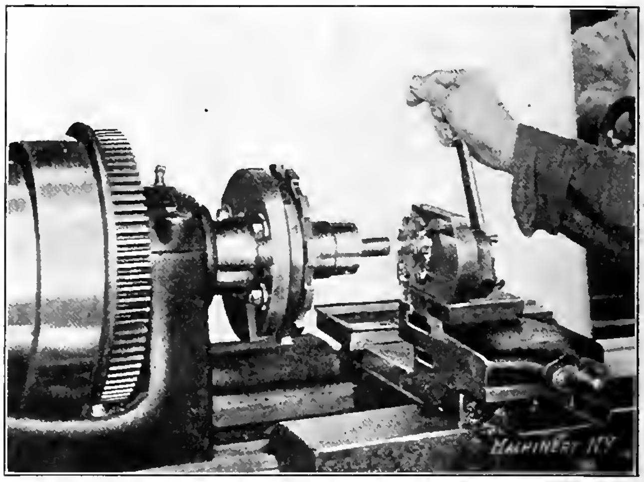

Fig. 12. Threading the Gear Case Covers with a Rivett-Dock Threading Tool

equalizing pinions are drilled, reamed and turned on the flat turret lathe. The ends are squared accurately to length in the engine lathe.

The equalizing gears are cut off to length from the bar stock (all gears and pinions are made of chrome nickel steel) and are bored, reamed, faced and filleted at the large end in the Jones & Lamson machine. The hole is reamed accurately to size so as to furnish a guide for the broach in forming a square hole. This is done on the La Pointe machine at a

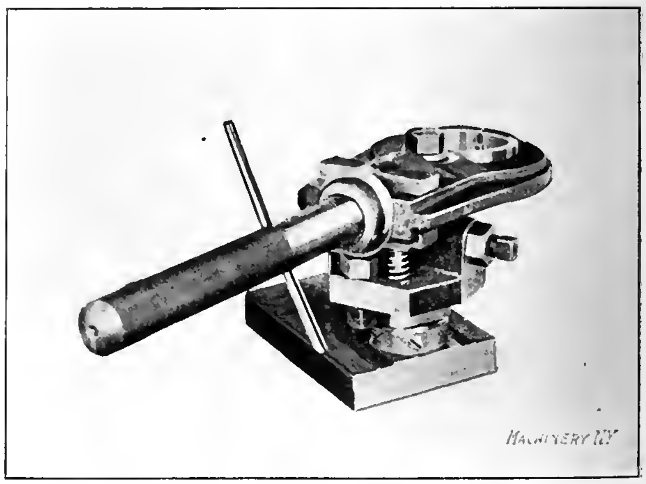

Fig. 13. A Special Fixture for Cutting Oil Grooves in the Equalizing Gear Bushing

single pass of the broach, which is a long one, having some 24 inches or thereabouts of cutting length. The outside surfaces of the gear are then rough turned on a square expansion chuck somewhat similar to that shown in Fig. 12 for the gear case cover, except, of course, that it is mounted on a square surface instead of a round one. In the next operation it is finish turned all over.

The spur gears and pinions are cut in a triple head indexing device which is one of the standard attachments on the Brown & Sharpe milling machine. Three cutters operate on three gangs of work simultaneously. By giving special shapes to the gears and by being very careful both in centering the cutters and setting them to the proper depth, first-class results have been obtained—better than are needed in fact, since normally these gears are stationary or nearly so, being in operation only when rounding corners, in the case of a deflated tire on one side, or the slipping of a wheel in the mud. After removing the burrs by file and reamer, the gears and pinions are hardened by the regular process recommended by the makers of the steel (the Carpenter Steel Co.), with

such modifications as the blacksmith of the shop has found advisable.

The equalizing gear bushings *D* and *D'* are cut out from a bronze bar in the flat turret lathe, being turned and bored complete to size. A stack of them are placed on the Mitts & Merrill keyseater for cutting the internal oil grooves. The radial oil groove is cut on the interesting tool shown in Fig. 13. This device is a modification of the principle used in attachments for slotting screws with a saw held in the speed lathe. The knurled handle shown controls three motions. By screwing it in or out the bushing is tightened or released in the jaws by which it is held. Tripping it up or down drops the bushing away from or brings it up toward the revolving cutter, while springing it to one side brings the bushing out from under the cutter where it can be removed without interference. A wire finger locates the work with relation to the internal groove previously cut.

Assembling

The operation of assembling the parts to make the complete mechanism includes some operations worthy of notice. In Fig. 14 is a case assembled with its two covers and dropped into a cast-iron reaming stand, where it is held from revolving by the projecting pin shown, which enters one of the three

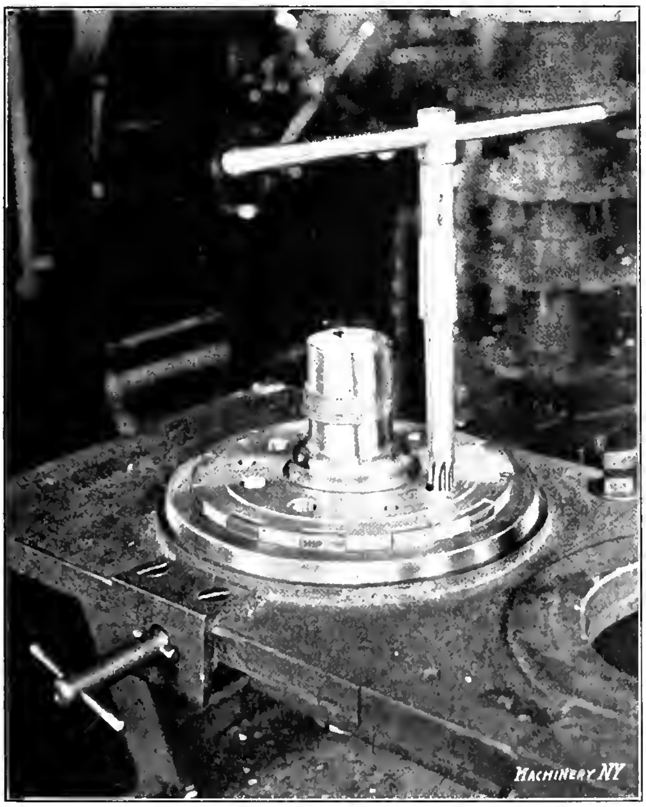

Fig. 14. Line-reaming the Pivot Holes in the Assembled Gear Cases and Covers

holes in its periphery. A line reamer is used, giving assurance that the two bearings in each cover will be true with each other. After this line reaming the covers are marked, numbered and burred so that the same parts will be reassembled together.

Studs *E* are next riveted to the covers, three on one side and three on the other, a hand hammer being used for this purpose. The ends of the rivets are cupped to facilitate this operation. The pinions are assembled on the studs, three on each side. The bushings are pressed into the covers under the arbor press, and burred. The equalizing gears *C* and *C'* are dropped into place and the whole structure is then assembled. A square wrench inserted through the bore into the squared hole in *C*, permits the gears to turn until they are all engaged. Three bolts and nuts *G* and *G'* are now passed through, binding the whole solidly together.

It is of extreme importance in the quiet running of an automobile that the bevel gears run true. For this purpose the bevel gear seat on the outside diameter of the casing is not finish turned until it has been assembled as described. To do this, the mechanism is mounted on the lathe on large centers, bearing on the countersinks in *A* and *A'*. These countersinks, being formed in the same operation with the ball bearing seats and the threads, are true with them. After this turning and facing, a jig fitting on this accurate seat is used for drilling the flange holes through which screws *H* pass to fasten the bevel gear to the casing.

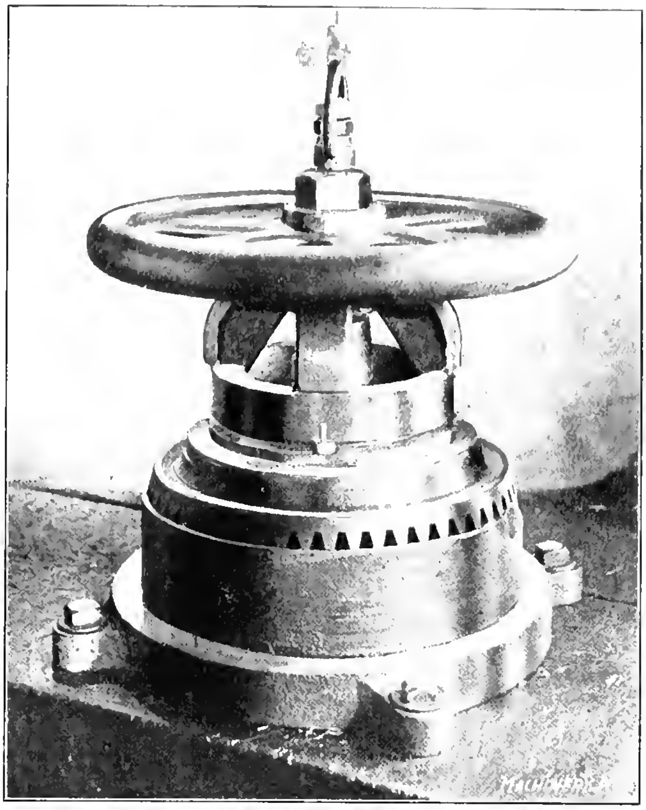

Fig. 15. A Convenient Fixture for Assembling the Gears on the Gear Case

The gear is pressed into place in its seat by a simple contrivance which illustrates the demand for conveniences created by the premium system. On the bench in front of the

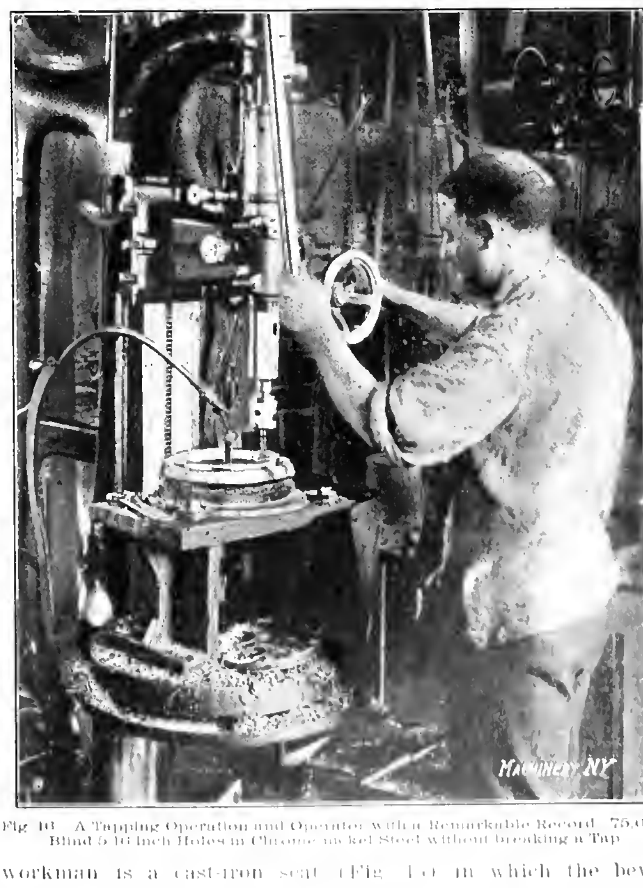

Fig. 16. A Tapping Operation and Operator with a Remarkable Record: 75,000 Blind 5/16 Inch Holes in Chrome-nickel Steel without breaking a Tap

workman is a cast-iron seat (Fig. 15) in which the bevel gear is placed face downward. The complete differential mechanism is then placed over the gear in a position to be forced down into it. The workman now reaches up above his head and brings down the hand wheel, clamping screw and clamp

shown, which is suspended by a counterweight so as to move freely up and down and remain stationary in any position. Entering the screw in the nut in the base of the device and turning the hand-wheel, forces the casing down into the gear and thus completes the assembling. The tap bolts are now put in and are wired through holes drilled through their heads, to prevent them from turning. This completes the making of the equalizing gear.

A Good Tapping Record

While the making of the bevel gear has not been described, it will not do to pass over one of the operations met with. This is the operation of tapping the holes by which the gear is held to the flange. These holes are 5/16 inch in diameter and 13/16 inch deep and are blind, being tapped to a bottom and not through. The tapping is done in a Cincinnati drill press (Fig. 16), using an Errington friction chuck. Tapping in chrome-nickel steel by power is, it will be agreed, no "fool of a job." One of the difficulties met with is the tendency of the metal to seize the tap and break it when backing out.

The operator shown broke many taps in becoming familiar with his job, but since he has gotten into the swing of it, he has tapped 75,000 of these blind holes in chrome-nickel steel without breaking a tap. The credit for this record must be divided between the man, the machine, the chuck and the tap, but there is enough to make a respectable showing for all four. It may be remarked that, in accordance with the well-known total depravity of inanimate things, the workman had the misfortune to break a tap a few minutes after the conversation in which I learned his record. His increase of effectiveness was obtained with practically no change in the tools or methods, being due simply to the training of his judgment in the feeling of the tap, and in the use of excellent tools. It might be said that a firm of the highest reputation for accuracy and for skill in manufacturing, had asked ten cents a hole for the job. This operator runs two taps in each of the twelve holes in a gear, twenty-four holes in all, in from 15 to 18 minutes.

Tests on the Finished Casings

Of course, the object that was aimed at in designing these equalizing gears for sale to manufacturers of automobiles, was to give them such strength that some other part of the machine would break first. In order to find out whether or no this result had been obtained a number of tests were made in the laboratory of the engineering school of Brown University.

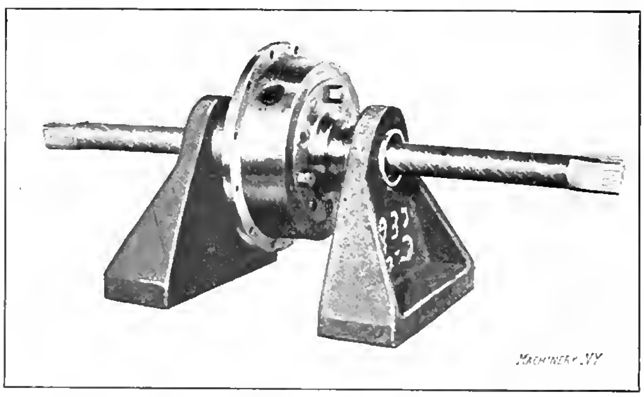

Fig. 17. A Completed Equalizing Gear, Set up for Testing to Destruction by Torsional Stress

In Fig. 17 the casing is shown as mounted in brackets for a torsion test, the power being applied through 1-inch, 3½ per cent nickel steel shafts specially treated. These failed at 20,300 inch-pounds, twisting through 800 degrees before rupture. Samples of broken shafts are shown in Fig. 18, and give some idea, in combination with the figures just given, of the excellence of the material used in these shafts. No damage of any kind was found inside the gear casing, the mechanism being unbroken and running as easily and smoothly as before.

The Providence Engineering Works feels perfectly confident in offering these equalizing gears to automobile manufacturers, after its experience with them in the laboratory, and their trial in the road conditions met with by the thousands which have been placed on the market.

EXPERIENCES OF A YOUNG TOOL-MAKER

T. COVEY

After Jim had completed his end mills ready for the hardening operation (as described in the August number), he turned them in and was given stock for some spiral surfacing mills, with instructions to make them like a sample given him, and to ream the holes 0.005 inch small so as to leave stock to grind out after the mills were hardened. He proceeded to chuck the pieces in a lathe and face one end and bore the holes. When a 1⅛-inch hole had been bored about an inch deep in the first piece, Jim began to have trouble. The steel was hard and tough, and the drill, which was somewhat worn, though apparently sharp, would not cut. Instead it would screech and stick until it stopped the lathe. After many efforts in grinding the drill and trying different speeds, he finally remarked to a man by the name of Anderson who was working on a machine near him, that that was the worst stuff he had ever tried to drill.

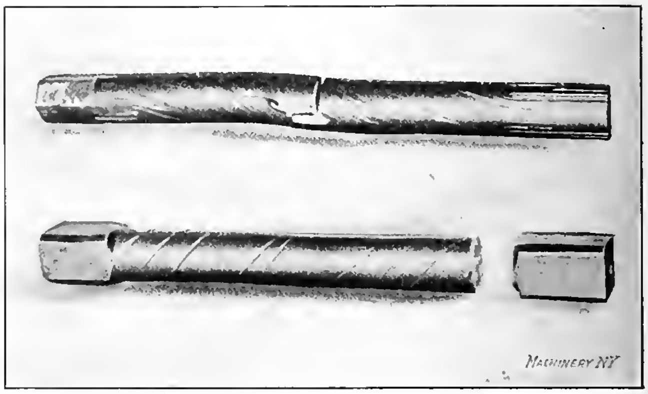

Fig 18. Condition of Shafts Broken in Tests shown in Fig. 17; the Gears were Uninjured

"What is the matter with it?" Anderson asked.

"That's what I would like to know; I can't get a drill to cut it," said Jim.

"Let's see your drill. Is that the best one you could get?"

"Yes. The boy at the window said the rest of that size were out. I guess he thought that was good enough for a kid to use anyway."

"Well, the clearance is gone for an inch at least. Do you know that you can grind a drill so that it will cut a hole larger than itself?"

"I never noticed it in particular."

"Well you can. You just grind one cutting edge longer than the other, so that the point is off center and the drill will cut large.

"I ground it on the drill-grinder and supposed it was all right."

"It probably would be if it was a good drill. Get a boring tool and bore out that hole as far as you have gone with the drill, at least a thirty-second of an inch larger and I will fix this drill so that it will work."

Jim got a tool and bored out the hole. When Anderson came back and handed Jim the drill he said, "There, that will cut large, and in that way it will have clearance on one side. Of course it can't bind much unless both sides rub. I think you will have no trouble in getting it to drill those pieces. I don't say that it is good practice to grind drills that way; a drill properly made and in good condition will clear itself and drill a hole to size, but when a drill is worn out it is no good, and for that reason you could not spoil it. It is a question, however, whether grinding a good drill off center would spoil it or not. Now if you are not accustomed to working tool steel, I can give you a pointer that may save you trouble. When you wish to ream a hole in tool steel, leave more stock for the reamer to cut than you would for cast iron or soft steel; a good thirty-second of an inch will not be too much. If possible use one of the special reamers that we have made for this work as they have more teeth and more clearance or reversed taper. The ordinary commercial reamer, while probably the best for general shop use, will ream too close to size for this job, and it also tends to stick in tool steel."

"I am glad you told me about it," said Jim. "I was of the opinion that the less stock left for the reamer to cut the

better, and I thought one kind of reamer as good as another. This drill is working all right now, and I guess I'll get a hole through *this* piece anyway."

Jim got his first piece bored and reamed without further mishap, but in making a starting hole for the drill in the next piece, he broke his tool by pushing it into the work before he got it central. George happened along about that time and Jim asked him for the loan of his centering tool until he could get his re-forged.

"A centering tool is something that I do not have, and very seldom use," said George. "What do you want to do? Start your drill? I'll show you how to start it without a centering tool. The first thing you want to do is to face the work off square so that the shape of it will not crowd the drill off the center; then place the drill in the chuck so that its cutting edges are in a horizontal position, and start it into the work, so!"

"But it is not running true," said Jim.

"We'll fix that; we will take this lathe tool, which is pretty square across the back end, and put it in the tool-post with the back end forward and clamp it fast, and then bring it up so that it bears against the drill close to the work; then feed the drill in a little, and crowd the tool against it until it looks as if it were central. When the tool is backed away, if the drill still looks central, go ahead; if not, repeat the operation until it is central. You see it saves the time and trouble of grinding and setting a centering tool and for ordinary purposes it is just as good."

As Jim was finishing up his lathe work, Mr. Corbin came along and picking up the sample mill said, "Jim, I want those mills for heavy roughing work and this sample mill has too many teeth; don't cut them like that but cut them about ⅝ pitch." Just then his attention was called to something else and he gave Jim no further directions. Jim was at a loss to know just what he meant but he did not like to let him know it. As Anderson was working near, he told him that he had been instructed to cut the teeth on his mills ⅝ pitch, but did not understand just what Mr. Corbin wanted.

"Well," said Anderson, "in this case ⅝ pitch means ⅝ of an inch from one tooth to the next."

"But why didn't he tell me how many teeth he wanted? How am I to know how many teeth he wants?"

"He would have to calculate the number before he could tell you, and be left that for you to do."

"I suppose it appears like an easy matter to you but I don't know how to go about it."

"Multiply 3.1416 by the diameter of your blank and divide the result by ⅝. That will give you the number of teeth. What is the diameter of your mills?"

"About four inches."

"Well, 3.1416×4 is 12.5664, and $12.5664 \div ⅝$, or 0.625 is a little over 20. Twenty teeth is what you want."

"Where did you get the 3.1416 from?"

"Why, 3.1416 is the ratio of the circumference to the diameter. That is, the circumference of a circle whose diameter is 1 would be 3.1416 and the circumference of a circle whose diameter is 4 inches would be 4×3.1416. If you want to demonstrate the truth of this take a piece of cord, pass it around one of your blanks and cut it off so that it goes around once with the ends just touching; take it off and measure it and you will find that it is very nearly 12½ inches long. Then if you wish to carry it further, cut the cord up in pieces ⅝ of an inch long, count the pieces and you will find 20.

"That is rather interesting, but is a machinist or toolmaker expected to have a knowledge of all such things?"

"I can only answer that in this way. I have noticed that the amount of a man's pay generally depends on his ability, and that toolmakers with a good knowledge of geometry and trigonometry combined with ability to do good accurate work are nearly always paid the best rate of wages."

With that Anderson went to grind a tool and Jim looked around for a milling machine to finish his job in. He found a small one idle and started to set it up when Mr. Corbin saw him and said, "That job of yours is too heavy for that machine; cutting spirals is pretty hard on any machine and you would be apt to strain this little fellow and impair its accuracy. Use that No. 1 over there—it may be more awkward to handle but it is suitable for the work."

Jim set the machine up for cutting the spiral according to the instructions on the table with the machine, and then as George was working near, he asked him to look it over to see if he had it right. George looked at the gears and referring to the table said they were all right; also the angle was right. Taking hold of the handle that moves the table he tried to turn it but it would not move. "You have not unlocked the index plate so that it can turn," he said. "You should always work the table back and forth once or twice to make sure that everything is free and working properly before starting the machine on a job of this kind."

"What angle cutter would you use for these?" Jim asked.

"Use a regular spiral mill cutter; they have a 12-degree angle on one side and an angle of 40, 48, or 53 degrees on the other. You want a right-hand cutter."

Jim obtained a cutter, a 1¼-inch mandrel, and a dog. On trying the mandrel into one of the blanks, he found, of course, that it was too large, and he went to Mr. Corbin and asked him what to do about it.

"We have hardened and ground mandrels 0.005 inch under size," said Mr. Corbin, "also reamers and expanding arbors of 1-inch, 1¼-inch, and 1½-inch sizes for work that is to be hardened. A great many shops ream mills and such work to size and depend on the hardening operation to close the holes sufficiently to allow them to be finished by lapping, but we make a great variety of mills that are of irregular shape and unless there is an equal amount of stock around a hole throughout its length it is apt to come back from hardening with one end of the hole larger than the other, making it a difficult and long operation to lap out the hole; and sometimes there is not enough stock to finish. For this reason we leave 0.005 inch stock in the holes of all work that is to be hardened, except the smaller sizes and special cases, and grind them out to size."

Jim took the mandrel back and asked for one 0.005 inch small, which he found fitted all right. When he got his cutter on the arbor and the work in position he began to realize that it was going to be a difficult matter for him to start a cut in the proper place for the simple reason that he did not know how. After thinking about it for awhile he came to the conclusion that it was beyond him. Looking around to see whom he could get to help him out of his difficulty, he saw a man by the name of Joe Waters who was working on a shaper near by and seemed to have lots of time at his disposal as he had just started a cut. Jim went to him and asked him if he would show him how to start a cut properly on one of those blanks.

"I'll try to," said Joe. "A good many fellows put a mill on a mandrel, put it between the centers and set their cutter to that, and I am afraid that there are some men that have laid claim to the title of toolmaker for a good many years that could do it no other way. I sometimes wonder what they would do if they had no sample to go by. You have your cutter on wrong; the side with the 12-degree angle should be next to the machine. Now get a surface gage and set the scriber to the height of the centers of the machine. Generally you will find a line on the footstock center that indicates this height, but where there is none, put the work between the centers and set the surface gage scriber as near to the center as you can guess and scribe a line on both sides of the work, index the work half around and scribe another with the gage at the same height; the center will then be just half way between the first and last lines. The gage is then set as near this point as possible and the operation repeated. When the gage is at the right height, you will be able to make only one line with the scriber on turning the index head half around. Now get some of that acid and rub it on the ends of your blanks so that you can see the lines that you scribe—use a little piece of waste moistened with it."

"Say! that is funny stuff," said Jim; "what is it?"

"It is nothing but water with bluestone, which is the same as sulphate of copper, dissolved in it, with a very small amount of nitric acid added. When it is applied to iron or steel it deposits a thin coat of copper on it. Now move the table of

the machine along until the end of the work next the footstock center is just half under the arbor on which the cutter is mounted and let it stay in this position for the present. How many teeth are you to cut?"

"Twenty," said Jim.

"That means just two turns of the index handle for each tooth, and we will put the index pin in the 21 hole circle. Now scribe a line across the end of your blank next the footstock center, index for one tooth and scribe another, and so on until you have gone clear around the blank. This may seem unnecessary, and it is, so far as starting the cut is concerned, but we need two and the rest serve as a check on the indexing and also would show if the work should at any time slip on the mandrel. When you scribe the last line mark it with a pencil or piece of chalk and turn the index handle 10 turns bringing this line on top. Now the edges of the teeth you are going to cut should be perfectly radial the same as the lines you have just scribed, and the side of the cutter that is to make these edges is to be at an angle of 12 degrees with a vertical line. Let the line that you have marked and turned to the top represent the first one of these edges that you are going to make; now what we want to do is to set this line in position so that the 12-degree side of the cutter is parallel to it, and as the 12-degree side is next to the machine, the line on top must be turned toward the machine 12 degrees; 360 ÷ 12 is 30, so we must turn the index head 1/30 of a turn, and to do this the index handle must be turned 1 1/3 turn, or one turn and seven holes in the 21 hole circle. There! Now the line you have marked is parallel to the 12-degree side of the cutter, and as your cutter is just half over the end of the blank that has the lines on it you have only to move the saddle in or out until the cutter is over the space between the line you have marked and the one next it at the top. Start the machine and raise the work up under the cutter until the 12-degree side cuts up to the line you marked and the other side comes about 3/64 inch from the next line. If you wish, you can keep away from both lines until you have taken a cut to see how it looks and satisfy yourself that it is coming all right. You should note the reading on the dial of the handle that operates the knee, and every time you finish a cut drop the work down away from the cutter before you run the table back for another cut, then raise it up again, after running it back, until the dial reads the same as it did before it was disturbed. If you don't lower the work, the backlash in the gears will allow the cutter to cut up the sides of the teeth and make a bad job. You will not need to set up your machine but once for this lot of mills as they are all of the same size and have the same number of teeth. It would be well, though to index each blank and lay out each tooth with the surface gage, and when you have scribed the lines all around move the index handle 1 1/3 turn and one of the lines will come in the proper place providing your blank sets with the end next the footstock center just half under the cutter when you are laying out the teeth. Very few toolmakers bother to lay out the teeth before milling, but it is a good idea for a beginner to do so as it gives an opportunity to watch the cutter when it is starting into the blank on each tooth, and if a mistake is made in indexing, or if the blank slips on the mandrel, it will be readily noticed and may be remedied before much, if any, damage is done."

"Thank you for the information," said Jim. "It's a good thing for me that I don't have to cut teeth on the ends of these mills or I would be in trouble again."

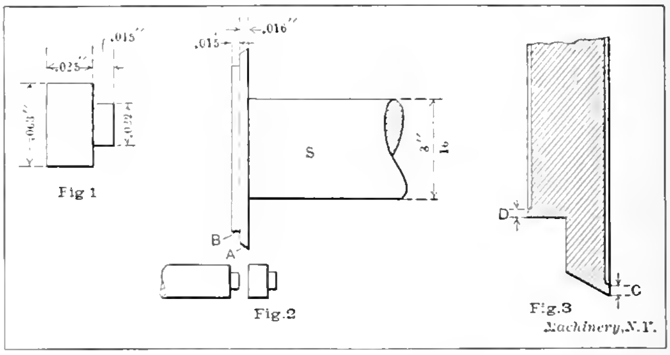
"That is not such a difficult job," replied Joe. "We have cutters in the tool-room that have a 12-degree angle on one side and 65 degrees on the other, which will generally cut the teeth in the ends that have a negative rake, and we usually cut the teeth in the end that would be undercut if the form of the spiral were followed, with a regular 65-degree cutter, not bothering to carry out the form of the spiral on this end, although it may be done quite easily where the index head can be lowered enough from the horizontal to bring the lands equal, by swinging the table around enough to bring the spiral in a position at right angles to the cutter (which would be to the same angle as given for cutting the spiral) and feeding the work in a vertical direction past the cutter. Well my cut is over and I will have to get busy."

MAKING PINS FOR IRIS DIAPHRAGM LEAVES

WALTER GRIBBEN*

The brass pin shown in Fig. 1 is used in the iris diaphragm of a camera, one pin being used in each end of each leaf of the iris. A few of these were wanted by a repair shop, or "camera hospital," to use in repairing diaphragms where a few of the leaves were damaged. On account of the limited number wanted, the job would not admit of very much rigging up. The teat left on the end for riveting in the hole in the leaf should be cupped out a little to facilitate riveting, but permission was asked to omit this cup, as by so doing the pins would be cheapened somewhat, and a solid teat was considered plenty good enough for repair jobs, although it might not do when manufacturing.

The pins were made of brass wire 0.063 inch diameter and were to be 0.035 inch long in the body, while the teat was to be 0.032 inch diameter and 0.015 inch long. No screw machine



Figs. 1, 2 and 3 Small Pin used in the Iris Diaphragm of a Camera, and Disk Tool used for Turning it

was available for this job, so it was done on a bench lathe. The details of the fixtures used are shown in the line cuts, but they are not all drawn to the same scale.

A disk tool, Fig. 2, was made of 3/8-inch drill rod. The shank *S* by which it is held, is in one piece with the disk. The part *A* is the cut-off, while the part *B* forms the teat on the next pin to be made. Fig. 3 is an enlarged section through part of the disk tool, showing how the sides were cupped out a few thousandths to make the cutting parts *C* and *D* quite narrow, with the object of making the tool cut more freely and thus throw up less burr on the work.

The halftone engraving, Fig. 4, shows the general arrangement of the improvised apparatus for getting out this job. The iron casting *E* was fastened to the top of the slide rest, and a hole bored in place which eventually held the hard steel bushing that guided the stock. This bushing is held by the set-screw *F*. The rock-shaft *G* is mounted between pointed screws, the one on the left being screwed clear up to the head, while the screw on the right-hand end has a check-nut by which to adjust for a close-running fit without shake. The arm *H*, shown in detail in Fig. 5, is tight on shaft *G*, while arms *K* and *L*, shown in detail in Figs. 6 and 7, are both loose on *G*. The two screws *M* and *N* hold *H* and *K* together, and serve to adjust the disk tool *A* for depth of cut, and thus produce the proper size of the teat on the end of the work, *M* being tapped into *K*, while *N* is tapped into *H*. When *M* and *N* are both tight, *H* and *K* act as one piece. The crank-shaft *O* was made of 1/8-inch Bessemer rod, and it carries two eccentrics *P* and *R*, made of 5/16-inch Bessemer rod with the hole bored off center. Eccentric *P* works in the open slot in the end of lever *K*, and causes the disk tool *A* to alternately move to and from the stock wire. Eccentric *R* works in the closed slot in the end of lever *L*, and causes the upper slide of the slide-rest to feed along after each cut has been made. The feed is accomplished by means of the pawl *U*, the bell-crank *V*, and the stationary rack ratchet *T*, clamped to the lower slide, the regular feed screw of the top slide being temporarily removed. The bell-crank is pivoted to *E* by a shouldered screw *W*, while another shouldered screw *X*, connects its horizontal arm with the end of lever *L*. Screw *X* had to be a rather loose fit in the end of the bell-crank arm, as *V* and *L* vibrated in different planes, but as the vibration was only

* Address: 314 Halsey St., Brooklyn, N. Y.

over an arc of a few degrees, no trouble from binding was apparent. The rack T was cut on one of the edges of a piece of angle brass, the pitch of the teeth being equal to the total length of the finished pin plus the width of the cut-off part of the disk tool, or 0.066 inch altogether. The bell-crank was made of two pieces of sheet brass taken from the scrap box and soft soldered together. This may look like a slovenly way of making a bell-crank, but it was quickly made, and held together long enough to do the job, besides having the advantage that the vertical arm could be made longer or shorter by simply melting the solder. The arm carrying the pawl was adjusted in this way until the pawl moved a little more than one tooth of the rack, but not as much as two teeth. As the movement of the top slide is governed entirely by the pitch of the rack teeth and not by the amount of movement of the pawl, any lost motion in the feed works does not affect the length of the pins, unless it amounts to as much as the distance between two consecutive teeth of the rack. The two eccentrics P and R were adjusted around on the crank-shaft until the two movements were correctly timed relative to one another; that is, so the feed did not start until after the disk tool had been withdrawn from the work, and also so that the feed was completed before the disk tool started to cut.

As this work is so small in diameter, it was realized that a high speed of rotation was desirable, both to prevent the formation of much of a burr on the edges of the work, and also to reduce to a minimum the little teat left by the cut-off tool. With this object in view, the high-speed drive shown in Fig. 4, which was originally made to drive an internal grinding device, was changed a little to adapt it to present needs. The drive is shown in section in Fig. 8. It consists of the brass casting A, the upper end of which is slotted and carries the adjustable stud B, on which runs the double wooden pulley C, the large part of which is for a flat belt, and the small part for a round belt from the countershaft. This pulley has screwed fast to it a brass flange and hub D, into which are forced two hard steel bushings, one in each end, leaving on oil chamber between them. The end of the

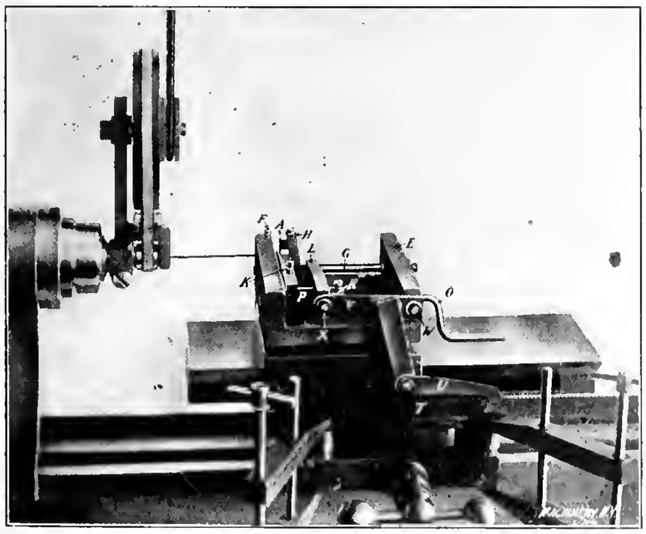


Fig. 4. Bench Lathe Attachment for Turning the Small Pins shown in Fig. 1, at the Rate of Sixty per Minute

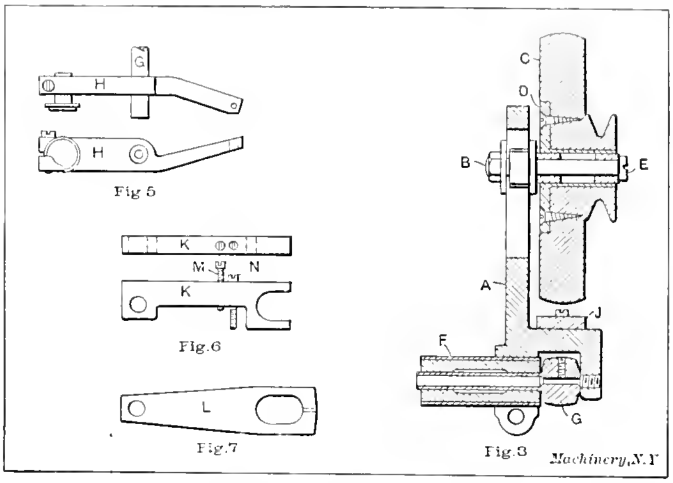
stud is tapped, and the large-headed screw E is screwed in tight, which prevents the pulley from coming off. The lower part of A is bored 1/2 inch diameter, and has a saw cut and pinching screw to clamp it on the piece of 1/2-inch brass tubing F, which was tinned with soft solder on the inside and then poured full of babbitt metal. After cooling, it was bored 3/16 inch clear through and the ends faced. The middle of this hole was bored a trifle larger than the ends, in order to form an oil chamber. The pulley G also performed the office of a chuck to hold the brass wire of which the pins were made. It is made of 1/2-inch cold-rolled steel, with a long stem on one side 3/16 inch diameter, this stem being bored 1/8 inch as far as the pulley, and 0.063 inch the rest of the way. A small headless set-screw in G holds the work in place. The part of F that projects to the left is grasped in a 1/2-inch draw-chuck, and the lathe spindle locked to prevent it from rotating. An ordinary flat rubber band did duty as a belt to connect C and G, but it had this peculiarity, that considerable crowning on the pulleys seemed to have very little effect on keeping the belt in the middle of the pulley face, so a guiding fork J of sheet brass was attached. There seemed to be some structural irregularity in the rubber itself, as there was a tendency for it to crawl to the right when one side of the rubber was next the pulley, but to crawl to the left when the rubber band was turned over.

The mode of operation was to lift the feed pawl and draw the top slide as far to the right as it would go. Then a three-foot length of wire was passed through the lathe spindle and into the hardened guide bushing, in E (Fig. 4), after



Figs. 5 to 8. Details of the Attachment shown in Fig. 4

which the small set-screw in pulley G (Fig. 8) was tightened and the countershaft started. This gave an estimated speed of 10,000 revolutions per minute to G, providing the belt did not slip. Then the crank on the end of O was turned by hand, a finished pin dropping off for each turn, until the top slide reached the left-hand end of its travel, when the power was shut off, the slide moved to the right again, the stock wire released and pulled through until it was in the guide bushing once more. After tightening the set-screw and starting the power, a few dozen more pins could be made at the rate of about 60 per minute, when the stopping and returning to the right had to be repeated. The handle O could be turned much faster than this, but in that case the momentum of the top slide would be apt to carry it a little too far, and thus make the pins of varying lengths, so it was thought advisable not to exceed the rate mentioned. This fixture left the pins with practically no burr on them, and they were all ready for immediate use.

* * *

At the present time when we are prone to assume that everything undertaken in the mechanical field surpasses in magnitude or difficulty of production anything made in past centuries, it is of interest to recall that the so-called Great Bell of Moscow, made in Russia in 1734, is, according to the *Brass World*, not only the largest bell ever cast, but is also the largest casting of any kind ever made. The making of a casting of the size of this bell would startle the world even to-day. A great Chinese bell weighing 120,000 pounds is another example of ancient casting. As far as is known, these bells were cast from metal melted in close proximity to the mold. One or more furnaces capable of melting the required quantity of metal were so arranged that a trough connected the tap hole with the mold, for tapping the metal directly from the furnace into it. As a matter of fact, this method would, even to-day, be the only practicable one for casting a piece of similar size.

* * *

That the gasoline or alcohol engine is destined to be the farmers' future source of power in preference to the horse, seems to be reasonably sure. It now drives his automobile, shells his corn, grinds his cattle feed, pumps his water, threshes his grain and plows his land. Kansas farmers are using traction gasoline engines to haul their plows, and it is claimed that four men with a traction gasoline engine can do as much plowing as twenty men with horses

DIE SINKING AND SHOP PRACTICE IN THE ARMSTRONG BROS. PLANT

ETHAN VIALL*

The business of the Armstrong Bros. Tool Co., "The Tool-holder People" of Chicago, has grown from the almost insignificant product of a very small shop to the immense output of a factory that is second to none in equipment and which holds its own in size with those far in the front rank. This last statement means something, for as a rule, the business of a shop making small tool specialties does not require a large plant. The growth has not been of the mushroom kind, but has been a strong, steady increase, the result of good sound business management pushing a line of tools that were needed and which were made in a first-class manner. The Armstrong brothers have always been good, steady advertisers, but no amount of advertising could have built up the business that they have to-day, had the tools, the material and the workmanship not been right.

Besides the regular line of lathe and planer tools, the company now makes drop forgings and machine shop specialties

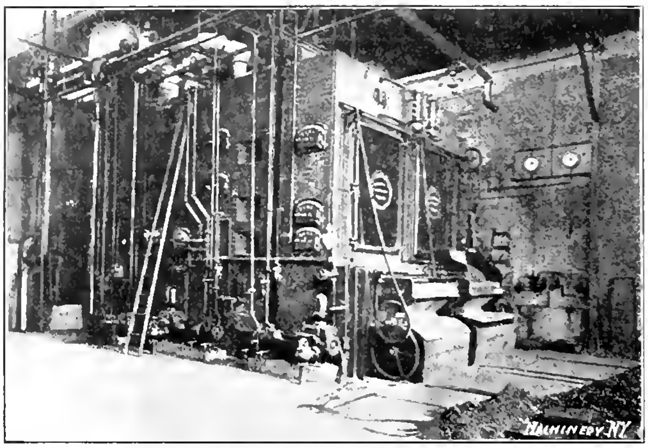


Fig. 1 View of the Boiler Room at the Armstrong Bros. Shop

of several kinds. The factory has its own power and light plant, and the boiler room, a partial view of which is shown in Fig. 1, is a model of neatness and careful planning; it is light, well drained and amply large enough for future expansion. Automatic stokers are used, and the condition in which the place is habitually kept is plainly shown in the engraving, the picture having been obtained one noon when no one knew that it was to be taken, so that no cleaning up for the occasion was possible.

The forge room is partially shown in Fig. 2. The arrangement of alternate steam hammer and trimming press is good. The heating furnaces are also well located, but, unfortunately,

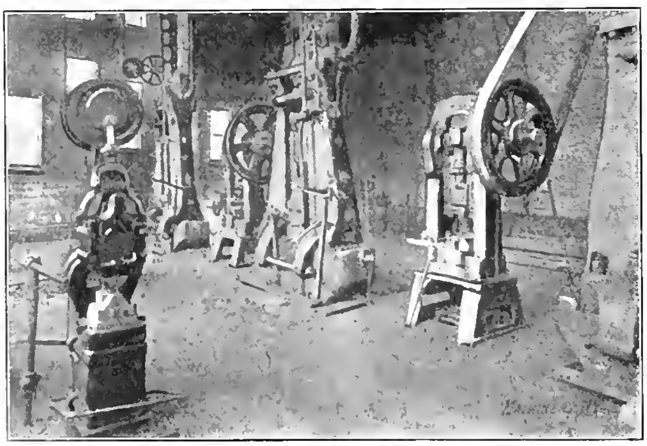

Fig 2. Arrangement of Steam Hammers and Trimming Presses in the Forge Room

the position from which the picture was taken, would not allow of their being shown. This department, as well as all the others, has been planned with an eye to both present and future needs.

A great many of the articles manufactured, especially the tool-holders, are case-hardened by being packed in large iron boxes with raw bone and charcoal, and heated in furnaces in the usual way. The method of handling the iron boxes is not, however, as common as it might be. These boxes are made with grooves or corrugations on each side, extending the entire length of the box, and a large iron fork, the prongs of which just fit these grooves, and which is swung from a

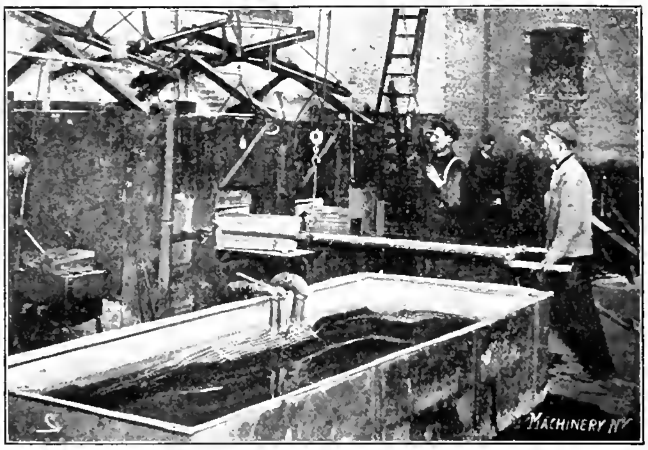

Fig 3 Case-hardening Furnace and Cooling Tank

traveling tackle, is used to put the boxes into the furnace and to remove them when they are sufficiently heated. When the boxes are removed the contents are dumped into the cooling tank, which is fitted with a screen to keep the parts off the bottom and insure more even and thorough cooling, all of which may be seen by referring to Fig. 3. The screen just referred to, can be easily removed to clean the burnt bone out of the bottom of the tank. When the picture was taken the water was purposely lowered to show the position of the big screen in the tank.

The tool holder set-screws, which are made of tool steel, are heated in a special furnace that heats only the points and

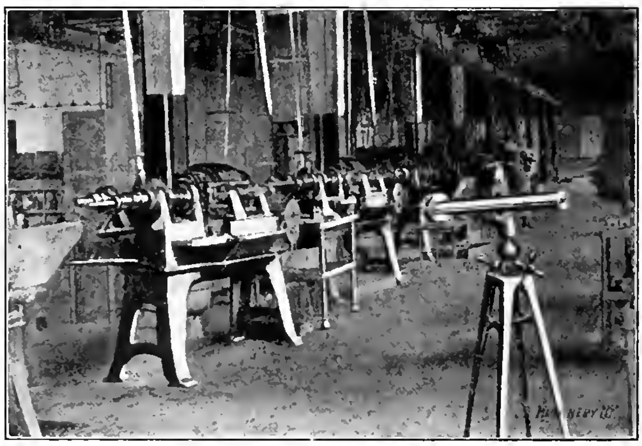

Fig. 4. Battery of Automatic Screw Machines which make the Tool-holder Set-screws

drops them into the hardening bath as fast as the operator can feed them in. The burner of this furnace is the same as that used on a bicycle brazer, and, in fact, the furnace is principally made from the parts of an old brazing stand.

The set-screws just referred to are made by the battery of automatic screw machines shown in Fig. 4. In the foreground is an old universal bicycle vise that is used to hold the big quills while taking out or putting in the spring collets used for feeding the stock. Anyone who has ever run this class of automatics will see the convenience of the old vise, for something of the kind is very frequently needed.

The system used for detailing the dimensions of parts for different sizes of tools of the same class, will be of interest to many, as it saves a great deal of work in the drafting room by making one print do for all sizes. A sample drawing for the six different sizes of spindle and feed sleeves manufactured, is shown in Fig. 5, and for those not already familiar with this method, it will be a revelation in simplicity.

Naturally in a shop depending so much upon drop-forge work, the die making department is one of the most important in the works and is well equipped. This department is in charge of a man of long experience on this class of work,

* Associate Editor of MACHINERY.

though a comparatively young man. One of his remarks hits the drop-forging die problem squarely on the head, and it is that the great difficulty in drop-forge work is not so much in making the die, but in making the metal go into it, meaning, of course, that the breaking down, roughing or bending operations are really the most important and the most difficult to plan out properly. Almost any toolmaker can sink a finishing be judged from it. For very large forgings such as the C-clamp just mentioned, cast-iron roughing and forming dies are used. The piece is first broken down, bent and rough formed in these dies and then reheated and finished in the tool steel finishing die. Fig. 8 shows a set of wooden patterns for a pair of cast-iron dies weighing 1,600 pounds, or 800 pounds apiece.

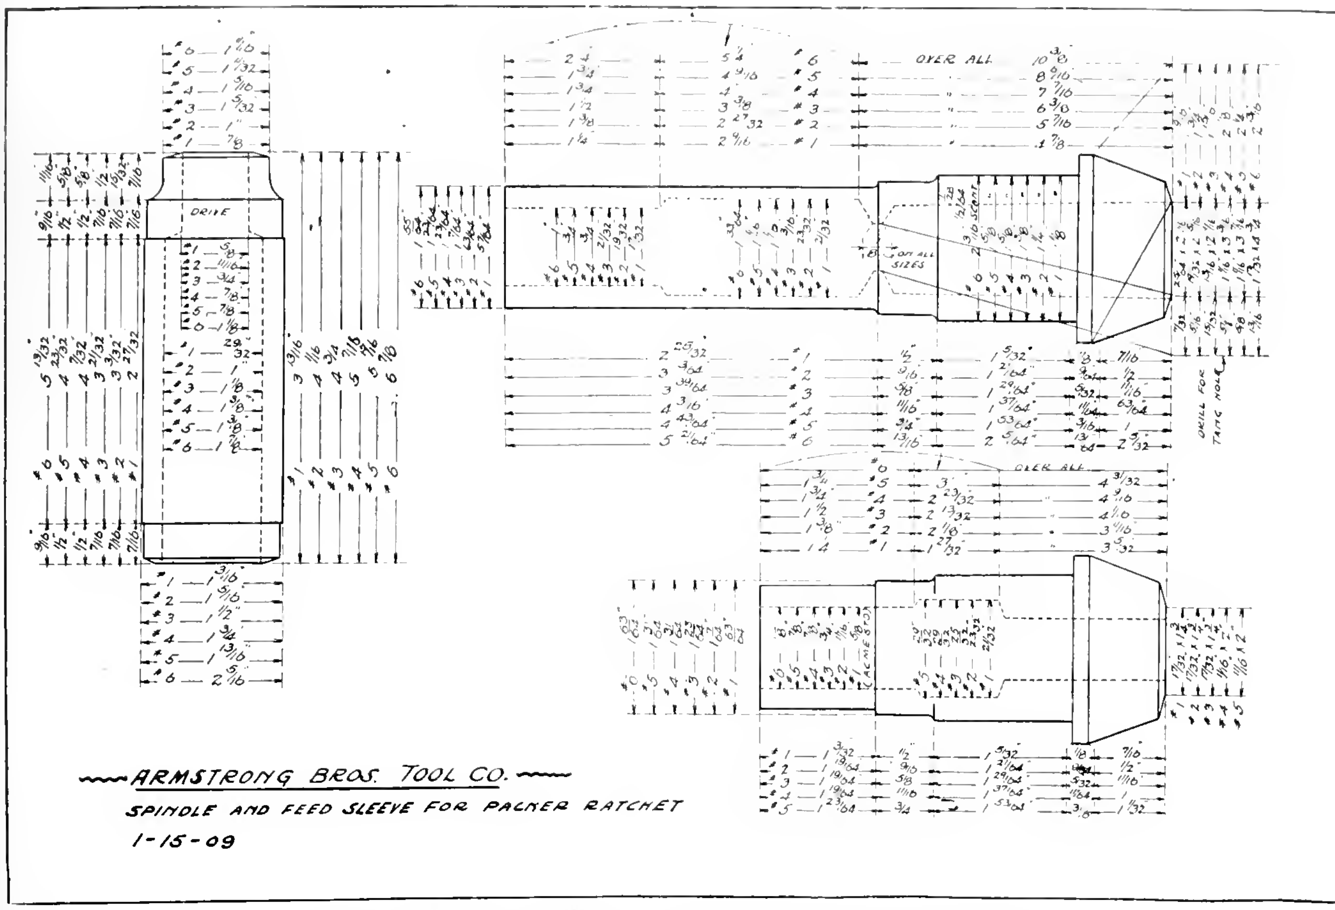

Fig. 5. Drawing giving Dimensions of Six Different Sizes of Spindle and Feed Sleeves

die from a model, but it takes brains and experience to plan and work out the other parts of the die so that it will work satisfactorily without unnecessary waste of time or material. In planning dies or die parts of especially difficult shapes, plaster of Paris models are often used in order to find the best shape or position for the part to lie in; this is especially important in so planning a die as to get that great desideratum of the drop-forge shop—the finishing at one heat.

Many small pieces are forged in "pony dies," which are made of a shoe of tool steel two or three inches thick, which is keyed into a heavy cast-iron or cast-steel block. These pony dies are very economical, as one set of shanks can be made to do duty for a large number of shoes, the shoes all being located by dowel pins and keyed in with a taper key, in the same way that the shanks are keyed into the steam hammer anvil and head.

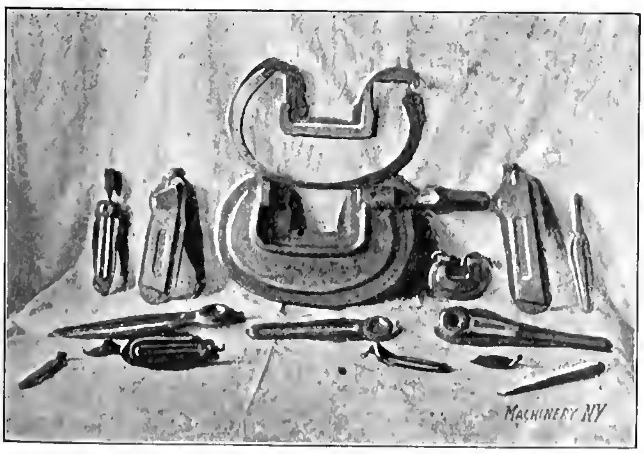

Fig. 6. View of Drop Forgings as they appear when taken from the Dies

Fig. 7. Lead Proofs of Various Parts which are to be drop forged

Fig. 6 shows a number of drop-forgings, including toolholders, wrenches, drifts and a C-clamp with the flash still in place. These forgings are just as they came from the steam hammer. A trimmed-off flash is shown on top of the large C-clamp in the middle of the group. Fig. 7 shows a lot of lead proofs of dies for making various sizes of drop-forgings from the smallest to the largest. The big C-clamp shown is 18 inches long and the sizes of the other parts can

For working out difficult dies on the profiler, the universal angle-plate or profiling-block, shown in Fig. 9, is used. In this engraving, *A* is the die and *B* is the top of the block, which may be swung around in a complete circle, while the part *C* can be tilted about 45 degrees each way and clamped at any point on the base *D*. These adjustments give almost any angle required in die sinking, that cannot be obtained in the regular profiler vise.

A special center-bracket used to steady small mill arbors held in the spindle chuck of the profiling machine while working out cylindrical cavities, is shown in Fig. 10. The

[illegible] same diameter as the cavity wanted, and [illegible] way of getting a perfect cavity of the

The making of dies for the Armstrong boring tool, so that the metal would come out of the die, was quite a difficult problem. This was one of the few cases where getting the metal *into* the die was not the most important thing. It was easy enough to make a die that would forge up the shape required, but owing to the peculiar shape of the boring tool.

the metal would be wedged in too tight to be easily removed. This problem was worked out by using plaster of Paris in the way previously referred to, and the die as it was finally successfully made is shown in Fig. 11. One of the boring tool holders is shown lying on top of the die. The truck shown in this engraving is very useful, as it is just the height of the work benches and a heavy die can be easily pushed from one to the other. Another very handy truck used to carry finished tools from the assembling benches or shop to the storage shelves, is shown in Fig. 12. This truck is also used to carry tools packed in boxes to the shelves, and as the shelves of the truck are made the same height as the four lower shelves of the store-room, the boxes can be easily slipped into place.

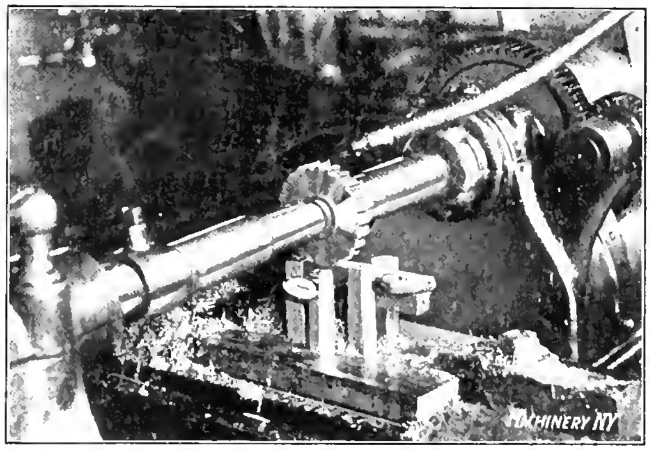

Fig. 20. Milling the Slots for the Blades in Cutting-off Tools

Fig. 13 shows an indexing jig used to hold the hubs of the universal ratchet drills, the construction of which is too plainly shown to need explanation.

In Fig. 14 is shown the milling jig used to hold two C-clamps at once while machining the faces.

Gang planer tool-holders are broached out in a punch press as in Fig. 15. The fixture used to hold the gang tool-holder, is mounted on a slide which is fed under the broach one hole at a time, by lifting the dog-lever *A* and pushing the fixture along until the dog engages the next notch. The view shown was taken from the back of the press. The gang tool-holders are next placed in a very similar fixture, shown in Fig. 16, and the set-screw holes drilled.

Many employers and foremen complain about their men grinding away the tool-holder when sharpening the cutters; consequently a set of special holders has been made for customers, in which to place the steel while grinding. A set of these holders is shown in the rack on the grinder column in Fig. 17, and the man at the left is using one, holding it at the proper angle by pressing it down on the adjustable grinder rest. At the right in this engraving is shown a man cutting high-speed steel into suitable tool-holder lengths with a metal wheel. This wheel is 16 inches in diameter and runs at 2,500 revolutions per minute. It is simply a thin tool steel disk clamped between two big soft-steel washers. The steel bars are not cut off entirely but are just cut into slightly on the four sides and snapped off, the cuts on the sides being as clean as if made by a milling saw in soft metal. No teeth or anything of the kind are used on the cutting disk and the hard high-speed steel does not quickly wear the softer metal, as a "saw" lasts for a long time.

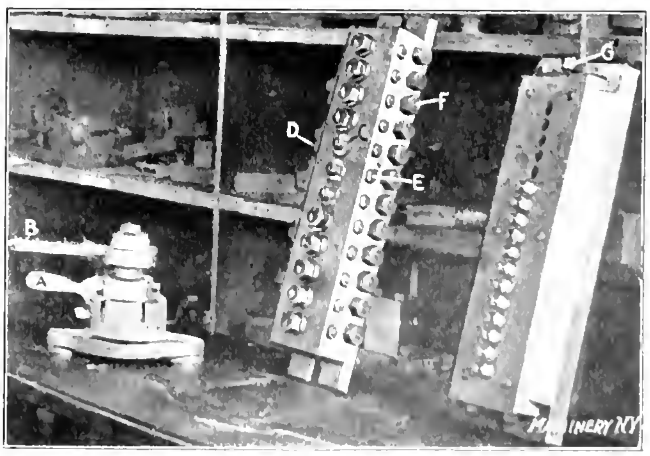

Fig. 21. Interesting Types of [illegible] Shoulder Nuts and Collar Head-screws. A[illegible]

One of the simplest possible drilling jigs for holding offset tool-holders while drilling the cutter hole, is shown in Fig. 18, while in Fig. 19 is shown a set of three jigs used for the progressive drilling of the long cutter hole in the straight lathe tool-holder. After the cutter holes have been drilled as shown, they are broached out square in special turret broaching machines.

Slots for the blades of cutting-off tools are milled in the holder, as shown in Fig. 20. A close inspection of this jig will show that the tool-holder is pressed from below up against stops. This method makes all slots the same depth regardless of any slight difference in the thicknesses of the forgings. The pushing up of the clamping-block is done by a cap-screw underneath which is turned with an end wrench.

Three very interesting milling fixtures are shown in Fig. 21. The tool at the left is an indexing fixture for milling large hexagon shoulder-nuts, using either one or two mills at a time. The indexing is done by the lever *A*, the nut being held in the chuck which is operated by the lever *B*. The fixture in the center is for holding twelve shoulder-nuts while

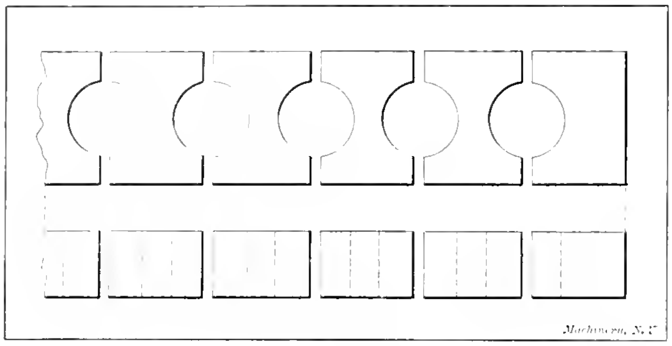

Fig. 22. Detail of the Clamping Blocks used in one of the Fixtures shown in Fig. 21

milling them hexagon, using straddle mills. The blanks are first faced and threaded and then screwed tightly down on the studs *C*, which are kept from turning by tightening the screws *D*. These screws are so arranged as to tighten two studs at a time. The nuts and screws *E* are simply lock nuts and pointed retaining screws, the ends of which fit into a groove turned in the stud shank. At *F* are the spring-actuated indexing stop-pins which are made to engage six notches in the stud shank, so that by simply loosening the lock screws *D* the nuts may be easily indexed with the fingers. Square-headed collar-screws are milled seventeen at a time, in the jig shown to the right. This jig is simple and easily operated. The screws to be milled are held by a series of clamping blocks, shown in detail in Fig. 22, which are set into a channel in the cast iron base of the jig, held in place by an iron top plate and tightened or loosened by the single set-screw *G*. No indexing device is used, but after the first straddle mill cut is taken the set-screw is loosened and the screws are turned a quarter way around by hand and lined up by using a gage with teeth in it like a big comb. The set-screw is again tightened and the final cut taken.

* * *

THE SMALLEST STEEL HAND STAMP

The engraving of the Lord's prayer on one side of a ten-cent piece and other feats of expert engravers even more remarkable have interested and astonished the public from time to time. The letters in these examples are of a microscopic size, and can be read only with the aid of a magnifying glass, but the difficulty of cutting them in copper or silver is small compared to cutting tool steel in relief, as is required for a stamping die. An interesting example of very small steel stamp work is now on exhibition at the New York store of William Dixon, Inc., 39 John St., which is said to be the smallest ever made. The die, which is of the common hand form hardened and tempered, stamps the name WILLIAM HOWARD TAFT in letters one two-hundredth (0.005) inch high, the seventeen letters making a line only 11/64 inch long. The name even when printed by the stamp on white paper with black ink cannot be read, without the aid of a magnifying glass, by any but the very sharpest eyes. The letters are all capitals, clean-cut and well-shaped. A page of MACHINERY on the same scale would be about 1/2 inch x 1 inch.

WATER REQUIRED TO COOL A GAS ENGINE

S. H. SWEET*

The water pump for a gas engine is generally designed to carry off one-half the heat produced by combustion. At times one-quarter would be sufficient but one-half is the amount that should be figured on. If the heat per minute generated by an engine is represented by q, then for a thermal efficiency of 12½ per cent, $q = 339.2 \times$ I. H. P., and $q \times 0.5 =$ the heat to be carried off by the water.

The constant 339.2 is obtained from the formula $q = \frac{\text{I. H. P.}}{E} \times \frac{33{,}000}{778}$. $E =$ the thermal efficiency, which for gasoline is taken as 12½ per cent. Hence, $q = \frac{\text{I. H. P.}}{0.125} \times \frac{33{,}000}{778} = 339.2 \times$ I. H. P. Other constants may be obtained by substituting the thermal efficiency expected or known. So far as I know the maximum efficiency of gasoline is 19 per cent, and a number of very good engines have shown about 15 per cent efficiency, but for the general run, the safe figure to use is 12½ per cent.

Let

$t - t_1 =$ allowable rise in temperature.

$t =$ maximum temperature of water in degrees F. (About 180 degrees should be the maximum temperature allowed.)

$t_1 =$ normal temperature of water in degrees F.

$W =$ the number of pounds of water required per minute,

then

$$W = \frac{169.6 \times \text{I.H.P.}}{t - t_1}$$

$t - t_1 =$ the number of B. T. U. absorbed per pound of water.

As the pump is generally attached to the engine shaft, it will have the same number of revolutions as the engine. Let p equal pounds of water required per revolution, then

TABLE GIVING PART OF A GALLON PER STROKE FOR VARIOUS SIZES OF SINGLE-ACTING PUMPS

Diam.	Area	Stroke 1	1½	2	3	4	5	6
½	0.196	0.0008	0.001	0.002	0.0025	0.003	0.004	0.005
5/8	0.307	0.001	0.002	0.003	0.004	0.005	0.007	0.008
¾	0.442	0.002	0.003	0.004	0.006	0.008	0.010	0.012
7/8	0.601	0.0025	0.004	0.005	0.008	0.010	0.013	0.016
1	0.785	0.003	0.005	0.007	0.011	0.014	0.017	0.020
1¼	1.227	0.005	0.007	0.010	0.016	0.021	0.026	0.032
1½	1.767	0.007	0.011	0.015	0.022	0.030	0.038	0.045
1¾	2.405	0.010	0.015	0.021	0.031	0.041	0.051	0.062
2	3.142	0.014	0.021	0.027	0.041	0.054	0.068	0.082

$$p = \frac{W}{\text{R. P. M.}}$$

As one gallon of water weighs 8.33 pounds,

$\frac{p}{8.33} =$ number of gallons required per revolution.

Let us take an example and assume that we wish to design a pump for a 20 I. H. P. gas engine which turns at 300 R. P. M.

$$q = 339.2 \times 20 = 6{,}784 \text{ B. T. U.}$$

$q \times 0.5 = 6{,}784 \times 0.5 = 3{,}392$ B. T. U., which is the amount of heat the water is to carry off.

$t = 180$, $t_1 = 60$, $180 - 60 = 120$.

$$W = \frac{169.6 \times 20}{120} = 28.267 \text{ pounds.}$$

$$p = \frac{28.267}{300} = 0.0942 \text{ pound per revolution.}$$

$$\frac{0.0942}{8.33} = 0.0113 \text{ gallon per revolution.}$$

By referring to the accompanying table we see that a pump 1½ inch bore by 1½ inch stroke will answer. The number

* Address: 190 Orchard St., Bridgeport, Conn.

of gallons pumped per minute is equal to the number of R. P. M. of a single acting pump multiplied by the number of gallons per revolution as given in the table.

[If the thermal efficiency of a gas engine were 100 per cent, that is if all the heat were converted into work, there would be no rejection of heat into the cylinder walls, and consequently no need for cooling water. Again, if the thermal efficiency were 50 per cent, one-half the heat would be rejected into the walls and exhaust while the other half was converted into work. The formula, therefore, is not strictly correct, as it does not take into consideration the percentage of heat converted into energy and which thus disappears.

Using the same notation, the formula should properly be:

$$q = \left(\frac{\text{I. H. P.}}{E} \times \frac{33{,}000}{778}\right) - \left(\frac{33{,}000 \times \text{I. H. P.}}{778}\right)$$

$$= \frac{(33{,}000 \text{ I.H.P.} \times 778) - (33{,}000 \text{ I.H.P.} \times 778\,E)}{778\,E \times 778}$$

$$= \frac{25{,}674{,}000 - 25{,}674{,}000\,E}{605{,}284\,E}$$

If $E = 12\frac{1}{2}$ per cent, then:

$$q = \frac{25{,}674{,}000 - 3{,}209{,}250}{75{,}660.5}$$

$$= 296.8$$

The thermal efficiency of gas engines being rarely more than 20 per cent the error in Mr. Sweet's method is not important and for practical purposes it is to be preferred because of its simplicity.—EDITOR.]

HOW BILLY CENTERED SHAFTS

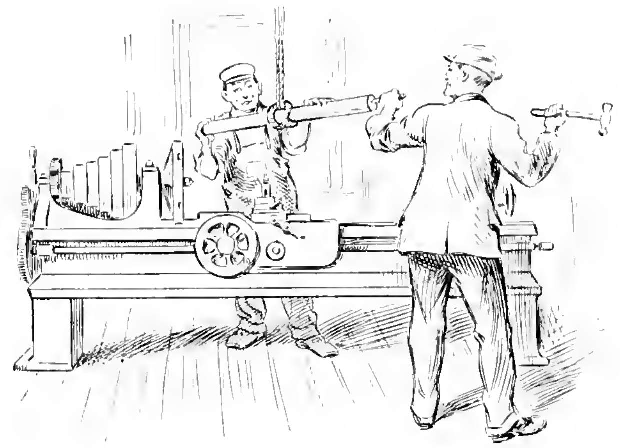
H. A. D.

Mr. William Collis, affectionately known amongst the boys as "Billy," was the foreman of the turning shop some twenty years or so ago. He was a working foreman too—not one of the kind who was afraid to dirty his hands—and to fill in his time between Monday morning and Saturday noon, when he was not giving out work or looking after his men he ran the shafting lathe—or rather the shafting lathe ran itself even when he was looking after the men, or when he was dozing on the top of his tool-chest, for in that shop there was no tool-room and each man kept his own special fancies in the way of tools, etc., under lock and key. High-speed steel was in the dim and distant future, and a cut over a shaft lasted a long time.

Now Billy's method of centering was as primitive as could be, the usual tools consisting of a center punch and hammer only. A square center was used sometimes, but this gave trouble in changing centers, putting something in the tool-post to press the shaft, and other little worries which could be avoided; therefore, by placing the center punch where he guessed the center of the shaft should be, and hitting it several good smart blows the thing was done—except, of course, when he had miscalculated as to the exact position of the center. It was then necessary to try the shaft in the lathe, and if too much eccentricity was found he would mark the "high side" with chalk, remove the shaft and "draw" the center by means of the punch, the shaft being swung in and out of the lathe by means of pulley blocks.

His assistant on the operation was generally one of the newer lads knocking around, and for the particular shaft in the story the services of Harry had been secured. Now Harry's sense of humor (?) was strongly developed, and he hated this particular job just as much as he was afraid of Billy, but his love of a joke overcame his fears one day, and here is the story:

Billy had made a particularly bad guess as to the position of the center of the shaft and had followed his usual practice up to the point of swinging the shaft out of the lathe, when he was called away to attend to some other duty. As Harry lolled around waiting for the work to proceed again, the little chalk mark persistently stared him in the face in such a manner that finally an idea struck him, that it would be funny if he rubbed it out and placed another on the *opposite side*. Of course, as in most things of importance, the main thing was to have the idea, the rest was easy and was soon accomplished. It was too good a joke to be enjoyed alone and several others soon knew what had been done, amongst them being one of Billy's own particular cronies. Billy returned soon afterwards, and resuming operations, drew the center towards the mark. His surprise was very pronounced when he saw the result of his latest efforts and the remarks he made about shafts in general and this one in particular are unprintable, but he fairly lost his temper when he caught sight of someone smiling, apparently at him.



"Now Billy's method of centering shafts was primitive"

Poor Harry wanted to laugh, too, but dared not, so offered what consolation he thought would meet the case, suggesting that Billy had perhaps made a mistake, and should have drawn the center *away* from the mark, but Billy said he might do that when he started his second apprenticeship and knew no better. From his manner towards his assistant the next day it was clear he had learned over night what had occurred, but he was not vindictive, and afterward enjoyed the joke as much as anyone.

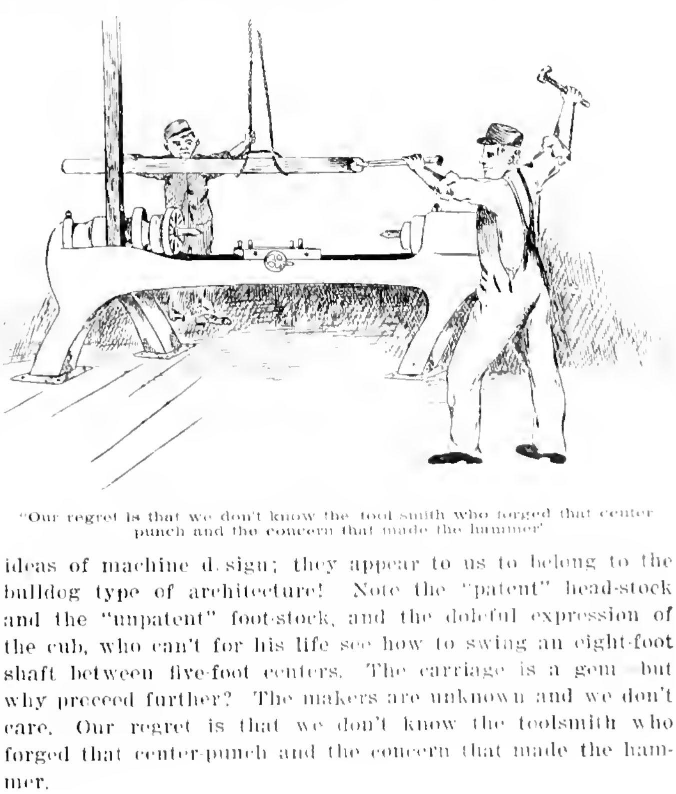
HOW BILLY DIDN'T CENTER SHAFTS

This startling sketch illustrates an amateur artist's weird conception of a shafting lathe and a machinist's way of handling centering tools. He was asked to make a drawing for "How Billy Centered Shafts," and the result exceeded our wildest expectations. We are impressed particularly with the lathe legs. How well they don't harmonize with modern



"Our regret is that we don't know the tool smith who forged that center punch and the concern that made the hammer"

ideas of machine design; they appear to us to belong to the bulldog type of architecture! Note the "patent" head-stock and the "unpatent" foot-stock, and the doleful expression of the cub, who can't for his life see how to swing an eight-foot shaft between five-foot centers. The carriage is a gem—but why proceed further? The makers are unknown and we don't care. Our regret is that we don't know the toolsmith who forged that center-punch and the concern that made the hammer.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

DECEMBER, 1909

PAID CIRCULATION FOR NOVEMBER, 1909, 21,213 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 650 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

CHINESE METHODS IN DESIGN

One of the most delightful of Charles Lamb's "Essays of Elia," deals with the alleged discovery of roast pig by the Chinese. As the story goes, a Chinaman's house was burned up and his pig lost in the flames. While poking around in the ruins the Chinaman came upon the body of the unfortunate beast, and in the handling found it necessary to cool his fingers, which he did by putting them in his mouth, when he tasted for the first time in the history of mankind the sweet and delicate flavor of roast pig. The narrative goes on to state that for some time thereafter Chinamen's houses were burned down regularly and frequently, and roasted pigs were always found in the ruins, until an inspired genius discovered a shorter and less expensive method of producing the same result.

It sometimes seems as though there are very few machine designers who have gotten out of what may be called the "house burning stage" in machine design. Why is it that nine times out of ten the first design of a new machine is too light, the second design a little heavier, the next heavier still; and only in the course of years is the tool designed so as to be strong enough for its work? Instead of wasting time and money all around in repeated strengthening, why not make the machine strong enough in the first place—or even too strong? It would be a welcome change to see a machine pared down a little in weight in successive developments, instead of having it corrected repeatedly in the opposite direction.

* * *

ELECTRIC DRIVE IN THE MACHINE SHOP

When electric drive was first being introduced into machine shops and factory equipment, claims were made for the power saved by elimination of line-shaft and belt losses, and the more important but not obvious economies were not pointed out, either because of ignorance or lack of appreciation. In the machine shop the greatest advantage of electric drive doubtless lies in the increase of product made possible by constantly adjusting the speed of the work to the full capacity of the cutter and thus working the machine always at its maximum rating, pre-supposing that variable speed motors are used to drive the machines. In a paper on the economy of electric drive in machine shops, to be presented before the A. S. M. E. in December, Mr. De Leeuw lays stress on this element of advantage, it being of much greater importance than the mere saving of power. In fact we may conclude that if it were simply a matter of saving power it is doubtful if it would pay in many cases to make the change from line-shaft drive to motor drive.

To illustrate, the conditions in a shop are quoted where an average of nine tons of metal is machined daily. The metal is, for the greater part, cast iron with a small percentage of steel, bronze and other metals. The chips removed amount to about 2,700 pounds of metal in a nine-hour day, making 300 pounds per hour or five pounds per minute. The power required is about 225 H.P. which, with a production of 5 pounds of chips per minute means that 45 H.P. per minute for each pound of chips removed is consumed. The power costs about $40 per H.P. per year or $9,000 per year including the steam for heating the building. Now, if one-half the amount spent for power could be saved by another mode of drive, the total possible gain would be only $4,500 per year. The shop employs about 500 men, and the gain per man would be $9 per year. The yearly product per man is about $2,000 from which it becomes evident that the small gain of 5 per cent in productive capacity would be much greater than the saving in power, and this is a large consideration in the economy of electric drive in the machine shop.

The importance of increasing the product by the substitution of electric drive for line-shafts and belts is greatest in the matter of capital investment when a plant is working practically to its limit, and any increase of capacity in the direction of new building and new machinery means perhaps a prohibitive cost, to say nothing of the delay in getting the equipment into shape. The substitution of electric drive to increase the capacity may make an increase in the number of machines unnecessary, and thus save making a large investment, much greater than the cost of the change. There are other advantages than those of electric drive that may be enumerated, but the increase in efficiency of machine and man made possible by the variable speed motor is the chief consideration for the machine shop manager.

* * *

STRESSES IN CURVED MACHINE MEMBERS

The A. S. M. E. paper on stresses in curved machine members, abstracted in another part of this number, engineering edition, is a valuable contribution to the society's proceedings, being one that can be studied with profit by designers of hooks, punch and shear frames, C-frame riveters and other similar structures in which the loads induce combined tensile and bending stress. The familiar formula $f_c = \frac{W}{A} + \frac{Wle}{I}$ found in text-books on machine design is based on the assumption that curved machine members under load act as do beams originally straight, but this supposition has been known for some time to be erroneous, the calculated factor of safety being much more than that known to actually exist. The results of tests on hooks of cast steel and wrought iron at Columbia University show conclusively that the old formula is very seriously at fault, the actual load at the elastic limit being, roughly, one-half, or less, of the calculated load.

So serious a discrepancy between the results of calculations and actual tests, and on the wrong side at that, cannot be tolerated. Future treatment of the subject in works on machine design must take into account the newer theory from which Andrews and Pearson have deduced a formula that appears to agree well with the results of tests. In fact, there is a surprisingly close agreement of the test loads and the calculated loads in the Columbia experiments when figured by this formula. Unfortunately it is not readily handled by a designer unfamiliar with higher analysis, but by the use of constants that have been derived for the common hook section, the use of the resulting modified expression is made comparatively easy.

It is cases like this that have given cause for the not uncommon belief that theory and practice do not agree, and it is not strange that the hard-headed practical man has some contempt for the purely theoretical designer, when machine members fall with no apparent reason in theory. But, theory and practice will agree when the theory takes into consideration all the factors affecting the problem and the mathematical formulas are correctly deduced. Effort to fit a fact to an untenable theory must necessarily fail, and when it fails, as in this case, in producing results that are tolerable, we must change the theory to fit the fact.

* * *

TURBINE PUMP MOTOR DRIVE

The turbine pump has come to be recognized as a practical pumping machine peculiarly well suited to certain conditions, the same as the steam turbine prime mover. It has been used for pumping against very high heads with success, but notwithstanding its essential simplicity, some peculiar problems have been met in its design and construction that have baffled the designers. One of these problems concerns the matter of drive. When a turbine pump is driven by an electric motor, the motor conditions become very bad if the head fluctuates. There is great danger of over-loading the motor with a low head, strange as it may seem at first thought. The natural inference is that with a low head the load would become less than with a high head, but the contrary is the case. A turbine pump designed to deliver a certain quantity of water against a head, say, of 100 feet will operate smoothly when driven by an electric motor so long as the water approximates the given head, but should the head fall to 75 or 50 feet, the chances are that the motor would be over-loaded. A larger quantity of water than normal is pumped at lower efficiency, the work done increasing rapidly with decrease of head.

The reason for this action is that the turbine pump operates under conditions analogons to those affecting the electric generator. A generator carries its normal load so long as the resistance in its circuit is that for which it is designed. But, should a short circuit or reduction of resistance through other means occur, the generator at once becomes over-loaded, and will break down or burn out if continued in operation. In the case of a turbine pump, the head corresponds to the ohmic resistance and the quantity of water pumped to the amperes of current. When the head under which a motor-driven turbine pump is working decreases, the pressure or resistance is decreased and the quantity of water handled is increased, the consequence being that the pump is over-loaded while working at a low efficiency, the same as the generator. The over-load must be carried by the motor and unless the motor has good over-load capacity it will not stand up under the service. However, the characteristics of the best turbine pumps have been improved so that considerable fluctuation of head will not greatly increase the load or decrease the pump efficiency.

GASOLINE AND ALCOHOL MOTORS COMPARED

The United States Geological Survey, has just issued a bulletin on "Commercial Deductions from Comparisons of Gasoline and Alcohol Tests on Internal-Combustion Engines," by Robert M. Strong. The tests, which were under the technical direction of R. H. Fernald, engineer in charge of the producer-gas section of the technologic branch, were conducted at the fuel-testing plant in St. Louis, Mo., and at Norfolk, Va. The tests dealt primarily with gasoline, forming part of the investigation of mineral fuels provided for by acts of Congress. To determine the relative economy and efficiency of gasoline it was compared with denatured alcohol. When the series of tests was started, it was found that it took from one and one-half to two times as much alcohol as gasoline to produce a given power. With special alcohol engines, entirely suited to the use of alcohol, the latter fuel has been made to do as much work, gallon for gallon, as the gasoline.

By using alcohol in an alcohol engine with a high degree of compression (about 180 pounds per square inch above atmospheric pressure—much higher than can be used for gasoline on account of pre-ignition from the high temperatures produced by compression) the fuel consumption rate in gallons per horse-power per hour can be reduced to practically the same as the rate of consumption of gasoline for a gasoline engine of the same size and speed. The indications are that this possible 1-to-1 fuel consumption, ratio by volume, for gasoline and alcohol engines, will hold true for any size or speed, if the cylinder dimensions and revolutions per minute of the two engines are the same.

The low heating value of completely denatured alcohol will average 10,500 British thermal units per pound, or 71,900 British thermal units per gallon. The low heating value of 0.71 to 0.73 specific gravity gasoline will average 19,200 British thermal units per pound, or 115,800 British thermal units per gallon. Thus the low heating value of a pound of alcohol is approximately six-tenths of the low heating value of a pound of gasoline. A pound of gasoline requires about twice the weight of air for complete combustion as a pound of alcohol.

A gasoline engine having a compression pressure of 70 pounds but otherwise as well suited to the economical use of denatured alcohol as gasoline, will, when using alcohol, have an available horse-power about ten per cent greater than when using gasoline. When the fuels for which they are designed are used to an equal advantage, the maximum available horse-power of an alcohol engine having a compression pressure of 180 pounds is about 30 per cent greater than that of a gasoline engine having a compression pressure of 70 pounds, but of the same size in respect to cylinder diameter, stroke and speed.

Alcohol diluted with water in any proportion, from denatured alcohol which contains about 10 per cent of water, to mixtures containing about as much water as denatured alcohol, can be used in gasoline and alcohol engines if they are properly equipped and adjusted.

When used in an engine having a constant degree of compression, the amount of pure alcohol required for any given load increases and the maximum available horse-power of the engine decreases with a diminution in the percentage of pure alcohol in the diluted alcohol supplied. The rate of increase and decrease respectively is such, however, that the use of 80 per cent alcohol instead of 90 per cent, or denatured alcohol, has but little effect upon the performance of the engine; so that if 80 per cent alcohol can be had for 15 per cent less cost than 90 per cent alcohol and could be sold without tax when denatured, it would be more economical to use the 80 per cent alcohol.

The relative hazard involved in the storage and handling of gasoline and denatured alcohol is of particular importance in considering their use as fuels for marine and factory engines and engines to be placed in the basements of office buildings, in coast defense fortifications, or in like places where a general fire would be likely to result from the accidental burning of the fuel stored or carried for immediate supply, or where the forming of explosive or inflammable mixtures of the fuel vapors and air in the immediate vicinity would be hazardous. It is indicated by statistics and is also the general consensus of opinion of those experienced in handling gasoline, kerosene, and alcohol that the hazard involved in the use of denatured alcohol is very much less than in the use of gasoline and possibly less than in the use of kerosene, but as yet the relative fire risk has not been definitely established. Considerable work has been done on this phase of the investigation and a series of tests that will be of assistance in determining the relative hazard involved in the use of these fuels is in progress at the testing station of the Survey in Pittsburg.

In regard to general cleanliness, such as absence of smoke and disagreeable odors, alcohol has many advantages over gasoline or kerosene as a fuel. The exhaust from an alcohol engine is never clouded with a black or grayish smoke, as is the exhaust of a gasoline or kerosene engine when the combustion of the fuel is incomplete, and, it is seldom, if ever, clouded with a bluish smoke when a cylinder oil of too low a fire test is used or an excessive amount supplied, as is so often the case with a gasoline engine. The odors of denatured alcohol and the exhaust gases from an alcohol engine are also not likely to be as obnoxious as the odor of gasoline and its products of combustion.

Very few alcohol engines are being used in the United States at the present time, and but little has been done toward mak-

ing them as adaptable as gasoline engines to the requirements of the various classes of service. Engines for stationary, marine, and traction service, automobiles, motor trucks, and motor railway cars designed especially to use denatured alcohol have, however, been tried with considerable success.

The price of denatured alcohol is greater than the price of gasoline, and the quantity of denatured alcohol consumed by an alcohol engine as ordinarily constructed and operated is, in general, relatively greater than the quantity of gasoline consumed by a gasoline engine of the same type. Considerable attention is being given to the development of processes for the manufacture of alcohol from cheap raw materials which are generally available, and it seems reasonable to expect that the price of denatured alcohol will eventually become as low or lower than the price of gasoline, especially if the price of gasoline advances. It also seems reasonable to expect a greater general improvement in alcohol engines than in gasoline engines.

When used as a fuel, denatured alcohol is not always so classed as to be exempt from restrictions placed on the use of gasoline by the rules of insurance and transportation companies or city ordinances. The restrictions that are placed on the use of denatured alcohol are, however, never greater than those placed on the use of gasoline. In some places, they are such that the use of an alcohol engine is permitted where the use of a gasoline engine is prohibited. For instance, alcohol motor trucks and automobiles are admitted to many steamer piers that are not open to gasoline machines.

When the restrictions placed upon the use of denatured alcohol are less than those placed on the use of gasoline or where safety and cleanliness are important requisites, the advantages to be gained by the use of alcohol engines in place of gasoline engines may be such as to overbalance a considerable increase in fuel expense, especially if the cost of a fuel is but a small portion of the total expense involved, as is often the case. Denatured alcohol will, however, probably not be used for power purposes to any great extent until its price and the price of gasoline become equal and the equality of gasoline and alcohol engines in respect to ability to service required and quantity of fuel consumed per brake horse-power, which has been demonstrated to be possible, becomes more generally realized.

A further general development in the design and construction of engines that use kerosene, or cheaper distillates, and the crude petroleums may be reasonably expected and may delay the extensive use of denatured alcohol for some time to come, but as yet comparatively few data pertaining to this phase of the general investigation are available.

* * *

AUTOMOBILE SPRINGS

The development of the automobile has proved that the ordinary carriage spring is inadequate to meet the severe requirements of automobile service. Manufacturers have experimented with many grades of foreign and domestic steels including chrome-nickel, tungsten, vanadium and other special alloys with results more or less satisfactory depending largely on the heat treatment. The experience of some makers, members of the A. L. A. M., appears to indicate that silico-manganese springs endure longer than high carbon steel, but whatever steel is used, it must be made to certain specified analyses and heat treated in an approved manner to yield satisfaction. It is necessary to have the furnaces under pyrometer control, and so closely regulated that there is but very slight variation in temperature. The most commonly used heat treatments are annealing, hardening, tempering, hardening and annealing, double annealing, and double hardening. A long flat spring is preferable to a spring with considerable arch as the fiber stress is lower for the same load and deflection. The deflection should not be more than one-fourth inch per hundred pounds. The reason leaf springs are preferable to coil springs is the greater dampening effect of the leaf springs, because of the friction between the component parts of the spring. A leaf spring does not return to its normal position so quickly and forcibly as a coil spring of the same capacity, hence its easier effect upon the car and its occupants.

THE DESIGN OF CURVED MACHINE MEMBERS UNDER ECCENTRIC LOAD*

Machine members, such as frames for punches, shears and riveters, hooks and the like, when subjected to load, are generally supposed to behave like beams originally straight and subjected to the same conditions. The usual analysis applied to such beams in determining the proportions required to withstand safely a given stress assumes that the maximum tensile stress equals the load considered as uniformly distributed over the section plus the stress due to the eccentricity of the load. Symbolically expressed

$$f_t = \frac{W}{A} + \frac{Wlc}{I}$$

f_t = maximum intensity of tensile stress,
W = load on beam,
A = area of section,

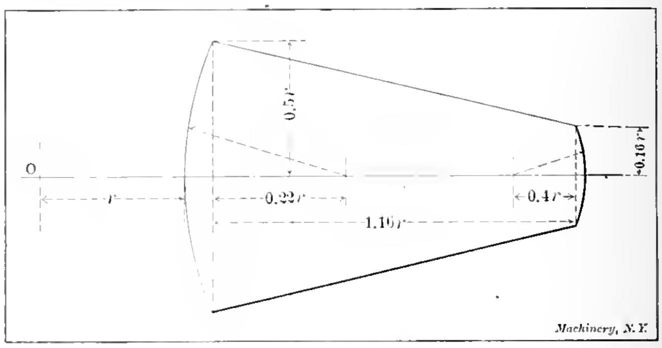

Fig. 1 Section of Crane Hook

l = eccentricity of loading,
c = distance from gravity axis of section to point under stress f_t
I = moment of inertia.

This analysis is unfortunately prevalent in textbooks on the design of machine elements and strength of materials, and has been accepted generally because of long standing. However, it does not agree with the results of experiment on members of this kind; in fact such experimental results are so different from results calculated by this formula that no confidence whatever can be placed in it, and safe proportions can be obtained only by the use of a large factor of safety.

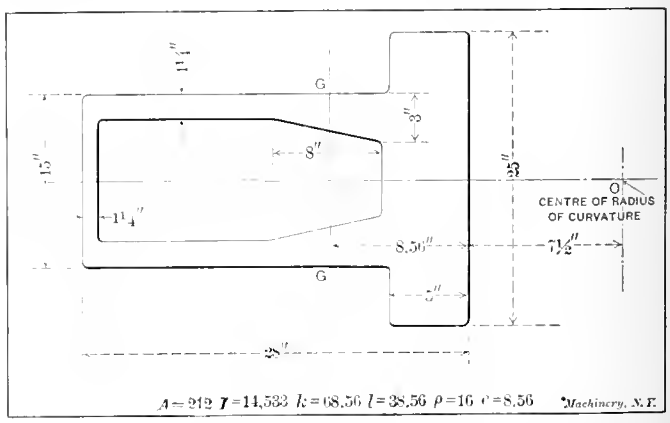

Fig. 2. Section of Punch and Riveter Frame

The results of a series of experiments which are remarkable in their disagreement with the results obtained by the formula are given in the accompanying table. The crane hook was taken as an example of a beam of this sort and experiments were conducted on ten hooks ranging from two to thirty tons rated capacity.

It is very evident that the assumptions on which the conventional formula is based are not correct, and that machine members designed on this basis have a much smaller factor of safety than is generally supposed. While this has been known in some quarters and attempts have been made to bring about an adjustment, no theory which has been developed seems to fit the case better than that evolved by E. S. Andrews and

* Abstract of paper by Prof. Walter Rautenstrauch, read before the November, 1909, meeting of the American Society of Mechanical Engineers.

Prof. Karl Pearson of London University. Their investigation gives the following expression for the tensile stress at the most strained point in the principal section of beam:

$$f_t = \frac{W}{A}\left[\frac{l}{\rho\gamma_2}\left(\frac{1}{\left(1-\frac{e}{\rho}\right)^{\gamma_1}}-\gamma_1\right)+1\right]$$

f_t = tensile stress at most strained point of section, pounds per square inch,
W = load on hook, pounds,
A = area of section, square inches,
l = distance from load line to gravity axis of section,
ρ = radius of curvature of belly of hook at gravity axis,
e = distance from gravity axis to point of maximum tensile stress,
γ_1 and γ_2 are functions the values of which are determined for each section by means of rather complicated higher analysis; approximate values are given in the following.

This formula was applied to each of the hooks tested, with the results recorded in the third line of the accompanying table. An inspection of this table will show how nearly the analysis of Mr. Andrews and Professor Pearson fits the case.

ANALYSIS OF HOOKS TESTED

Load at Elastic Limit, Pounds

Rated Capacity	30-ton Cast Steel	20-ton Cast Steel	15-ton Cast Steel	15-ton Wrought Iron	10-ton Cast Steel	10-ton Wrought Iron	5-ton Cast Steel	5-ton Wrought Iron	3-ton Cast Steel	2-ton Cast Steel
By test	56,000	30,000	48,000	16,000	18,000	16,000	18,000	14,000	8,500	4,700
By standard formula	115,000	70,000	145,000	73,000	43,000	26,000	52,300	20,800	11,900	14,900
By new formula	55,080	29,925	50 570	15,000	16,500	15,000	18,950	14,100	8,600	4,400

In its present form it is a rather unwieldy instrument in the hands of a designer, but it may be made more applicable to design than might be thought at first. The functions γ_1 and γ_2 are constants for all sections of similar form, that is, for all sections the proportions of which may be expressed as a function of some unit of dimension, for example, the radius of curvature. Under the same circumstances the entire expression within the brackets is a constant. The equation for a series of sizes and sections may therefore be written $f_t = \frac{W}{A}K$, or $A = \frac{W}{f_t}K$. The area is a function of the unit squared and therefore we may write $A = C'r^2$, or

$$r = \sqrt{\frac{K}{C'} \times \frac{W}{f_t}} = C\sqrt{\frac{W}{f_t}}$$

Applying this to the case of a series of hooks ranging from the minimum to the maximum to be manufactured, a standard form of section may be laid out as in Fig. 1, and the constant established. For the hooks tested by the writer the following values for the constant were found:

30-ton hook, cast steel	3.00
30-ton hook, cast steel	3.10
15-ton hook, cast steel	3.23
15-ton hook, wrought iron	4.29
10-ton hook, cast steel	3.49
10-ton hook, wrought iron	3.42
5-ton hook, cast steel	3.12
5-ton hook, wrought iron	3.12
3-ton hook, cast steel	3.78
2-ton hook, cast steel	3.74
Average	3.43

To make the case representative of present practice let such ratio of proportions be assigned to the section shown in Fig. 1 that $C = 3.4$. The design of a series of wrought iron hooks to sustain loads of from 2 to 40 tons with a limiting intensity of tensile stress of 30,000 pounds per square inch will require the following computations:

$$\text{40-ton hook, } r = 3.4\sqrt{\frac{80000}{30000}} = 5.54$$

$$\text{30-ton hook, } r = 3.4\sqrt{\frac{60000}{30000}} = 4.7$$

$$\text{20-ton hook, } r = 3.4\sqrt{\frac{40000}{30000}} = 3.94$$

$$\text{10-ton hook, } r = 3.4\sqrt{\frac{20000}{30000}} = 2.76$$

$$\text{5-ton hook, } r = 3.4\sqrt{\frac{10000}{30000}} = 1.95$$

$$\text{2-ton hook, } r = 3.4\sqrt{\frac{4000}{30000}} = 1.23$$

The proportions obtained above will be for loads giving a maximum stress at the elastic limit of the material. For cast steel different values will necessarily be obtained. The establishment of such a standard would lead to a very simple process for the determination of the principal section of a hook for any capacity; the proportions of the shank and other parts of the hook may readily be established on the same basis. The bottom of the hook, being subjected to much wear, cannot of course be proportioned on the basis of the stress analysis. The above standard section selected as an average representative of present practice is not, however, the most economic form of section from the standpoint of equal maximum tensile and compressive stresses. It has been pointed out by Professor Pearson that a section with such proportions is approximately an isosceles triangle with a radius of curvature of 1.75 of the height. The more nearly this form could be approached, the less would be the weight of hook.

Professor Goodman points out that for hook sections the functions γ_1 and γ_2 are expressed approximately as follows:

$$\gamma_2 = \frac{ke}{1.2\,\rho^2}$$

$$\gamma_1 = 1 + 1.1\,\gamma_2$$

where k = radius of gyration of the sections, the other symbols being as before noted.

In applying these empirical formulas to punch and riveter frame sections the writer has found that the results are not accurate, but that the values are better expressed as follows:

$$\gamma_2 = \frac{ke}{0.7\,\rho^2}$$

$$\gamma_1 = 1 + 1.1\,\gamma_2$$

For example, consider the design for a punch frame shown in Fig. 2. Computing the values for the functions γ_1 and γ_2 by the empirical formula, $\gamma_1 = 1.44$, $\gamma_2 = 0.4$. Whereupon the intensity of stress according to the new method of analysis for a force of 90,000 pounds at the punch will be

$$f_t = \frac{W}{A}\left[\frac{l}{\rho\gamma_2}\left(\frac{1}{\left(1-\frac{e}{\rho}\right)^{\gamma_1}}-\gamma_1\right)+1\right] = \text{8500 pounds per square inch, approximately}$$

According to the old formula used almost exclusively in text books, the value of f_t is expressed by $\frac{W}{A} + \frac{Wle}{I}$, whence $f_t = 2,450$. It may be clearly seen that were the punch in question designed for a limiting intensity of stress of 2,450 by the old formula, there would actually be a maximum stress of 8,500 pounds per square inch, which is hardly a safe value for cast iron and particularly for a large casting.

The above empirical formulas are derived from the results of computation of two sections and may not work out as correctly in all cases.

ASSEMBLING A 48-INCH MOTOR-DRIVEN PLANER*—1

ALFRED SPANGENBERG†

In planer erection, the principal points to be observed are that the housings must be parallel with each other and square with the bed; accuracy is essential in the fit of all sliding members and in the truth of all plane bearing surfaces; the gears should mesh properly and run smoothly; and the system must be such as to permit the various parts to be easily and quickly assembled, and avoid the necessity of fitting the members together for the laying-out operations. This, of course, presupposes the employment of jigs and gages, but, owing to the fact that planers of the 48-inch size and upwards are seldom built in large numbers at a time, and further, that there are many different types of drive, it is impracticable to indulge very freely in the use of elaborate jigs for duplicating the larger parts. However, many of the members used in the construction of planers are common to several different sizes and different types of drive, so that with a few very simple jigs and gages, the standard members can be made interchangeable, and in this way much expensive handling in laying out, and the consequent lost time, is avoided.

This article will deal principally with the erecting process on the bed, since the methods and processes employed in assembling the smaller units do not differ greatly from the practice used in assembling those of other machine tools. All the principles involved in the erection of a small planer are encountered in the case of a large machine, and many other complicating factors are added; hence, the erection a planer of the latter class will be described in detail. For this purpose a 48-inch motor-driven planer is selected, the general features of which are immediately apparent from a study of the half-tone Fig. 1.

As the machining processes are so intimately correlated with those of assembling, and as the methods employed in the latter are controlled to a great extent by the former, a brief description of the points to be observed in machining, together with the gages used for testing the larger members, will be illustrated and described. Referring to Fig. 2, A indicates a gage for testing the V-surfaces on both the bed and table, it being shown in position on the latter. The surfaces B, which support the gage, are finished first, and in this way the gage is always kept in a horizontal plane and both tracks are the same width, so that when the table is placed in position on the bed, the top of the table will be square with the housings. Another advantage of this gage over the usual form having a bearing on both sides of the V, is that only two parallel surfaces are finished and tested at a time, which often saves changing the planing tools and resetting the toolheads. The gage is squared by trying a 0.001-inch feeler on both sides of the gage as at C and C_1. To determine the width of the V tracks on the bed and table, measurements are taken at D and D_1, respectively.

The gage just described is not adapted for measuring the rack seat, however, and therefore another gage is provided which fits both sides of the V's, and is represented by the dotted lines. This gage carries a slide E which measures the rack seat. At F is shown a sheet iron support which fits either gage and prevents it from tipping over.

In the same illustration, at G, is shown the method of testing the table on surfaces H and H_1, which have a clearance of 0.005 inch between corresponding surfaces on the bed. As will be seen, the cast iron gage block I fits the V on the table and is provided with two surfaces, one, J, for setting the planer tool, and another, K, for testing surface H after the finishing cut is taken. To the right, at L, is shown another cast iron gage, this being used for setting the tools and testing the surfaces M and N; at L_1 the gage is shown in position in the V track of the bed. As will be pointed out later, the object of finishing the surface N last is to provide a locating surface for the jig for boring the bed. In this way, the rack gear shaft hole is bored the correct distance from the V tracks, so that when the table is in position, the table rack will mesh properly with its gears. Length gages O, P, Q, and R are for testing the measurements indicated, the latter also

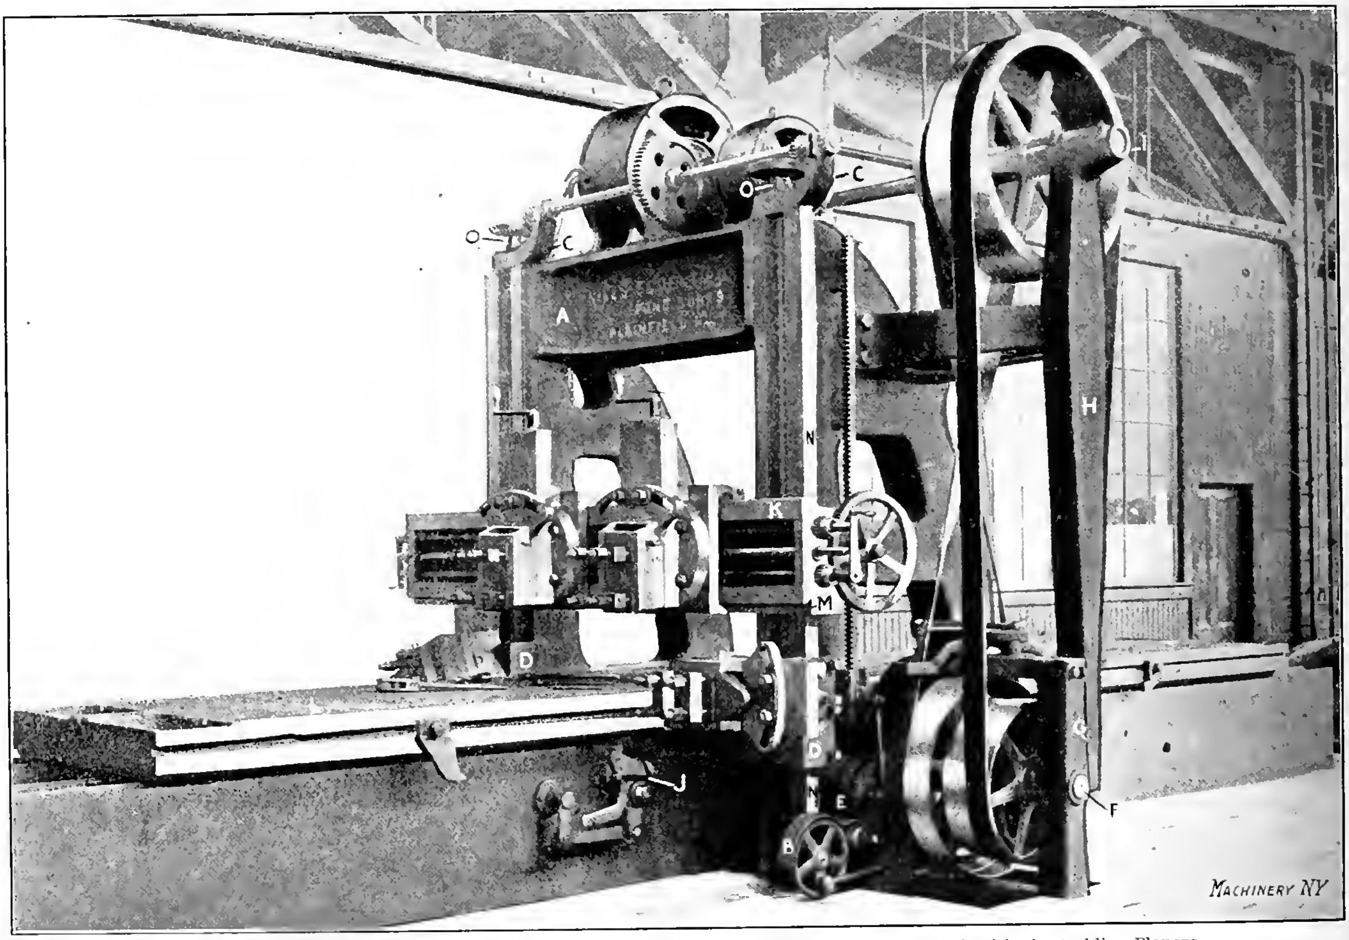

Fig. 1. Forty-eight-inch Motor-driven Planer, used as Example for Illustrating Principles Involved in Assembling Planers

† Address: 951 W. 5th St., Plainfield, N. J.

being used for taking the length of the arch *A*, Fig. 1.

It is essential, of course, that the housing cheeks on the bed be perfectly square with the V-tracks and parallel with each other. To accomplish this, the sweep *S*, carrying the Starrett indicator *T*, is used in connection with the straight-edge *U*, which reaches across the bed and extends a sufficient amount beyond one side to accommodate the swing of the indicator. By this means very accurate results are obtained. The operator holds the bar *V* in contact with the bed, and the flanged bearing *W*, being of ample diameter and ground true with the bar, keeps the bar in a vertical plane.

Boring and Drilling the Bed

The bed, having passed inspection with regard to the accuracy of the planing operations, is now sent to the horizontal boring and drilling machine where all the boring, drilling, and tapping operations are completed; one setting only is required, as the machine is provided with two separate columns carrying spindle heads, both working on each side of the bed simultaneously. In the line-engraving Fig. 3 the bed is seen resting on parallels *A* with the jig *B* in position ready for the operations just mentioned. As will be observed from the top view, the jig consists of three main castings *C*, *D*, and *E*, respectively, which are bolted to the three cast iron tie bars *F*; this construction permits adjustment of members *D* and *E* to compensate for beds having different widths over the housing cheeks. The jig rests on the top of the bed, and is located endwise with reference to the jig members *D* and *E* matching the bed casting, so that when the housings, which have been drilled by a separate jig, are bolted onto the bed, the castings will match properly. Set-screws *G* square the jig with the bed by holding the jig against surface *H*. Suitable stops, straps and bolts secure the jig and bed to the base-plate during these operations.

For boring and reaming the shaft holes *I*, *J*, *K*, *L*, and *M*, two boring bars having suitable cutters and reamers are used, similar to those shown in an article on Jigs and Fixtures, in MACHINERY, March, 1909, issue, Figs. 137 and 142, except that in the present case a middle support enables each bar to carry two cutters and two reamers. The jig is provided with removable hardened steel drill bushings for the housing bolt holes *N*, the tapping being accomplished at the same setting of the spindle. Drill and reamer bushings are used at *O* and *P*, while a fixed drill bushing *Q* permits a small hole to be drilled for the taper dowel pin, ample stock being left for reaming after the housings are bolted on and properly located. After the boring and drilling operations are completed, the bed is moved over to the erecting foundation where the erecting process proper begins.

Drilling the Housings

In Fig. 4, the front housing is shown at *A*, with jigs *B* and *C* in position for

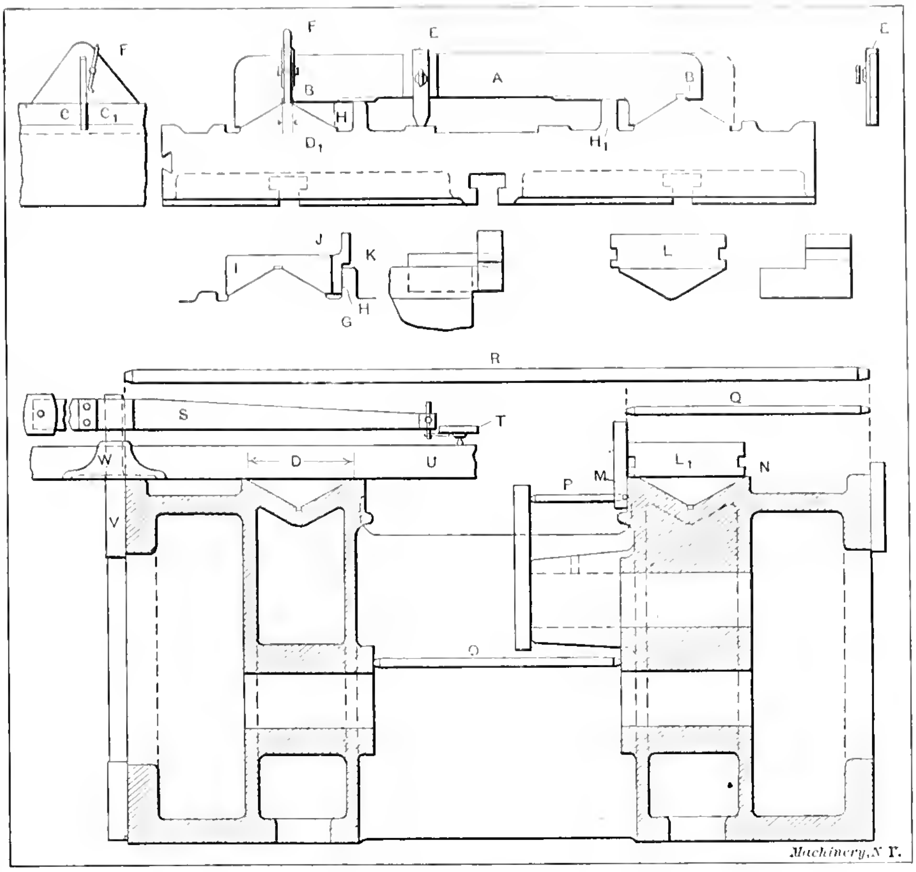

Fig. 2. Gages used for Testing Planing of Bed and Table

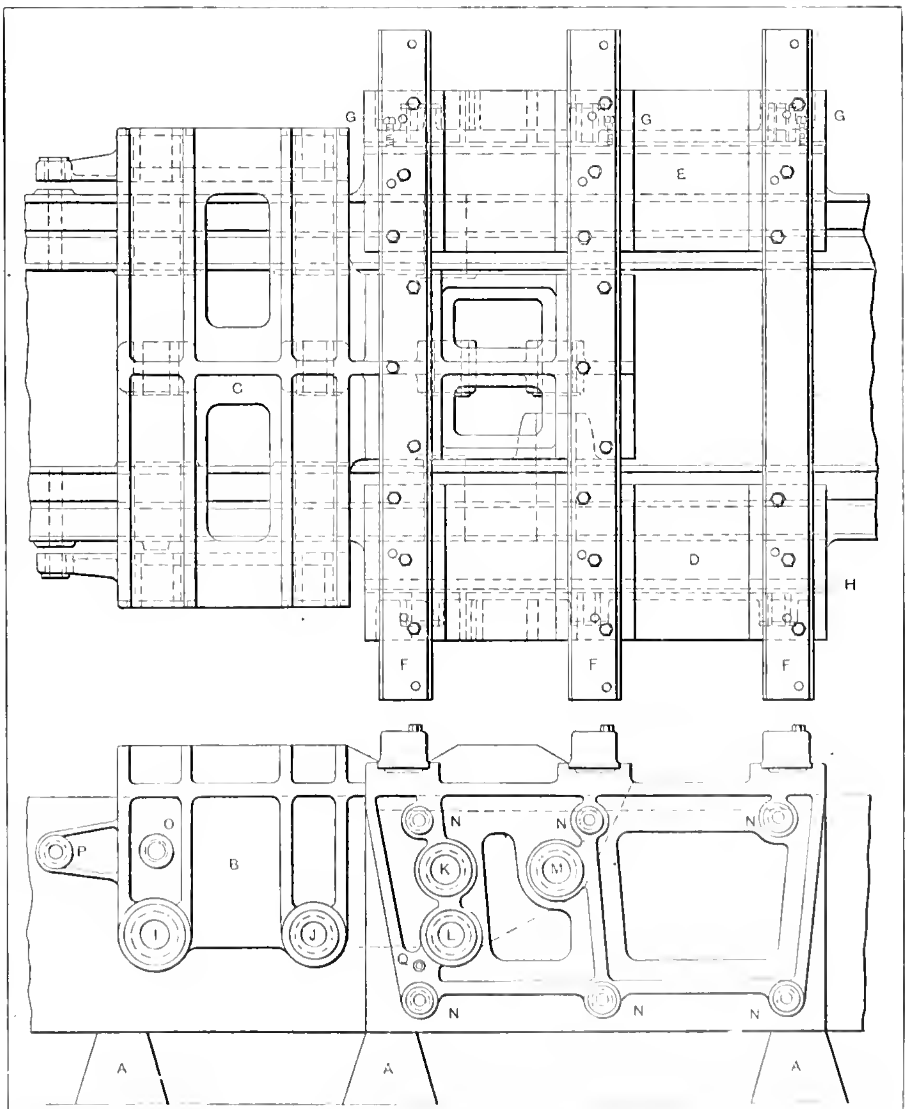

Fig. 3. Combination Boring and Drilling Jig in Position on the Bed

drilling the cheek bolt holes and the arch seat tap holes, respectively; the same jigs are used for the back housing, and jig *C* is also used for drilling the arch casting. The locating points and method of clamping the jigs are indicated in the engraving; as a matter of precaution, after the first hole is drilled in each case, a pin is inserted through the jig bushing into the drilled hole, thus preventing the jig from moving.

All drilling and tapping on this side of the housing being completed, jig *C* is removed, while *B* is secured by four bolts *D* having round heads fitting in place of the drill bushing collars, after which the housing is turned over in the position shown in Fig. 7. The drilling operations are performed on a cast iron base plate provided with a portable motor-driven radial drill, this base also serving the purpose of a surface plate for laying out the work. It is important that the driving shaft bracket hole *A* and feed box shaft hole *C* line up nicely with corresponding holes in the bed, so that the shafts will run perfectly free when assembled. In order to accomplish this without having to assemble the members and housing on the bed, jig *B* is provided with flanged bearings, as at *D*, which support arbors located in the exact center position of the respective driving and feed shafts. The location of the bearings in this jig, and also of the bolt holes *E* is found by clamping the jig to the bed jig member *D*, Fig. 3, and boring the former in this position, so that the two jigs are identical with respect to the locating points and center distances of the various holes.

Referring again to Fig. 7, driving shaft bracket *F* is first centered by the bushing *G* being pushed down into the hole; then the outboard bearing *H* and its member *I* are set approximately correct by means of shaft *J* and jig *K*, and held in this position by C-clamps, after which the truth of bearing *H* with respect to its being square is tested by means of sweep *L*, indicator *M* and test block *N*, as shown in the engraving. When it is determined that bearing *H* is square and properly set, so that bushing *O* enters the hole in jig *K* without springing the shaft, all the clamping bolt holes are marked off, the brackets removed, and the holes drilled and tapped; then the brackets are bolted on, reset in the same manner, and the dowel pins fitted. In setting and testing these bearing brackets, particular care is exercised to insure the accuracy of the work, thereby saving much time when assembling the parts. As was stated at the outset, the fact that these driving works generally are of a special nature, is the reason jigs are not provided for each individual member.

The cam operating lever bracket *P* is marked off after being set lengthways to the correct dimension *Q*, and sideways so that the center line of its shaft will coincide with a line laid off on the housing the right distance from surface *R*. A simple jig for drilling the feed rack casing holes is shown at *S*, the method of locating and clamping it being immediately apparent. Jig *T* is for drilling the feed-box clamping bolt holes; the jig consists of a flat plate centered by means of an arbor the same as at *D*, and located by a pin fitting into housing dowel pin hole *U*. A jig of similar construction and

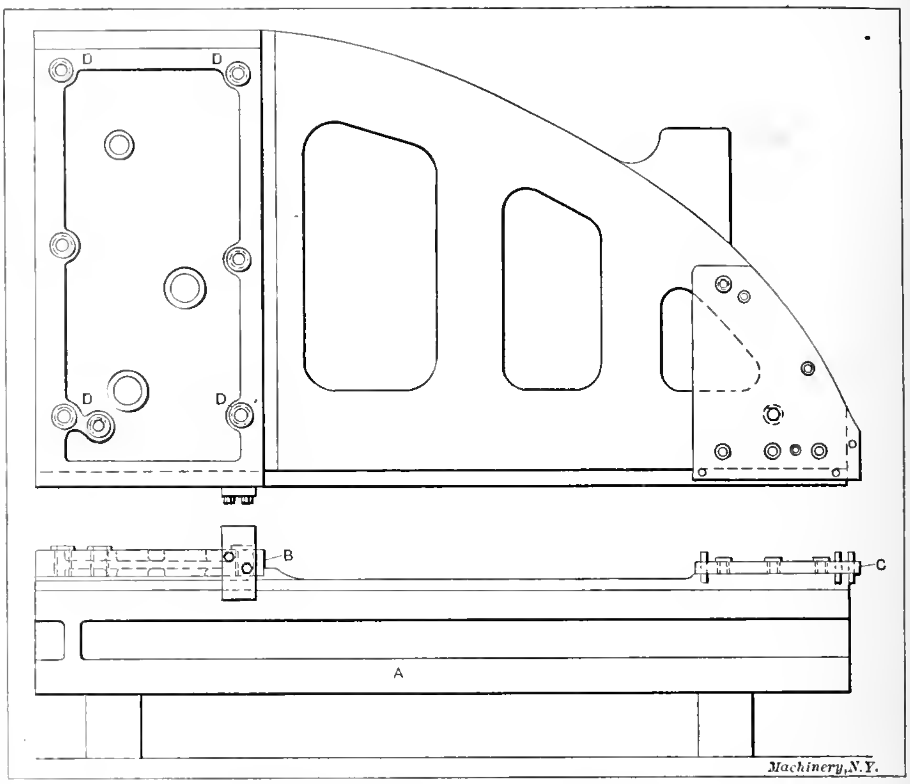

Fig. 4. Front Housing with Jigs in Position for Drilling Clamping Bolt Holes. Same Jigs are used for Similar Operations on the Back Housing

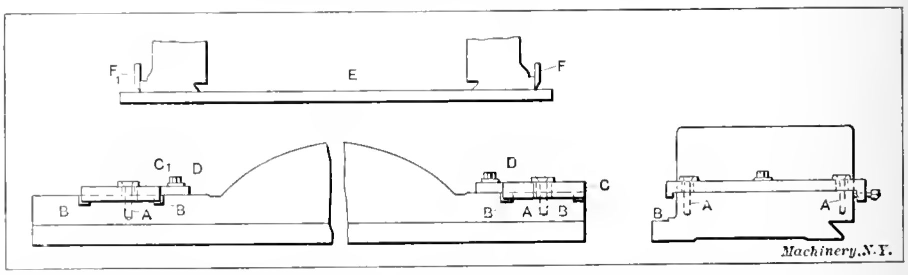

Fig. 5. Jigs for Drilling Stud Holes in Back of Cross-rail. Setting of Jig C_1 Endwise, is accomplished by transferring Measurement from Housings by Means of Wooden Straightedge E

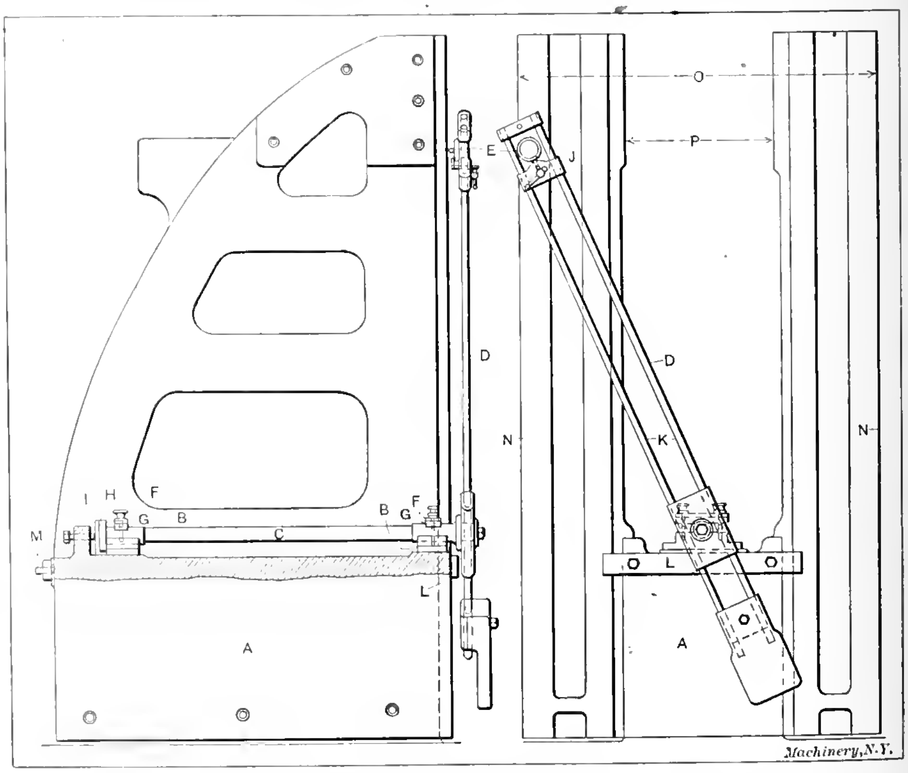

Fig. 6. Special Fixture used for Testing Alignment of Housing Faces and provided with Sweep for Carrying Starrett Indicator

centered in the same manner, is illustrated at *V*; this jig drills the clamping bolt holes for a bracket that carries the side-head feed shaft. Simple jigs, not shown, are provided for drilling for the feed bracket *B* and elevating screw brackets *C*, Fig. 1, these two operations being performed on a horizontal drill. This completes the drilling on the front housing, and after the necessary drilling is performed on the back housing, using the same jigs as previously explained, the housings are tested to determine the accuracy of the planing.

Testing the Housings

One of the essential requirements of a first-class planer is that it must produce accurate work when using the side-heads, and this means that the ways on the housings be perfectly true and parallel. When making this test, as shown in Fig. 6, the housings occupy the same position as when assembled

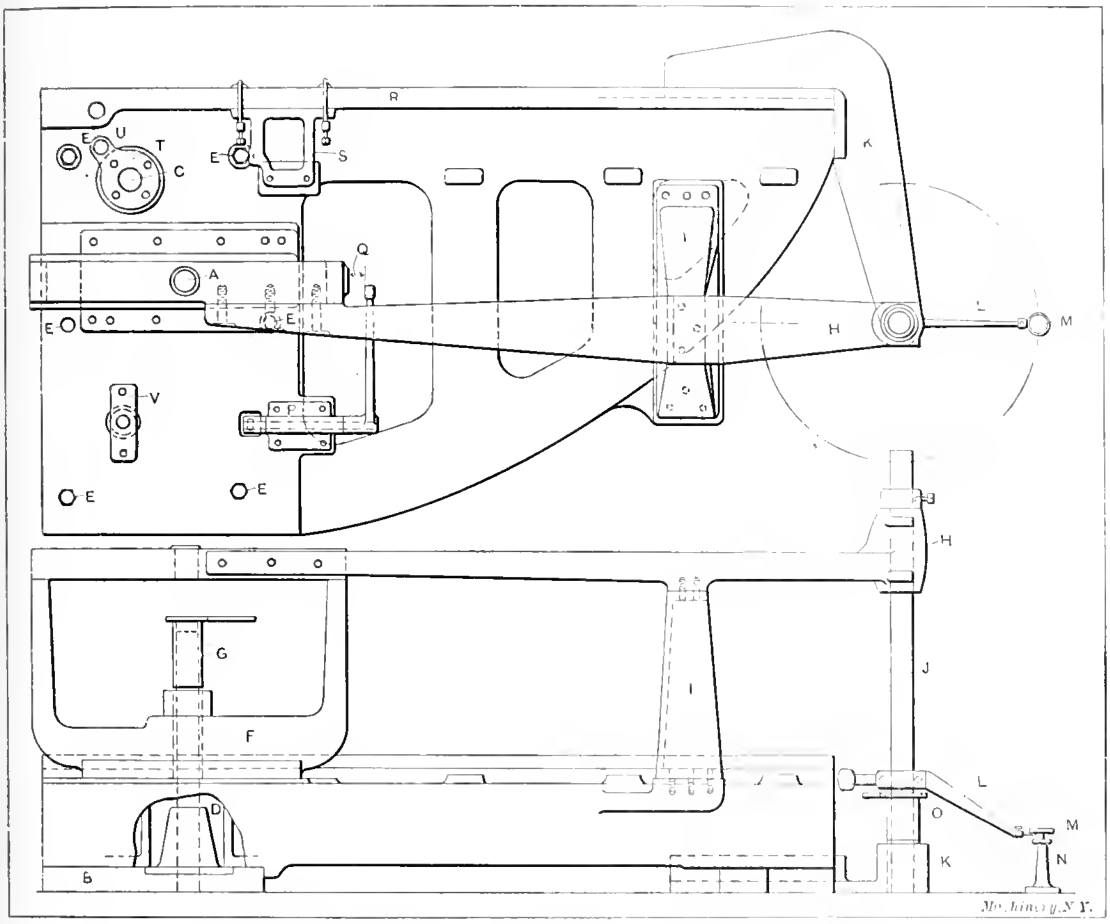

Fig. 7. Method of Setting and Laying out Holes for the Driving and Feed Members on the Front Housing

on their bed, and it is at once apparent that whether or not the front faces stand perfectly plumb, is a matter of little consequence, so long as the faces lie in the same plane. With respect to the side faces and angles, however, the conditions are different; these must be square with the bed. Casting *A* which corresponds to the cheeks on the planer bed, is bolted to a suitable concrete foundation and carries two V-blocks *B*, forming bearings for the sweep bar *C* which in turn supports sweep *D* and indicator *E*. The bar is held in the V-blocks by straps *F* and wooden blocks *G*, while collar *H* and its thrust bearing *I* take up all lateral motion. The construction of sweep proper, *D*, is such that clamp *J*, carrying the indicator, may be secured in any position of its travel between the two seamless steel tubes *K*, which enables readings to be taken at various points.

After being bolted onto the jig, the housings are located against strap *L* by means of screws as at *M*. It is desirable that the front faces show about 0.001 inch low at their outer edges, as at *N*, so that when the cross-rail is in position it will surely have a bearing across the entire face of each housing. Measurements are also taken across *O* at various heights, and between the arch seats *P*, to determine the parallelism of these surfaces. It should be explained that, in the side view, the front housing only is shown for the purpose of more clearly illustrating the sweep bearings. The housings having passed inspection in this test, are next turned face uppermost in a suitable pit for convenience in scraping on the side-head shoes *D*, Fig. 1, after which the housings are ready to be placed in position on the bed.

* * *

MODERN CONDENSER PERFORMANCE

Steam engineers in the past have generally considered that from the standpoints of coal consumption and plant operation, the reciprocating engine gained little from a vacuum above 26 inches of mercury. This opinion was in part due, especially in marine circles, to the practice of driving the auxiliaries from the main engine, so that, there being no auxiliary exhaust to heat the feed, a lower vacuum meant hotter feed water. The steam turbine, however, because of its ability to deal efficiently with steam in large volumes, easily shows a gain of from 5 to 10 per cent in steam economy for every additional inch of vacuum above 26 inches, and the heating of the feed water is properly left to the economizers or to heaters utilizing the exhaust of auxiliaries. The premium thus put upon condenser performance has resulted in a closer scrutiny of the several processes which go on in a condenser.

The activity of the several groups of tubes in a surface condenser can be quite accurately inferred from the rise in temperature of the water passing through them. By inserting thermometers in the water-boxes it has thus been discovered that in the ordinary surface condenser most of the heat is absorbed—that is, most of the steam is condensed—in the first few rows at the top. The transmission of heat through condenser tubes may be affected by the flooding of the lower tubes by the water descending from those above or by the tubes being immersed in air. The velocity of the steam and of the circulating water, and the cleanliness of the tubes, are also governing factors.

While much scientific investigation has been devoted to the effects of water velocity and of steam velocity, the possibilities of improvement in this direction are limited by the fact that excessively high steam velocities mean back pressure while high water velocities involve the consumption of an excessive amount of power in the circulating pumps. The avoidance of air-drowning and of the flooding of the tubes has, however, resulted in greatly reducing the amount of condenser tube surface for a given amount and temperature of circulating water; that is, with the same surface, less, or water of a higher temperature, will maintain the same vacuum.

Air-drowning is prevented by avoidance of air leaks, provision of sufficient air pump capacity and arrangements for removing the air at the lowest possible temperature and hence at the greatest density. The flooding of tubes has been met in various ways. To avoid this flooding effect, the four "Dry Tube" condensers, installed by the Wheeler Condenser and Engineering Co. in the Williamsburg power station of the Transit Development Co. of Brooklyn, are equipped with horizontal baffle plates which are interposed between the sev-

eral banks of tubes. The exhaust steam from the double-flow Westinghouse turbines installed on the floor above, enters the condensers at the top and upon condensing falls upon these baffle or rain plates, which catch the water and carry it to the outside against the shell, down which it flows to the hot well without coming in contact with other tubes. To permit the passage of the steam past these rain plates there are openings, around the edge of which the plate is turned up to form a vertical lip, preventing an overflow of water. These openings are so staggered that the steam will reach all parts of the tubes, insuring complete utilization of all the surface. Simple as this expedient appears, the results obtained by means of it have been remarkable, as will be apparent from a consideration of the rate of heat transfer developed in this condenser under working conditions. It was formerly customary to assume the rate of heat transfer through surface condenser tubes, closed feed water heaters, and similar appliances as between 200 and 300 British thermal units per square foot per hour per degree difference of temperature between the water inside the tubes and the steam outside.

After a series of tests of one of the condensers in the plant referred to, which was designed to handle 180,000 pounds of steam per hour and to give a vacuum equivalent to 2 inches absolute pressure with 70 degrees F. circulating water, the transmission of heat per square foot per hour per degree difference of temperature was found to be between 800 and 900 British thermal units which is two to three times greater than is obtained from the ordinary surface condenser. During the tests the rate of condensation varied from 164,586 pounds to 220,200 pounds of steam per hour. These results show that the guaranteed vacuum could have been maintained with even less condensing surface than was actually installed, although the latter is considerably below usual practice. That is, while the ordinary condenser would contain 2 or 3 square feet of surface per rated horse-power, this condenser contains only 1.5 square foot per rated electrical horse-power.

With the jet condenser, it is not so much a question of improving the rate of heat transmission as of insuring thoroughness of intermixture, that is, of bringing each particle of water so intimately in contact with the steam that it will be heated to the steam temperature and its full capacity for absorbing heat realized. This is desirable in order to reduce the amount of circulating water and to prevent loss of temperature in the hot well. By reducing the amount of circulating water, the power required for pumping it is minimized and less air is brought into the condenser. At first thought it would seem an easier and simpler matter to secure high temperature in the circulating water leaving a jet condenser than in that leaving a surface condenser, since in the jet condenser the water and steam come into actual immediate contact; nevertheless, the fact remains that the water discharged from most jet condensers does not rise nearer than to within 10 to 20 degrees F. of the temperature of the steam.

The results of tests of a Wheeler "Rain Type" jet condenser connected with a Westinghouse-Parsons 1,000-kilowatt steam turbine are given in the accompanying table.

Vacuum, inches	Absolute Pressure, Ins. Mer.	Corresponding Temp.* of Exh. Steam	Injection Temperature In	Injection Temperature Out	Difference in Temp. of Steam and Cir. Water
28.65	1.25	85.5	44	85	0.5
28.7	1.2	85.	44	85	0.0
28.7	1.2	85.	44	83	2.0
28.75	1.15	83.5	44	80	3.5
28.75	1.15	83.5	44	81	2.5
28.55	1.35	88.5	44	87	1.5
28.75	1.15	83.5	43	79	4.5
28.75	1.15	83.5	43	76	7.5

* Temperatures given in degrees Fahrenheit

As will be seen, the outgoing circulating water kept within from ½ to 7½ degrees of the temperature corresponding to that of the exhaust steam. This condenser is of a new design and is so constructed that the steam enters through an opening at the left, passes horizontally across through a shower of water, ascends to the second level, passes to the left through an upper shower, and finally all that is left of the steam vapor together with the air, and other gases, passes horizontally to the right, and over the entering and coldest water at the top to the dry vacuum pump suction opening in the uppermost part of the shell. The water is introduced at the upper right hand corner into an extended trough or pan, from which it overflows through numerous short tubes, falling into a second and similar pan provided with similar overflow pipes and weir, and finally falling into the lower part of the shell, and overflowing thence to the barometric column or to the centrifugal or other type of pump serving to overcome the atmospheric pressure. The water is finely divided by small baffle plates hung below the tubes.

On the day of the test, the barometer stood at 29.9 inches, while the street railway load on the turbine varied from full load to 10 per cent overload. Temperature readings were taken by thermometers placed in the exhaust pipe and in the hot well, while the vacuum readings were taken from a mercury column connected directly to the condenser. The number of pounds of circulating water required to condense 1 pound of steam was found by calculation to be 24.3. As a matter of fact, the amount would be less than this, since not all of the exhaust is steam when it arrives at the condenser, some of it having already condensed in the turbine and in the exhaust pipe, due to work performed and to radiation.

LENGTH OF RECESS IN THE BORE OF MILLING CUTTERS

The accompanying table has been compiled with a view of giving at a glance the length of recess in the bore of milling cutters, including cutters from one-half inch width of face up to cutters six inches long. It will be seen, by studying the figures in the table, that, in general, the length of the recess is about half of the total length or width of the face of the cutter, and the length of the bearing at each end is about one-quarter of the total length. A.

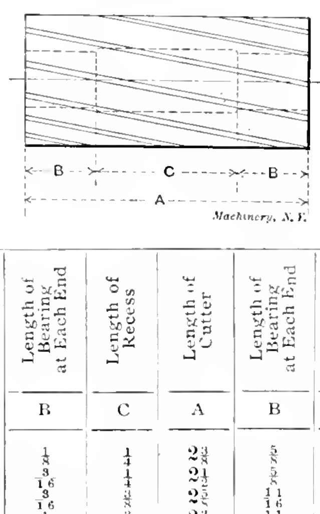

TABLE GIVING LENGTH OF RECESS IN THE BORE OF MILLING CUTTERS

* * *

A remarkable demonstration of the possibilities of gas producers and producer gas engines for boat propulsion was described in the August issue of the *International Marine Engineering*. A boat 40 feet long over-all, 9 feet beam, driven by a four-cylinder 35 horse-power gas engine, covered between 800 and 900 miles at an average speed of from 8 to 9 miles an hour on one ton of pea anthracite coal, used for producing the gas in a small gas producer installed on the boat. In addition to the greater safety, it is stated that the cost of operation is about one-tenth that of a gasoline engine using gasoline at fifteen cents a gallon.

INTERESTING TOOLS AND METHODS OF CINCINNATI SHOPS—2

THE LODGE & SHIPLEY MACHINE TOOL COMPANY

ETHAN VIALL*

The names of Spring Grove and Colerain Avenues become very familiar to the man who visits the Cincinnati tool and machine tool shops—more so perhaps than the names of any

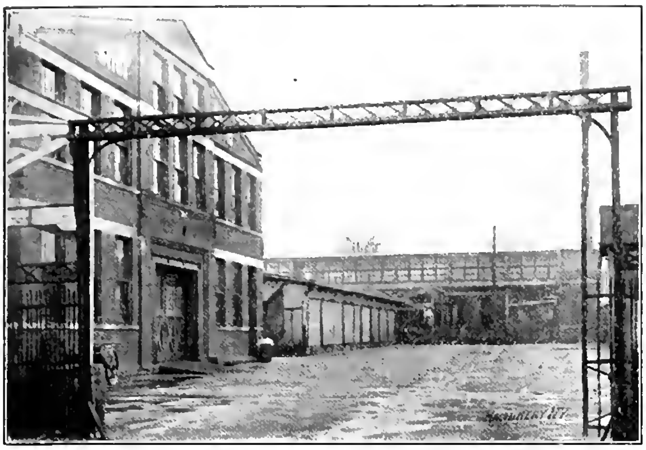

Fig. 1. Paved Court at the Lodge & Shipley Plant for Teaming Purposes

other streets there, for some of the best-known machine tool building shops in the world are easily reached by taking the cars that run from Fountain Square in the heart of the city

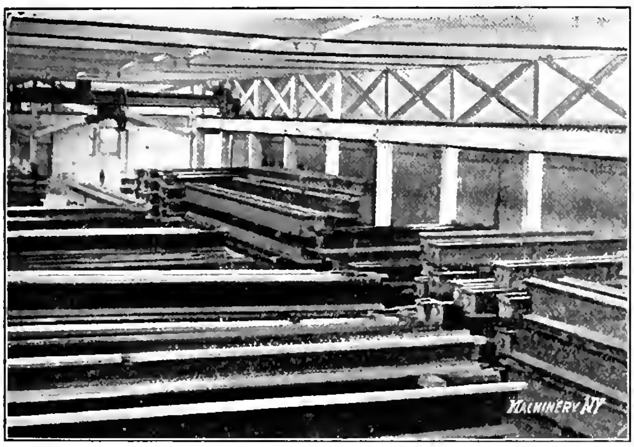

Fig. 2. Lathe Bed Storage House with Traveling Crane and Sliding Doors along the Side

out along these two avenues. It is worth while for any mechanic who can possibly do so to take the time to go through a few of these shops at least, and all of them if he can, and naturally, even if only a few were selected, he would not overlook as large and well-known a plant as that of the Lodge & Shipley Machine Tool Co., at 3055-3065 Colerain Ave., which makes nothing but lathes and lathe attachments or fittings, and where he will be given a hearty welcome and a guide who will show and explain everything to him that is worth while. In a trip through this plant, a reader of MACHINERY would see many old mechanical acquaintances in the line of tools and methods that have been introduced to him from time to time through these columns, yet there are many things to be seen which have never been described and many things impossible to describe—adequately at least. The present article does not aim to go very deeply into descriptions of shop methods or practice, but simply to present a few of the "high spots" touched here and there in a recent tour of inspection.

System and neatness prevail everywhere and many time- and labor-saving devices are to be found on every hand. The old way for a workman to get the big traveling crane, by going out in the runway, waving his arms like a windmill and yelling until he was hoarse, at the sleepy crane operator two or three hundred feet away, has all been done away with, and now the workman presses one of the buttons set at convenient distances along the shop runway, a red light is flashed in plain view of the crane man and unless already employed, he at once runs his crane to where it is needed. Then, too, there is a messenger system in use that obviates the necessity of a machinist leaving his work to get a new jig or tool, as he has only to press a button close to his machine and an annunciator near the tool room indicates to a waiting messenger boy where he is wanted, as all machines are numbered; he then goes at once and finds out what is wanted, gets it for the man and returns to his place ready for another call.

The traveling crane system is unusually complete and is so arranged that castings can be removed from a wagon by the yard crane and stored, or carried within reach of one of the shop cranes. New machines are loaded with the same ease. The court into which the heavy wagons are driven for loading or unloading is shown in Fig. 1. This is well paved and drained and is large enough for several teams to maneuver in at once. In this engraving the main shop is partially shown in the background; shop Number 2 is at the left and one of the storage sheds is in between the two.

In Fig. 2 is shown the way lathe beds are stored, some of these being in the rough, while others are partly finished and left here to "season." Lathe carriages are stored close to the assembling floor in upright racks, as shown at the right in Fig. 3, and compound rests on the iron shelves covered with cloth, shown at the left.

A satisfactory and economical way to stack quantities of round bars of various sizes and lengths, is often a puzzle to the man in charge of stock, but the problem has here been very happily solved, as shown in Fig. 4, by using short lengths of square iron bars curved up at each end and placing them

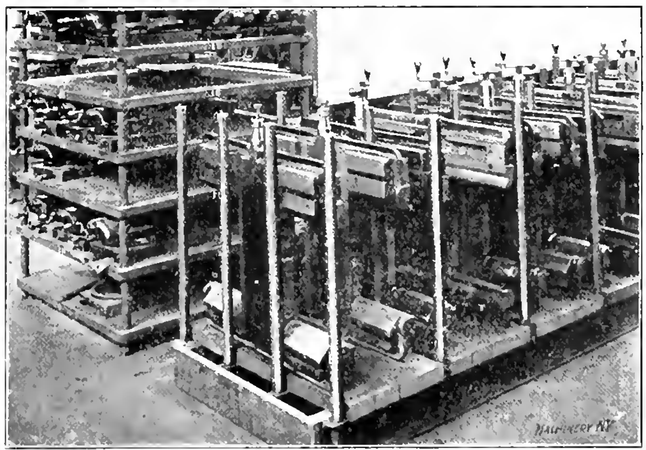

Fig. 3. Racks and Shelves for Holding Carriages and Compound Rests

as shown. Where a rack of some kind is wanted for storing large amounts of stock, a very good type is shown in Fig. 5. This rack has adjustable supports for the cross-pieces, so that

Fig. 4. Method of Piling Round Stock, which is both Convenient and Economical as to Space

compartments, to suit the different sizes or amounts of stock, can be readily arranged.

In the machine shop, a portable motor-driven variable speed countershaft, shown in Fig. 6, is used to run lathes that are being assembled or tested. A planer equipped with a regular Lodge & Shipley variable-speed lathe countershaft (Fig.

* Associate Editor of MACHINERY.

7) is something unusual, but it ought to be very handy for some classes of work.

The hand scrapers used by the assemblers and fitters are sharpened on the portable oil-stones shown in Fig. 8. These stones are motor-driven and may be set in any convenient place close to the machine or machines upon which a group of men may be working.

After the gears and parts of a lathe head are in place, the shift-gear lever-lock holes *A*, Fig. 9, are drilled in the head-casting so that they will line up properly with the correct position of the lever and gears. This is done by removing the locking pin from the lever, meshing the gears, spotting each hole to be drilled in turn through the locking pin hole, and then finishing the holes, using the electric drill and adjustable stand shown. Braces and locks to hold the drill to the work for this and other jobs are shown lying on the floor.

Large lathe beds are placed on the four-wheeled trucks, Fig. 10, while the different holes are drilled with a big radial drill, and in this way the huge castings may be moved along with comparative ease. The ends of these large beds are faced off with the portable milling machine shown in Fig. 11.

Hand-wheels of all kinds have the rims ground on the special machine shown in Fig. 12, which does splendid work and is very conveniently and rigidly built. The emery wheel spindle is run with a belt in the usual way, but the spindle carrying the work is driven by a universal jointed shaft and set of bevel gears, connected to the countershaft, in the same way that drills in a screw machine turret are independently driven. The work is fed up to the grinding wheel by means of the ball-crank *A*; a rotary movement is given to the table by turning the hand-wheel *B*. The wheel to be ground is fastened on the end of the work spindle by a nut and it is kept from turning by a pin in the face-plate which engages one of the spokes.

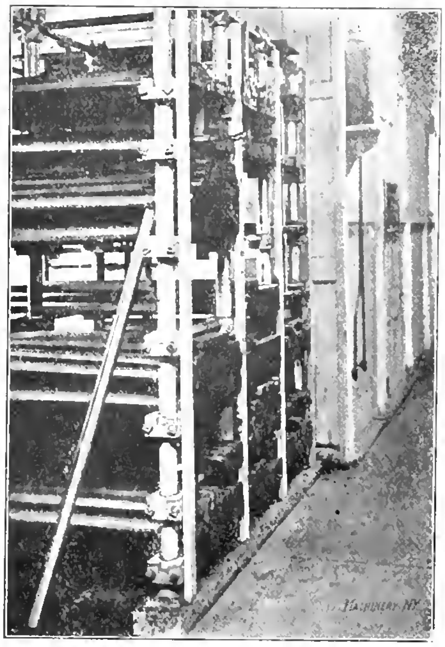

Fig. 5. An Adjustable Storage Rack for the Stock-room

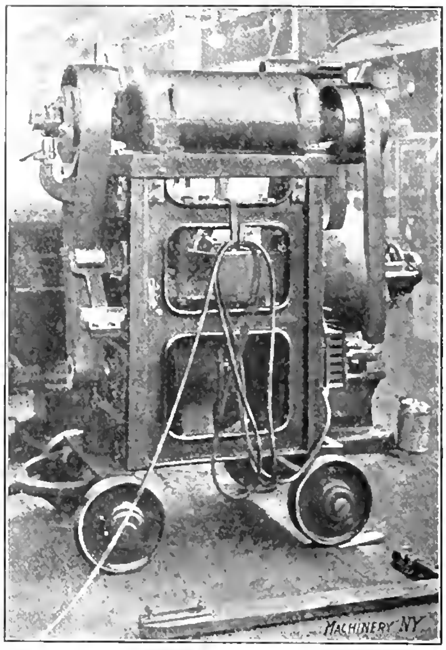

Fig. 6. Movable Variable-speed Countershaft for Testing Purposes

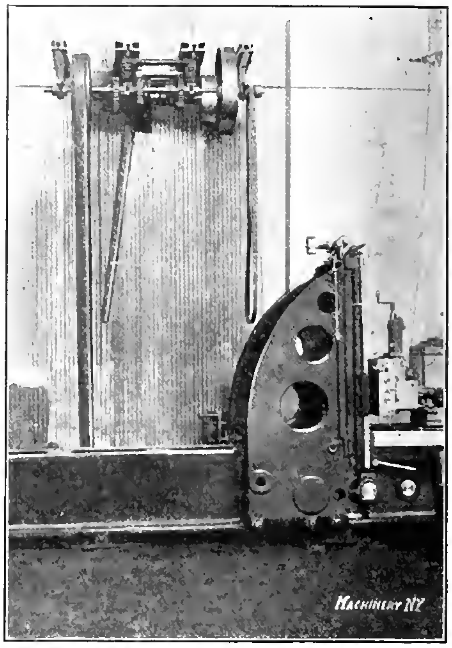

Fig. 7. Planer equipped with a Lodge & Shipley Variable-speed Lathe Countershaft

The small straightening block or screw-press (Fig. 13) is made considerably lighter than usual by bracing the top with an eye-bolt as shown, which makes it just as good for most purposes. It is also easier to handle because of the decreased weight.

Bushings like *A*, Fig. 14, are screwed into the lathe aprons by taking advantage of the oil groove in them and using it for a wrench-hold, the wrench-plugs *B* being made with a corresponding ridge.

Small reverse-plate gear-bushings are held while turning the outside, as shown in Fig. 15. The mandrel used is fastened securely in the lathe spindle and has a pin or key in it which fits into the oil notch in the bore of the gear-bushing and keeps it from turning. The outer end of the mandrel is supported by the tailstock spindle of the lathe which has been fitted with a bushing for the purpose. This spindle also has

a handle attached so that it can be shifted out or in easier while taking off or putting work on the mandrel.

Fig. 16 shows how the circular T-slots are cut in the compound rest bottom slides. They are located on the face-plate by means of a plug mandrel in the lathe spindle, which fits the hole bored in the casting. The circular slot is cut out by using the two cutters A and B, shown in the turret, and feeding them straight in. The slot is then made T-shape by

using two L-shaped tools set in the turret in a way similar to *A* and *B*. These tools are run in flush with the bottom of the slot which is finished by cross feeding the turret the desired amount.

The "spots" *A*, *B* and *C*, Fig. 17, on the countershaft friction parts, are milled on a lathe, to the carriage of which has been fitted the fixture shown. The friction band is milled at *D*, *E* and *F*, Fig. 18, using the same fixture, with another cutter which machines both the face and outside of the contacts at once while the casting is held in a regular lathe chuck.

Fig. 22 shows the series of jigs used to hold lathe heads on the planer, and Fig. 23 shows a lot of lathe carriages being planed up for the cross-slides.

This article would not be complete without a brief description of a few of the many things that are provided for the comfort and welfare of the employes. In Fig. 24 is given a partial view of the neat washroom with its individual wash basins, and along the walls are shown dust-proof individual lockers for the men's clothing and lunch boxes. Ample space is also provided elsewhere for bicycle storage.

Fig 23 Planing Lathe Carriages

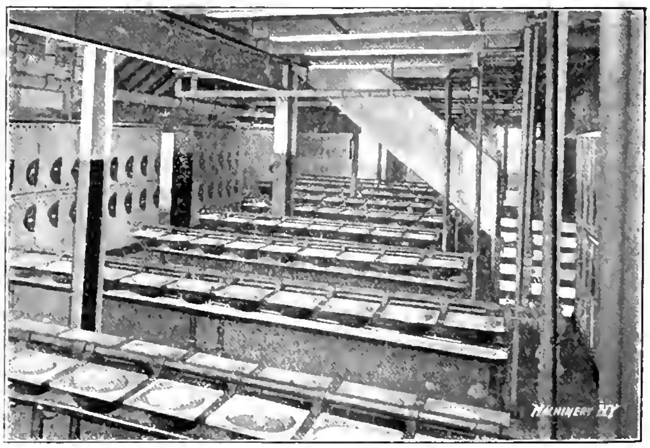

Fig 24 Employes' Locker and Wash-room

Countershaft brackets are bored out while held on a lathe in the jig shown in Fig. 19, using a double-headed boring fixture operating two boring-bars at once.

Lathe heads are bored out as shown in Fig. 20. All lathe spindles used in this shop are drilled out of solid metal on the machines shown in Fig. 21. The standard method of rotating the work and feeding in the drill is used in these machines. Lodge & Shipley also makes a motor-driven lathe attachment for deep drilling.*

The employes have a mutual benefit association, which for a small sum provides a fair amount of protection for members who are sick or injured.

* * *

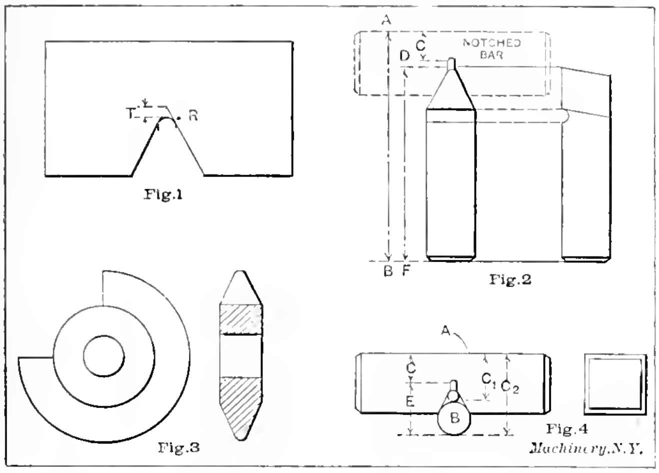
The electrification of a street railway line in London has been brought to a standstill on account of possible disturbances to the delicate instruments at the Greenwich observatory. The Astronomer Royal has the power to pass upon any undertaking within three miles of the observatory that is liable to affect the instruments, and the railroad company must obtain his consent before proceeding with the electrification.

* Complete information on this subject will be found in MACHINERY'S Reference Series No. 25 on Deep Hole Drilling. A description of the Lodge & Shipley deep hole drilling attachment will also be found in this pamphlet.

MAKING WHITWORTH THREAD TOOLS*

In order to produce interchangeability in screw threads, the tools for the screw cutting operations require very careful consideration. Even with accurate tools, the form of thread cut by any threading device depends considerably on the material in which the thread is cut. For instance, a tap used to cut a thread in cast iron is withdrawn with ease, but when the same tap is used in machinery steel it is not as easily withdrawn, the cause evidently being that the threads in the cast iron are thinner and that the pitch diameter of the screw thread is correspondingly increased. This being the case, it is very evident that it is necessary to have the original thread cutting tool as nearly perfect as possible, in order that the subsequent deviations may be minimized. A method is briefly described for generating and measuring thread tools for cutting threads with rounded top and bottom, such as the Whitworth and British Association standard threads.

In the specifications of these standards the radius of curvature, R in Fig. 1, at the top and bottom is given. In originating tools for these thread forms templets are usually made



Figs. 1 to 4. Whitworth Thread Tools and Methods used for Making

by drilling a round hole of the required radius and cutting an angular notch with sides running tangentially into the hole as shown. Fairly accurate work can be done in this way, but a method originated by Mr. W. Taylor permits of greater accuracy in gaging the angle of the thread tool, this being of more importance than the exact curvature of top and bottom.

In shaping the original thread tool as shown in Fig. 2, a notched bar of hardened steel, as shown in Fig. 4, is used for measuring. The face A of this bar is lapped flat, the V-notch is lapped so that its center is perpendicular to A and apex of the V-notch. Anyone familiar with trigonometry can easily calculate the dimensions C and E when C_1, C_2, the angle of the notch, and the diameters of the cylindrical gages are known. This notched bar is applied to the tool as shown by the dotted lines in Fig. 2, the angular faces of the tool having been previously ground. The total distance AB is measured, and from this we subtract the constant dimension C of the bar and the distance T, Fig. 1, from the rounded surface of the thread to the true apex of the V-point of the tool. We then obtain the required finished length DF, Fig. 2, to which the tool must be shortened by rounding its extreme point.*

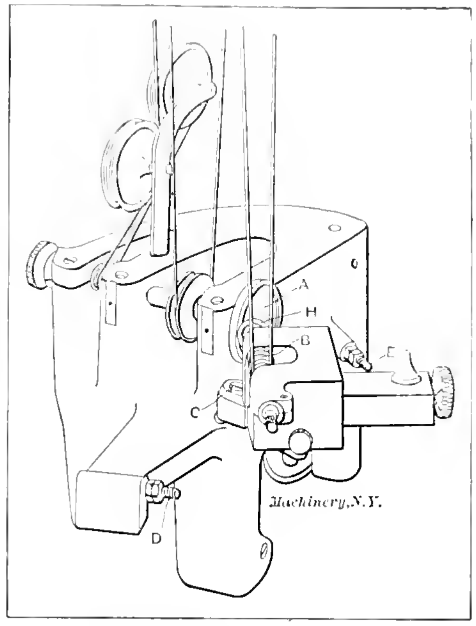


Fig. 5. Machine for Grinding Circular Formed Thread Tools

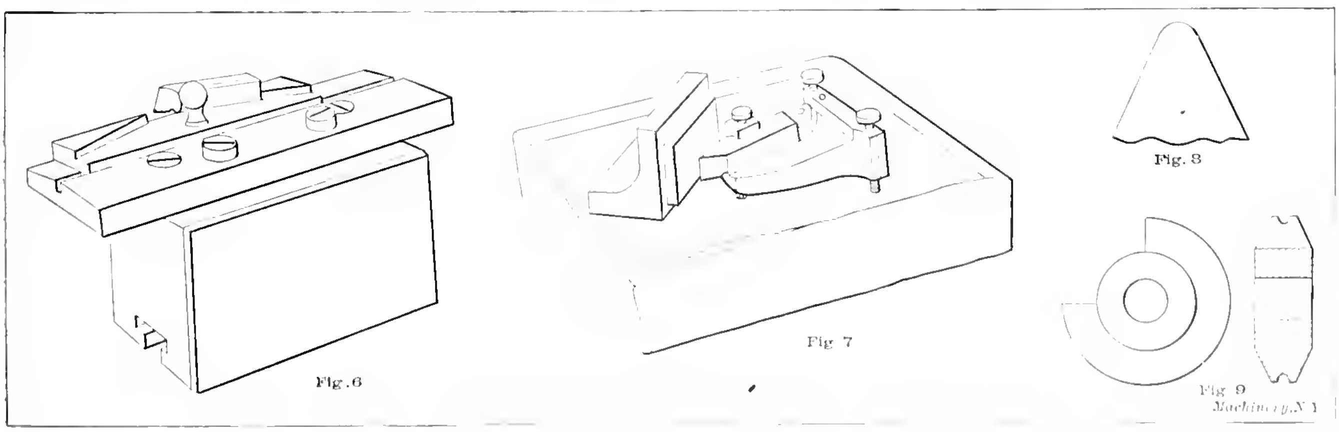
In rounding the tool point the radius of the curvature is not directly measured. It is sufficient that the curve be circular, that the angular sides of the tool join it tangentially, and that the distance from the top of the curve to the apex of the tool angle be obtained correctly by measurements as described. The first two conditions above are most easily obtained in circular formed threading tools of the shape shown in Fig. 3, which can be sharpened without losing their form. Cutters of this form are invaluable for constant use, but cutters shaped as shown in Fig. 2 can be made by simple means.

The grinding machine shown in Fig. 5 is used for forming correctly the circular tool. In this the previously shaped and hardened cutter is finished by grinding with a cup-shaped wheel A, which, while rotating, moves in an eccentric circular orbit so it wears truly flat. The cutter H is mounted and rotated on the horizontal spindle B, and while rotating can be swung around a vertical axis C as far as permitted by the stops D and E, which are set so as to limit the movement to the angle of the tool (55 degrees for the Whitworth thread), so that it has the thread angle required. Its apex is cut away entirely, as shown, and by means of two or more small cylindrical gages placed at B, the measurements C_1 and C_2 are taken, by which the accuracy of the angle may be verified and from which is found the distance C between the face A and the true



Figs. 6 and 7. Appliances for Making a Tool with Rounded Nose or Cutting Point and with the required Clearance Angle, as shown in Fig. 2

Fig. 8. Enlarged View of Tool Point made by the Process described. Fig. 9. Tool for Forming Top of Thread

The tool, when ground, is again tested by the notched bar in Figs. 2 and 4.

In Fig. 6 is shown a simple holder with guides mounted on a slide, which serves to support the tool shown in Fig. 2, and

* From a paper entitled Interchangeability and Methods of Securing It in Screw Threads, read before the Institution of Mechanical Engineers of Great Britain, by Mr. H. F. Donaldson.

* A description of a method used for measuring, by the micrometer, the amount to be removed from a Whitworth tool having front clearance was included in an article entitled "Measuring Width of Flat on U. S. Standard Thread Tools," MACHINERY, April, 1907.

present it accurately to a flat-faced rotating metal lap so as to grind the angular sides of the tool point. In Fig. 7 is shown a holder with adjustable feet and with a stop against which the tool may be clamped. This is placed upon a piece of plate glass and worked against a small angle plate faced with an Arkansas oil-stone. With these simple appliances, and with the exercise of a little skill, it is possible to round the tool point so accurately that when magnified 100 to 200 diameters and compared with the circular field of a microscope, no error is perceptible. In Fig. 8 is shown a tool point of a British Association standard thread No. 6 rounded in this way, magnified 30 diameters, and correctly copied. In Fig. 9 is shown the form of the tool used to round the top of the threads, the groove not being as deep as that of a full half circle.

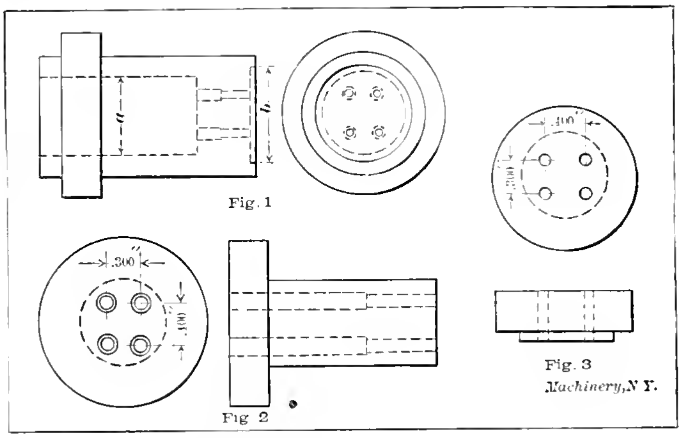
MACHINE SHOP PRACTICE*

JIG AND DIE WORK IN THE BENCH LATHE—2

A. L. MONRAD†

Those who read the first installment of this article in the November number will recall that the method of making two small jigs to be used in connection with drilling four holes in the die shown in Fig. 1 was explained. We shall now consider the drilling of this hardened die with a hollow diamond drill, and also the way in which the holes are ground in a bench lathe. Of course, drilling into hardened steel is a



Figs. 1, 2 and 3 Die and Jigs for Drilling

very unusual operation. It was resorted to in this case because of changes in the die, which made it necessary to either drill holes or make a new die. As less time would be required for drilling, this was done, and while the operation is one rarely performed, it will doubtless be of interest to those not familiar with it.

It was first necessary to locate the jigs (shown in Figs. 2 and 3), which had been previously fitted to the die, so that the holes in each jig were in alignment. This was accomplished as follows: First, the jigs were placed in each end of the die which rested in a V-block, one being in hole *a* and the other in recess *b*. This block, in turn, was on an accurate surface plate. Two close-fitting plugs were next inserted in the two upper holes in each jig, and these plugs were then tested with a surface gage until they were all parallel with the surface plate, the necesssary adjustments being made, of course, by turning the jigs with relation to the die. When the jigs were correctly set, they were clamped together and then fastened to the die temporarily with a little solder, after which the clamp was removed.

The drilling was done in a sensitive drill press. The die with the attached jigs is shown on the drill press table in Fig. 2. As the work was hardened, the drilling operation was performed with a hollow drill *D*, the end of which was charged with number 4 diamond dust and number 80 alundum. The drill was first charged with diamond dust mixed in sperm oil, by having the diamond on a hardened and ground parallel block and by dropping the drill onto it about a dozen times by a movement of the handle *A*. This pounded the diamond into the end of the drill. While the drill was being charged, the drill press remained stationary. The drilling operation was performed by dropping a little alundum and then a drop of sperm oil in the hole, and pounding the drill, which was run at a high speed, against the work. The drill was recharged with diamond about every ten minutes. The large or counterbored part of the holes was first drilled to the proper depth with jig *B* guiding the drill. The work was then inverted and the small part of each hole drilled in until it met the larger part, when the small plug *E* in the center dropped down and left a clean counterbored hole.

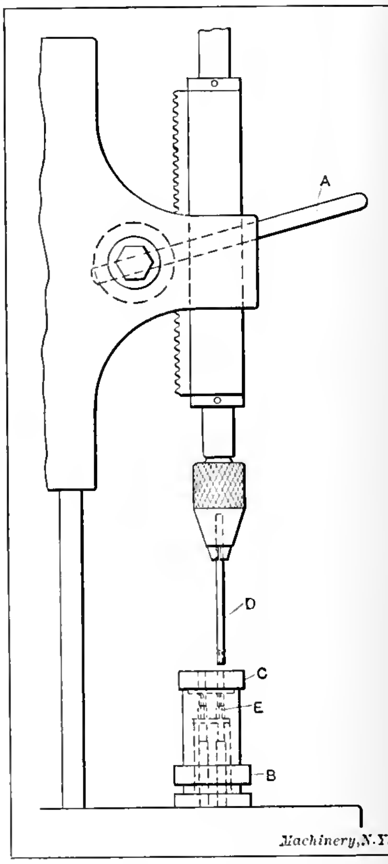


Fig. 4. Sensitive Drill Press with Hollow Diamond Drill and Work in Place

As the hollow drill will cut a hole a little large, it was made 0.010 inch smaller than the diameter of the small holes (which were 0.052 inch) and this gave sufficient allowance for grinding in the bench lathe, which was the next operation performed. The master-plate *M* with the brass disk *G* attached to it was strapped to the faceplate *F* with the locating plug in the spindle inserted in the central hole in the master plate. A recess was then turned in disk *G* to fit the end of the die as shown in Fig. 5. The die was then inserted in this disk and located so that the four holes in it were approximately in alignment with those in the master-plate. The die was then soldered to disk *G*, which, it will be remembered, was provided with elongated slots for the clamping screws. A diamond lap was used when grinding the small holes. This lap *N* was made of tool steel and was charged with number 2 diamond dust and sperm oil by being rolled between two hardened and ground blocks.

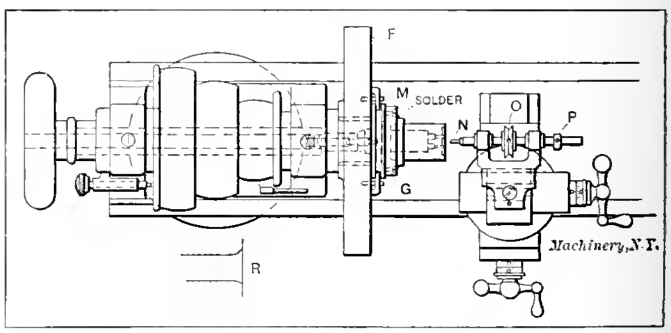

Fig. 5. Finishing the Hole in a Bench Lathe with a Diamond Lap

When grinding holes in this way, the lap should run at the highest speed that can be obtained and the die at the slowest. The feed may be obtained by placing the forefinger and thumb on the sides of the wheel *O* and pushing the grinder spindle back and forth at a moderate speed. Care should be taken to prevent the ends of the holes in the die from being ground "bell-mouthed," that is, rounding at the end as shown enlarged at *R*. This will not occur if the stop *P* and the wheel *O* are located so that the lap cannot move clear of the hole. It will be seen that if the lap were to leave the hole at the end of the stroke, there would be more or less springing action on the part of the lap, which, when it entered the work on the return stroke, would tend to grind the end of the hole rounding.

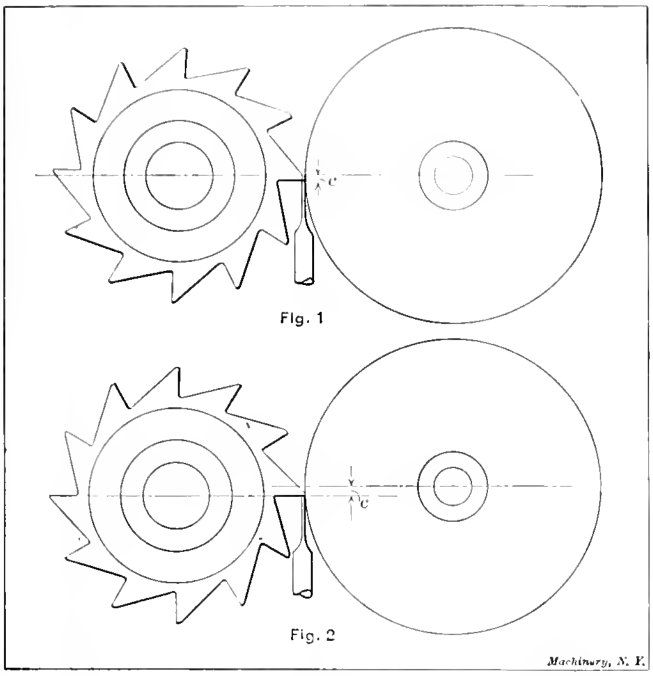
ERRORS IN GRINDING TAPERED REAMERS AND MILLING CUTTERS

H. A. S. HOWARTH*

There are two distinct methods that are commonly used for grinding the clearance on reamers and milling cutters. These methods involve the relative positions of the axis of the reamer, the grinding wheel spindle, and the guide finger. The first method is shown in Fig. 1, with the axes of the reamer and the wheel spindle in the same horizontal plane. The



Figs. 1 and 2. Common Methods used for Grinding Clearance on Reamers and Milling Cutters

finger is set so that the cutting edge of the reamer lies at sufficient distance below this plane to give proper clearance or backing off. The amount of clearance is decreased by raising and increased by lowering the finger.

The second method is shown in Fig. 2 with the axis of the reamer in the same horizontal plane with the cutting edge, *i. e.*, with the end of the guide finger; but the wheel spindle is above this plane a variable amount governed by the clearance desired. As the wheel is raised the clearance is increased and *vice versa*. Cylindrical reamers or cutters can be accurately ground by either of these methods, whether the flutes are straight or spiral; but tapered reamers or cutters *cannot* be ground accurately by the first method; they *can*,

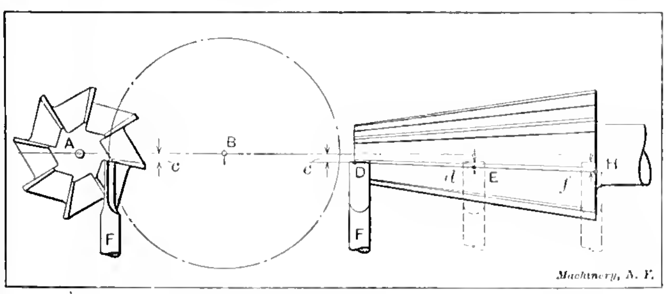


Fig. 3. Illustration showing Conditions when Grinding a Taper Reamer by Method shown in Fig. 1

however, be so ground by the second method. Because of the extensive use of the first method it is the purpose of this article to prove its inaccuracy and to discuss the errors introduced in grinding tapered reamers and cutters. The actual error will be calculated for a number of sizes and the reader can then form some idea of the probable error in cases under his observation.

By reference to Fig. 3, it will be clearly seen what takes place when a tapered reamer is ground by the method in Fig. 1. The finger F is set at a distance c below the plane of centers AB, and, being fastened to the frame of the grinder, it does not change its position relative to the wheel. The reamer, mounted on centers, is moved back and forth in front of the wheel with its cutting face resting on the finger. When the wheel is grinding at the small end, the cutting edge at point D rests on the finger a distance c below AB; but the points E and H on the same cutting edge are lower down by distances d and f, respectively. This is due to the conical form of the reamer. When the point E reaches the wheel and finger, it has been lifted the distance d and is ground also at distance c below plane AB. The same thing is true of the point H. It seems on the face of it that this method would produce a truly conical reamer. Hence it is that so many have fallen into the error of using it. However, by a formula which is derived below, the error is seen to be considerable in some cases while negligible in others.

The construction from which the formula is derived is shown in Fig. 4, which represents the method shown in Fig. 1. The end D of the finger is shown at a distance $GD = c$ below the horizontal plane of the axes of the reamer and the spindle. The end view shows a heavy line AHK which represents the cutting edge actually ground by this method.

Suppose the exact diameters of the ends of the reamer are known; A is a point on the circumference at the small end while K is a corresponding point on the large end. In setting up for grinding, the centers are set over so that as the edge AHK passes over the finger, the wheel will grind OA and OK to the proper radii. When A rests on the point of the finger, H and K will be below it, as shown; but as H reaches the finger A passes above it, and K still remains below it. Finally when K reaches the finger, the whole cutting edge except point K will be above it, and nearer the horizontal plane of the reamer axis.

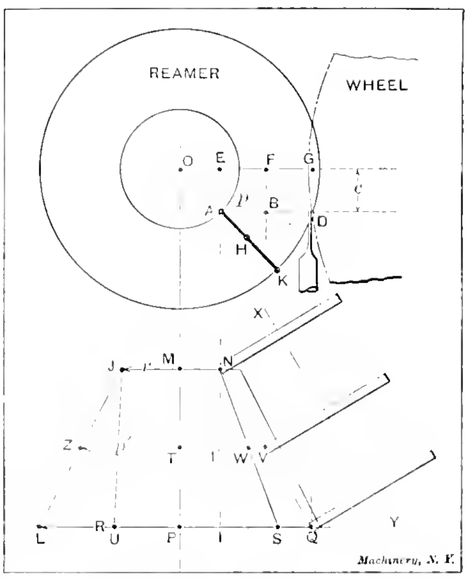

Fig. 4. Diagram for Calculating the Error Involved when grinding a Taper Reamer by Method shown in Fig. 1.

In order better to understand what takes place, the line XY, which represents the wheel spindle axis, is shown in the bottom view. The wheel is shown in three positions. The points N, V and Q are bottom views of the points ground in the three positions shown. These points will lie in a straight line, parallel to XY, and at distance c below the horizontal plane of the centers. This line NVQ is the line ABD in the end view. All points of the cutting edge AHK swing up into this line ABD to be ground. Since NWS is the bottom view of AHK, all of its points swing over into the line NVQ.

Let a point W be taken at a perpendicular distance MT below the end of the reamer so that $\frac{MT}{MP} = m$ which can have any value from zero to one. When W is ground, it is at point V and we have the further geometric relation that

$$\frac{TV - MN}{PQ - MN} = \frac{MT}{MP} = m \qquad (1)$$

This is taken from the triangles NPQ and NTV. Taking now the equivalents of TV, MN, and PQ in the end view we have $TV = OF$, $MN = OE$, $PQ = OG$. By substituting these values in Equation (1) we have

$$\frac{OG - OE}{OF - OE} = m \qquad (2)$$

It is from this equation that we must get the value of the radius $OH = OB \pm p$, which will be the actual radius ground

* Address: Box 174, South Bethlehem, Pa.

by the wheel at W. Let $OA = r$, and $OK = R$, being, respectively, the radii of the small and large ends of the reamer. Then from Equation (2) OF is solved and squared as follows:

$$OF = m\,(OG - OE) + OE$$
$$OF^2 = [m\,(OG - OE) + OE]^2$$
$$p = \sqrt{(OF^2 + FB^2)}$$
$$FB^2 = c^2,\ OG = \sqrt{(R^2 - c^2)},\ OE = \sqrt{(r^2 - c^2)}.$$

Then by substituting in (3) and simplifying we have the following value:

$$p = \sqrt{\{m^2\,[R^2 + r^2 - 2c^2 - 2\sqrt{(R^2 - c^2)\,(r^2 - c^2)}\,] - 2m\,[r^2 - c^2 - \sqrt{(R^2 - c^2)\,(r^2 - c^2)}\,] + r^2\}} \qquad (4)$$

While the above equation gives the value of p actually ground, it is necessary for us to know what the valne should be if the point W were on a true cone. This is shown by the

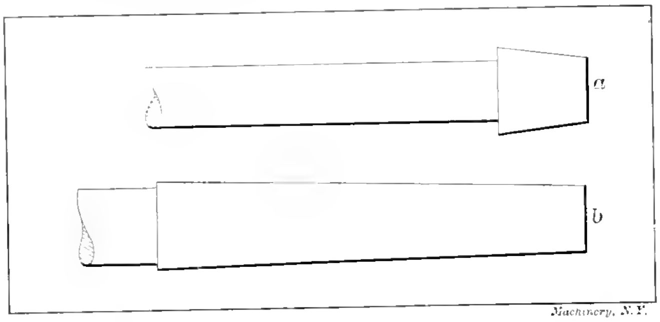

Fig. 5 Taper Reamers of Proportions given in Example 1

line ZT. The point Z is on an element of the cone and at a distance MT below the small end of the reamer. Hence we have the proportion following:

$$\frac{ZT - JM}{LP - JM} = \frac{MT}{MP} = m \qquad (5)$$

ZT is our true radius which we will call p', while $JM = r$ and $LP = R$. Then by rearrangement and substitution we have

$$p' = r + m\,(R - r) \qquad (6)$$

The error which we are seeking will be the difference between p and p'. Hence

$p' - p =$ error in radius.

$2\,(p' - p) =$ error in diameter.

The error will vary in amount from zero at either end to a maximum near the middle of the cutting edge. Hence m may be assumed at some value such as 0.4 or 0.5.

Example 1.—Take a reamer whose diameters are 1 inch and 1.2 inch at the small and large ends, respectively. Then $R = 0.6$ and $r = 0.5$ inch. We will assume in our calculations that c is one-fifth of r. Hence $c = 0.1$ inch. Then m will be taken at different values in order to show about what it should be in this case. The errors in diameters will be as follows:

m	$2\,(p' - p)$
0.35	0.000152
0.40	0.000154
0.45	0.000157
0.50	0.000157

It is evident that the greatest error in this case occurs when m is about 0.5. This is so because the taper is slight compared with the diameters. This also accounts for the very small error, which is a little over one and one-half ten-thousandths inch. Fig. 5 shows two reamers *a* and *b*, which have the proportions used above. The length of the flutes does not influence the result, because it does not appear in the formulas. The error depends on the value of the ratio $\frac{R}{r}$ and on the size of r.

Example 2.—Take the smallest or No. 1 B. & S. reamer; $r = 0.1$, $R = 0.16$, $c = 0.02$ inch; $m = 0.4$. Error in diameter is 0.000054 inch, which is very small.

Because the error in the above cases is relatively insignificant, it is not to be supposed that it is negligible in all instances. The following examples show errors of from 0.002 inch to 0.011 inch.

Example 3.—$R = 1.0$, $r = 0.5$, $c = 0.1$, $m = 0.4$.

Error in diameter is 0.00176 inch.

Example 4.—$R = 1.5$, $r = 0.5$, $c = 0.1$, $m = 0.4$.

Error in diameter is 0.00355 inch.

Example 5.—Use the same values as in Example 3, but give greater clearance by increasing the value of c to 0.15. Then $R = 1.0$, $r = 0.5$, $c = 0.15$, $m = 0.4$.

Error in diameter is 0.00408 inch, *i. e.*, more than twice as great as the error in Example 3. This shows how great an effect the amount of clearance has on the error.

Now assume some sizes that would be typical of milling cutters.

Example 6.—Use a value of c that is less than one-fifth of r, say about one-seventh. $R = 3$, $r = 2$, $c = 0.3$, $m = 0.4$. Error in diameter is 0.0016 inch which is smaller than expected because of the reduced ratio of r to c.

Example 7.—$R = 4$, $r = 2$, $c = 0.4$, $m = 0.4$.

Error in diameter is 0.00704 inch, which is four times the error in Example 3. This was to be expected because the dimensions were taken four times as great.

Example 8.—Take the same sizes as in Example 7 except increase the clearance by making $c = 0.5$ inch instead of 0.4.

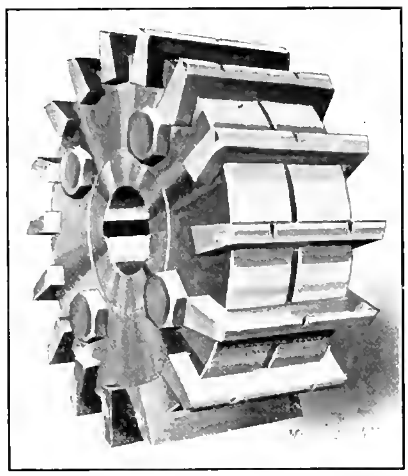
Error in diameter is 0.0112 inch.

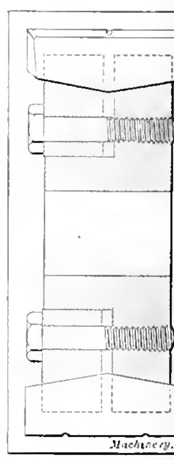
The errors shown above will explain many things that happen in connection with the making and the use of tapered reamers and milling cutters. Many persons have probably noticed that when grinding the clearance on a new tapered reamer or cutter the center will come up sharp before the ends do. The reason for this is now plain. When fitting an arbor into a tapered hole it seems frequently to bear hard in the middle. This may be due to the reaming of the hole in the first place by an improperly ground reamer. It is difficult even with a perfect reamer to avoid reaming the ends of the hole larger than the reamer itself. Hence any inaccuracy will tend to increase the trouble. The conclusion from the above discussion is obvious. Tapered reamers and milling cutters should be ground by the method shown in Fig. 2, *i. e.*, with the cutting edge and the point of the finger in the horizontal plane of the axis of the reamer. Then the proper amount of clearance can be obtained by lowering the reamer and finger together, or by raising the wheel.

* * *

MILLING CUTTER WITH INSERTED TEETH

An inserted tooth milling cutter of a design radically different from those commonly in use has been brought out by Messrs. Modes Eadon & Sons, Ltd., of President Works, Sheffield, England. The body of the cutter is made in two parts



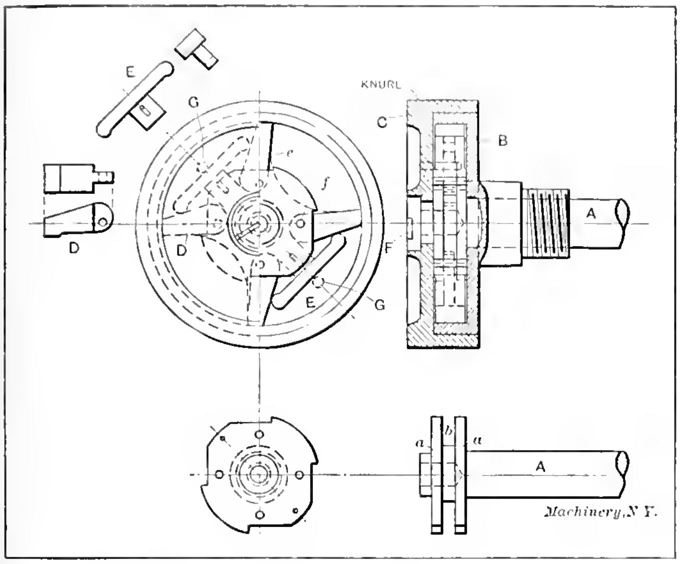


Figs. 1 and 2. Inserted-tooth Milling Cutter of English Design

as shown in the accompanying illustrations, the two parts being drawn together either by a central nut, or, preferably, by a number of screws. The teeth are made of dove-tail section, and the bottom of the tooth is made of a V-shape as shown in the line-engraving. The body, of course, is slotted to fit this shape of the teeth. When the teeth are placed in position and the two halves of the cutter body drawn together, the teeth are forced tightly into the upper portions of the dove-tail, thus providing for an extremely firm hold of the cutter teeth. Being held by a wedge grip in two directions, it is evident that any movement whatever is impossible. It is claimed that a single tooth cannot become loose, and that breakage of one tooth does not loosen the other teeth.

LOCKING DEVICE FOR ADJUSTING SCREWS

An automatic locking device is shown in the accompanying sketch, which is constructed as follows: Part A is the screw or shaft to be held rigid at any point that may be required. The hub parts a are turned solid on the shaft and far enough from the end to allow a bearing for the wheel C. The slot b is cut deep enough so that the lugs on pawls D and the pawl-releasing bars E have sufficient clearance to work freely. The pawls should be put in position as shown in the assembled view, and held rigidly while turning them to the inside diameter of the friction cup B; they are then relieved at the shoulders until their face edges come back almost on a line with the center, when the friction cup is removed. This friction cup is screwed or bolted to the casting carrying the shaft; the parts are then assembled. The pawls D are held in place by pins f and are forced outward by springs c. The pawl releasing-bars are put in position as shown, and the shaft is put in place with the releasing wheel C mounted on the end and secured by a screw F adjusted to allow the wheel to work freely. The pins G of the releasing wheel are in contact with the pawl-releasing bars E. By turning the wheel either to the right or left, these pins force the releasing bars inward, bringing the pawls away from the walls of the friction cup; the shaft is then readily moved in the required direction. It will be seen that when the wheel is released the springs c will force the pawls outward against the walls of the friction cup, and any attempt to turn the shaft will meet with a stubborn resistance at these points of contact. This little wheel is thoroughly practical and it relieves one of the dread of having an adjustment altered by the jarring of a machine.



A Device for Locking an Adjusting Screw in any Position

Baltimore, Md. ROBERT O'NEAL.

MAKING PRESS FITS

Making a press fit is looked upon by a great many machinists as a very difficult job, and undoubtedly this is true in cases where the machinist has no micrometer calipers and depends entirely upon his sense of feeling. Without the micrometer, it is impossible to know just what has been allowed in difference between the diameter of the plug and hole, and, consequently, the pressure required to force in the plug cannot be even approximately ascertained. Of course in manufacturing shops where one man does all the press fitting, does it continually, and calipers with gages made by the tool-maker, with the allowance calculated for him, he cannot be expected to do other than a good job. On the other hand, in contract or repair shops it is too expensive to make gages, as the jobs vary too often; consequently, making a press fit in such shops requires considerable skill.

It is only necessary to use an inside caliper with micrometer adjustment for this work, as this tool may first be set to the exact size of the bore and then to the required number of thousandths larger than the bore. A regular pair of outside calipers may then be set to the inside caliper. I have kept a record of press fits recording the kind of metal, allowance, area of fitting, and the pressure required to force the plug in the hole. This record has proved valuable to refer to when making press fits, but the handiest and most accurate data I have found is that given in MACHINERY'S Data Sheet for August, 1903. I have used this Data Sheet for some time, and find it to be so accurate that I can place absolute confidence in it; thereby removing that lump in my chest that used to settle there every time I made a press fit. If you want to do good work, buy or borrow a good inside micrometer caliper of good make, get this Data Sheet, study it until you understand it thoroughly, and you will soon be up-to-date. By taking the formula $P = \frac{A\,D\,(P\,F)}{2}$ and transposing it thus $D = \frac{2\,P}{A\,(P\,F)}$ the allowance when the number of tons pressure is known, is easily determined. In these formulas,

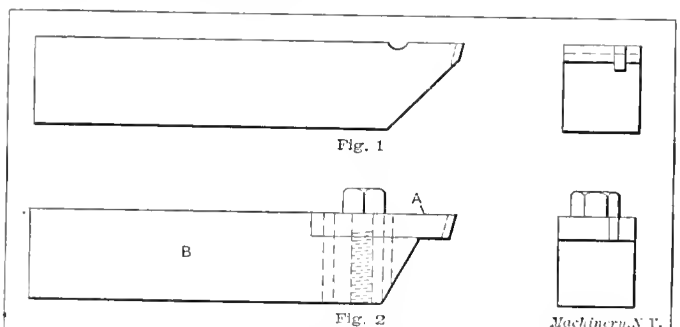
P = pressure required in tons,
D = difference in diameter between plug and bore,
$P\,F$ = pressure factor taken from Data Sheet,
A = area of fitting in square inches.

By using the last formula, and then calipering as described, one will be surprised at the accurate results obtained. A good lubricant to use when pressing the plug into a hole, consists of white lead and machine oil, just enough of the oil being added to make a paste of about twice the consistency of paint.

Augusta, Ga. J. S. VAN PELT.

MASTER FORM TOOLS

The extensive use of circular forming tools, brought about by the introduction of the automatic screw machine, has led to more or less experimenting to obtain an inexpensive method of making the master tools with which the tool used to form the circular cutter is made. In some shops this tool is made



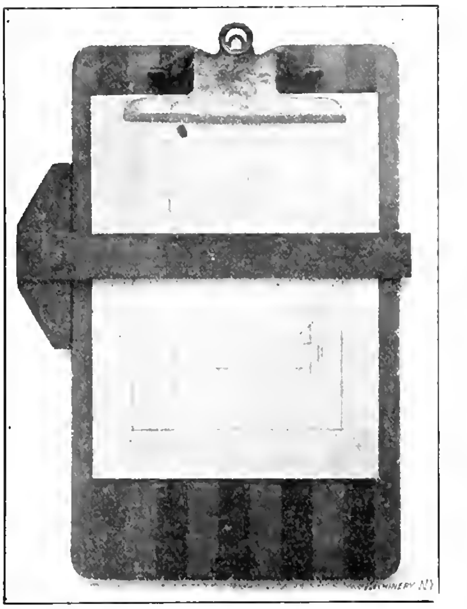
Master Tools for Making Circular Cutters

in the shape shown in Fig. 1, being a solid bar of steel. The outline is laid out on the cutting end and the tool is milled out and finished by filing. This type of tool is often annealed and recut for other forms after the completion of the forming tool. The blanks, of different widths desired, are carried in stock ready for use, and a minimum amount of labor is left for the form-tool maker, as the roughing out is all done with cheaper help. In other shops the master tool is always saved and filed away, in a cabinet, with the form tool, and when this is the case the design shown in Fig. 2 is superior because it occupies less space than Fig. 1, and it is also much easier and less costly to make. In Fig. 2, A is the tool proper which is fastened to the holder B by a hexagon head screw and two dowel pins. Both screw hole and dowel pin holes are drilled and reamed in a simple jig, so as to get the correct location from the back edge of the tool. In making these tools, much costly experimenting has led to the

adoption of "Intra" steel for the master tool, while the circular tool is made from several different brands of high-speed steel, depending on the material to be operated on and other considerations. F. CHAS. SCRIBNER.

Greenfield, Mass.

CONVENIENT DRAWING OUTFIT



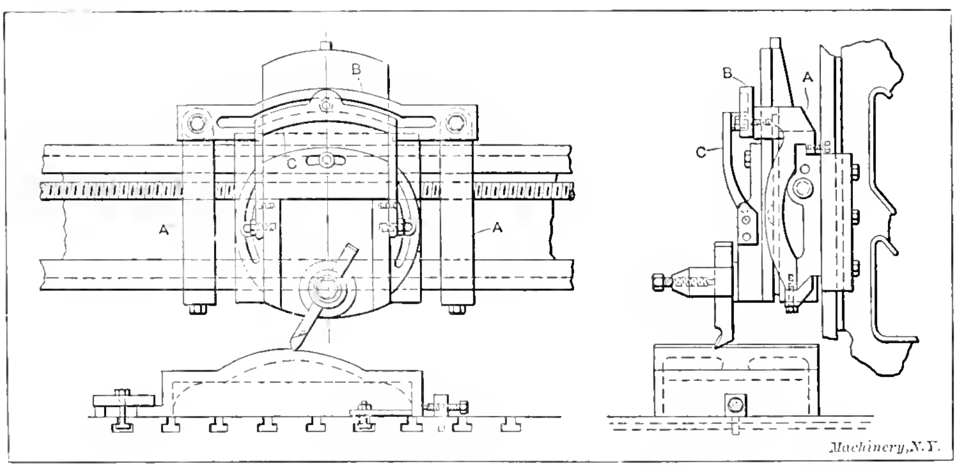
Filing Board used for Drawing

A very convenient drawing outfit for making sketches on small sheets of paper or calculating sheets, that has recently come into quite extensive use, is shown in the accompanying engraving. The outfit consists of an ordinary letter filing board, the left-hand edge of which is planed true, and a small T-square, both of which may be obtained in any stationery or drawing material store. The drawing paper is held by the spring clip as shown. MARTIN JOACHIMSON.

New York City.

PLANER ATTACHMENT FOR MACHINING CURVED SURFACES

An attachment for planing work of a convex or concave shape is shown in the accompanying engraving. The attachment consists of four parts all of which are of cast iron. These castings comprise the two side pieces or brackets *A*, the templet *B*, and the double-armed "leader" *C*, which is attached to the tool slide. Of course, different templets have to be used for different jobs, the shape of each being governed by the special requirements of the work in hand. The side brackets must be cast with bosses to allow the templet to clear the planer head, so that the latter can move along the rail. As shown, the brackets fit over the top guide on the rail and any slack is taken up by the set-screw shown in the end view. Separate pieces are fitted to the bottom of

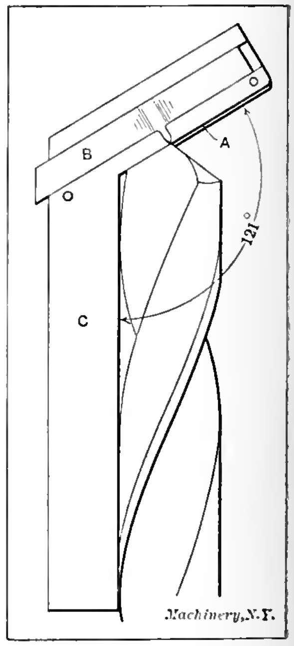


Planer Attachment which automatically guides the Tool when machining Curved Surfaces

each bracket which are put in place after the fixture is put on the rail. These brackets are at all times stationary. The templet is worked out on a profiler or slotter, and it is attached to the brackets *A* by bolts. It should be machined carefully to the required shape, for, obviously, when it is made it will produce any number of pieces which will be exact duplicates. Attached to the double-armed leader *C* is a stud upon which is mounted a loose sleeve which travels in, and fits the slot of the templet. As the head is driven along the rail the tool is automatically raised or lowered according to the formation of the guiding slot in the templet. Of course, when this attachment is in use, the screw of the slide is removed. The fixture is entirely automatic, and when it is in use the cross-feed may be put on, and the planer will take care of the work. This fixture is not new, but there are doubtless many who are not familiar with it. J. B. M.

GAGE FOR DRILL GRINDING

A gage to be used when grinding either flat or twist drills, in order to obtain the proper lip and clearance angles as well as equal lengths for the cutting edges, is shown in the accompanying line engraving. This gage is a great deal handier and more convenient to use than a protractor and scale, and, besides, it can be carried in the pocket. The surface *A* of the head forms an angle of 121 degrees with the shank *C*, which gives a lip angle to the drill of 59 degrees. Fitted to the head is a piece *B*, which slides in a dove-tailed slot and which has attached to it a pointer, as shown, which is used for measuring the lengths of the cutting edges. This is accomplished by setting the pointer as shown in the illustration, and then without moving it, turning the drill over so that the length of the other cutting edge may be measured. If the lengths of the cutting edges are unequal, the short one is, of course, ground off until the pointer coincides with the upper end of each edge. The surface *A* of the gage is beveled to an angle of 12 degrees so that the clearance angle may be tested when the drill is being ground.



Drill Gage for Testing the Lip and Clearance Angles and the Lengths of the Cutting Edges

Lestershire, N. Y. L. B. MINGES.

MILLING FLUTES IN REAMERS WITH IRREGULAR WIDTHS AND DEPTHS

For the purpose of eliminating the chatter marks sometimes found in holes finished with reamers having equally spaced teeth, a good method is adopted by most reamer manufacturers, which is perhaps known to all reamer users, of making flutes of irregular widths and depths. Having had the opportunity to cut reamers of this type, I have tried the following method which has proved quite satisfactory.

Suppose we want to cut a reamer with 6, 8, 10, 12, or any regular number of teeth. Knowing, as we do, that a circumference contains 360 degrees, and bearing in mind that opposite teeth are to be cut to the same depth (to facilitate measuring), it will readily be understood that instead of dividing 360 degrees into irregular spaces, we divide 180 degrees into one-half as many spaces as flutes required. Let us take for example a reamer to have 12 flutes; this gives us 180 degrees to be divided into six irregular spaces. We first divide 180 degrees by 6, obtaining 30 degrees, which would be the angular distance between the teeth for regular spacing. In order to get irregular spaces we must find six numbers that will total 180. In this case, we

have 26, 28, 30, 31, 32, and 33 degrees. The next move is to transfer the degrees to turns and holes for indexing. Nearly all milling machine dividing heads have worm-wheels of 40 teeth, making 40 turns equal 360 degrees or one revolution. This will make one turn equal 9 degrees, and by using a 27-hole circle, 3 holes will equal one degree. Going back to our irregular divisions, we first come to 26 degrees. It is not necessary to index for the first cut. The indexing for the remaining divisions is found as follows:

28 degrees ÷ 9 degrees = 3 1/9 = 3 turns and 3 holes
30 degrees ÷ 9 degrees = 3 3/9 = 3 turns and 9 holes
31 degrees ÷ 9 degrees = 3 4/9 = 3 turns and 12 holes
32 degrees ÷ 9 degrees = 3 5/9 = 3 turns and 15 holes
33 degrees ÷ 9 degrees = 3 6/9 = 3 turns and 18 holes

Having the degrees changed to turns and parts of a turn for the indexing crank, we now go ahead with the first cut, being careful not to go too deep, so that the required width of land can be obtained. It will now be seen that as the angle between the teeth changes, the depth must also be changed if the lands are to be made uniform. This depth is found more readily by practice than by figures. When large reamers are to be cut, instead of dividing 180 degrees, 90 degrees may be used, and in that case four teeth instead of two can be cut to the same depth. JAMES FRASER.

New Haven, Conn.

REMOVING BROKEN DEEP-WELL PUMP-ROD

An A. D. Cook deep-well pump-rod separated far down in the casing, part being pulled out at the top and the remainder staying at the bottom. In order to secure the lower part, a

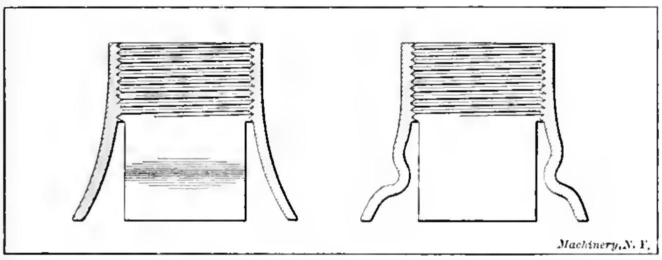


Fig. 1. Special Sleeve for Gripping the End of the Broken Rod

piece of iron pipe was split at one end into four leaves, as shown in Fig. 1, and the solid end tapped out and bushed down to fit the thread upon the pump-rod taken out. Two of these leaves were beaded to form a snap hook after all four of them had been bent out at the lower end to completely fill the well casing. These two beaded leaves were intended to form a hook smaller than the upper head of the lost pump-rod C (Fig. 2), so that when part B was lowered into the casing and forced down over the upper end of C, the leaves would spring back over the shoulder and grip the rod C, thereby enabling it to be pulled out. The device worked very satisfactorily. It was attached to the lower end of the upper section A of the broken pump-rod and lowered until C was gripped.

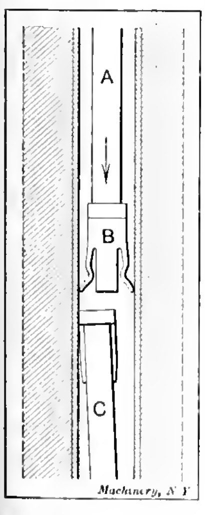

Fig. 2. Method of Removing Broken Pump-rod

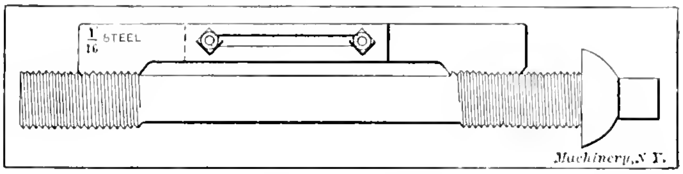
Wadsworth, Ohio. HOWARD D. YODER.

THREAD GAGE FOR STAY-BOLTS

Radial stays are a hard thing to fit into place, according to some boilermakers, because the threads in the boiler plates and the threads on the stay-bolt will not mesh in both sheets at the same time. I knew of one case where a boilermaker spent two days putting in five stays, and these were obtained by sorting over about one hundred stay-bolts. Schemes are tried of having the tap so made that the threads in both plates will be as on a continuous rod, and this helps a lot; in fact, it is necessary to have the holes exactly in line. But another trouble often comes from the fact that the stay-bolts are turned up in a lathe which is so worn that in a foot or two of length the pitch is a little off which changes the position of the threads so that they cross when the bolt is screwed into place in the boiler plates. It will pass through the outside sheet all right, but will not fit into the inner sheet. Now if



Thread Gage applied to a Stay-bolt

this stay-bolt is lengthened a little, by hammering, so that the threads are moved a little ahead until they will exactly fit into the threads of both sheets, everything works smoothly.

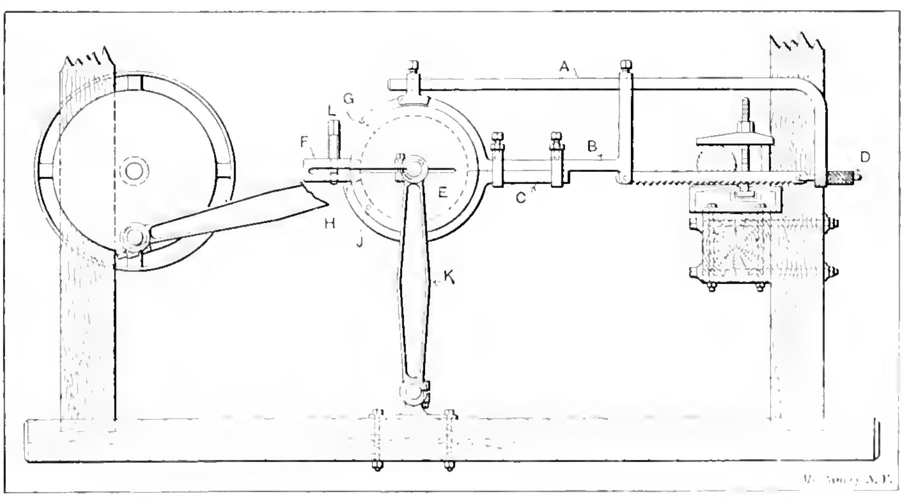
The illustration shows an adjustable gage that can be used in spacing these threads. This gage can be set by the tap that was used in making the threads in the plates, or it can even be placed in the holes and set to the actual threads in the sheets. Then the bolts can be drawn out with a hammer to fit the gage, and a lot of hard work will be eliminated.

Two Harbors, Minn. A. G. JOHNSON.

MULTIPLE POWER-DRIVEN HACK-SAW

Old, rejected street car axles were being cut into short lengths to be used for drop-forging stock, and other purposes for which this steel is suitable, but the work of sawing them on a single reciprocating saw proved too slow. A gang saw, a view of which is shown in the accompanying engraving, was built, which will cut simultaneously the whole length of an axle into any number of pieces required. The construction of the saw is simple, yet it is rigid, and will stand up under very heavy sawing.

The saw frame is composed of three pieces, A, B and C. The first is a machine steel bar 1¼ inch in diameter, the end of which is enlarged to receive an adjusting screw D. The two halves, B and C of the remainder of the frame are hand-forged from machine steel stock 1½ inch wide and ½ inch thick. The vertical part of B is slotted at the lower end to receive the saw, and the upper end is enlarged to provide for a hole through which passes bar A. The circular ends of B and C fit into a groove which is turned in the circumference of the cast-iron disk E 10 inches in diameter. To allow clamping this disk in any position on the shaft, a slot is milled partway through it as shown, and also in the clamping block F, which is attached by pins, to the disk on each side of the slot. It will be noted that the end of the saw frame is not a complete circle, as it terminates at G and H. This serves two purposes: After the saw has finished its cut, the end H



Elevation of a Multiple Hack-saw for Sawing Stock into a Number of Lengths, simultaneously

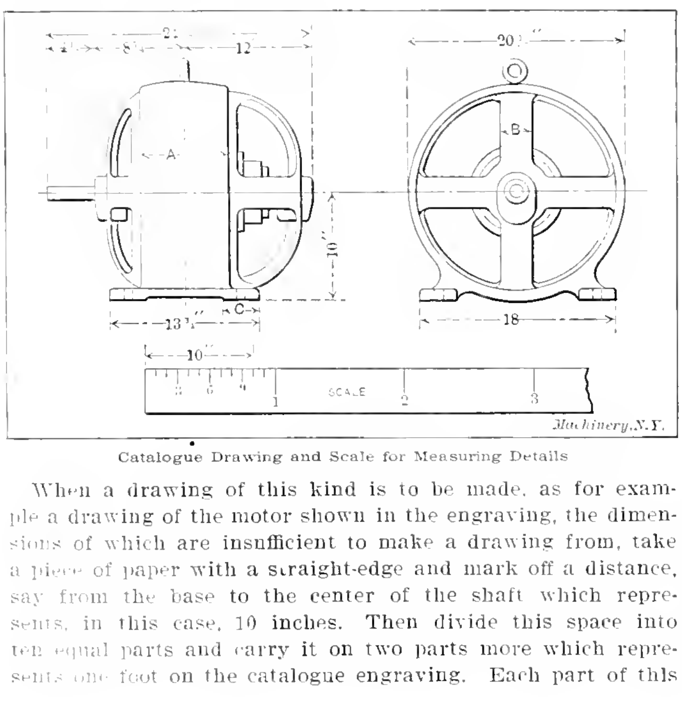
prevents it from cutting into the chucking table, by coming in contact with stop F, while the space between end G and the stop permits lifting the saw to take in any stock within the capacity of the machine. When it is desired to put one or more saws out of service, the frame is raised until the end H drops down past the hole J through which a stop-pin is inserted, thus securing the frame in an elevated position. The shaft upon which the disks are mounted, is turned down at each end to receive the vertical supporting rods K and also the connecting-rods. The latter are connected to the two crank disks mounted on either end of the driving shaft, which runs in bearings attached to wooden uprights. At the opposite end of the frame there are other uprights across which is secured a timber to which is attached a cast-iron plate with a T-slot which permits strapping down the stock at any place along the table. Any of the saw frames can be removed from their disk in five minutes, or replaced in the same time, and pieces of any length may be cut by simply shifting the disks to the proper position on the shaft. A key in the shaft prevents the disks from turning, and when they are properly located they are clamped by the screw L.

In forging the circular parts of the frame they are first formed as near the required shape as possible. After machining the joints between the two halves they are held together by the clamps shown, and the circular ends are tested on a surface plate, to see that the sides are flat, and that the vertical part of B is in a plane parallel with them. These ends can be faced on a disk grinder; if available, a double disk grinder is preferable. Just enough stock is removed to give a fair amount of trued surface. If no other means is at hand the inside of the strap can be machined in the drill press. By fitting the groove in the disk E to the strap, the latter may be ground without reference to any particular width. With a machine of this type it is possible to saw a number of pieces in about the same time as required for one; and obviously, the machine may be designed for any desired number of saws.

M. E. DAWSON.

A KINK FOR DRAFTSMEN

Very often a draftsman in laying out work, finds that he has to refer to outline drawings in catalogues where not enough dimensions are given to make a drawing from and have it to any kind of scale.



Catalogue Drawing and Scale for Measuring Details

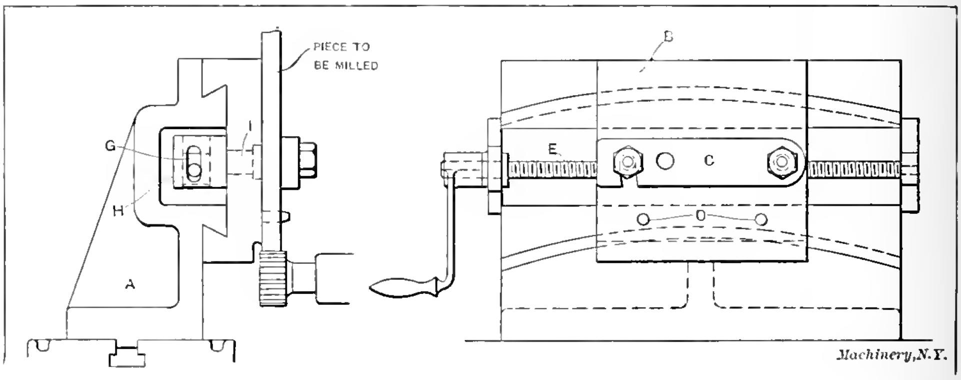
When a drawing of this kind is to be made, as for example a drawing of the motor shown in the engraving, the dimensions of which are insufficient to make a drawing from, take a piece of paper with a straight-edge and mark off a distance, say from the base to the center of the shaft which represents, in this case, 10 inches. Then divide this space into ten equal parts and carry it on two parts more which represents one foot on the catalogue engraving. Each part of this space represents one inch, and each division may be subdivided as required. The scale may be made any length by stepping off spaces equal to one foot, as shown in the engraving. By using such a scale, the dimensions of A, B, C, etc., may be easily found.

This is a very simple method and one which I find helps a great deal at times. A new scale has to be made for each different engraving, the proper proportions being obtained from some one of the dimensions given.

New Haven, Conn. J. H. SCHULTHEISS.

MILLING ATTACHMENT FOR MACHINING A CURVE OF LARGE RADIUS

Some time ago we had a large quantity of parts that had a finished surface on a radius of about five feet, and this surface had to be an exact distance from two holes in the piece. The radius was far too large for any lathe we had available, but the length of the surface to be finished was only a few



Milling Attachment for Machining a Curve of Large Radius

inches, so the device shown in the accompanying engraving was made. An angle casting A was made with a dovetail slide of suitable radius, to which a sliding block B was fitted. A feed-screw E engaged with a nut G attached to the back of B. To allow for the variations in height and angle as B moved across on the curved slide, the nut G could slide up and down in a slot in holder H, and H could swivel on its axle I. Two pins were put in block B in the proper position to take the holes in the piece to be milled, and a clamp-bar C arranged to hold the work in place. The attachment was put on a milling machine and the table adjusted vertically until the cutter was at the proper height. It worked satisfactorily, and we were able to make good time on what had been a troublesome job.

W. ALTON.

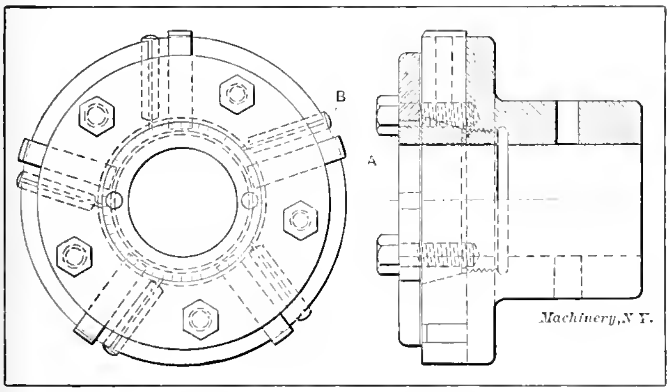
HOW WE GOT ELECTRIC LIGHTS

The shop where I learned the trade was a small one, and although the place was turning out a very good class of work and considerable of it, the "boss" was rather inclined to be a bit slow in putting in improvements for the benefit of the workmen. One of the improvements needed was electric lights, and many were the cuss-words which were fired at the measly old gas jets which were always in the wrong place and never gave sufficient light. One dark, dismal day one of the boys was working at the bench, and he had the gas jet down near the vise; he felt a warm sensation around the top of his head and when he put his hand up to find out what the trouble was he found that his cap and a good share of his "thatch" had gone up in smoke. Of course immediately there was added to the already pungent smell in the air, a distinctly sulphurous strata, which brought the boss post-haste to find out the cause of it all, and when Jack had finished telling of his misfortune and also consigned all such things as gas jets and behind-the-times employers to regions where we have reason to believe there is no need of gas, the boss said, "Well, Jack, that is too bad; those old gas jets are sort of a nuisance and don't give very good light anyway—I think that I'll have to get the electricity put in." Jack told him that he had just about the same sort of idea about it himself, and furthermore, that it had better be done P. D. Q. or there wouldn't be many of the boys working there.

Well, time went on into days, weeks, and months, and still we had no electricity, when one day another of the boys, Eli by name, came over to my lathe and said "Say, George, just keep a weather eye on the shipper handle of my machine. I am going over on the other side of the shop and there is going to be something doing around here in a few minutes. If things get too fierce, why stop them, but don't do it before the "old man" sees it, if you can help." I looked over to Eli's lathe and saw that he had carefully placed the gas jet so that the flame was just under the shipper handle, and in a couple of minutes the handle began to smoke and finally a bit of flame started creeping up it; just about when the flame was up to the ceiling and I was thinking it time to stop it, the "old man" came tearing down the line, jumped up on the lathe and swiped his hands down the handle and put out the fire. Of course Eli showed up on the scene about then and innocently wanted to know what the trouble was. He told the boss that he thought he had that bloody gas far enough away so that there was no danger of the handle catching fire, but it had always been a mystery to him that such things did not occur oftener. The old man did not say much except that we ought to be more careful, but I guess it started something going in his "think tank," for when, a few days later, another of the boys working at that same lathe accidentally (?) allowed the same thing to happen and the fire had even started in on the ceiling, the boss said: "Well, boys, this won't happen again—I've ordered the electricity put in this week." And sure enough, a couple of days later the men were down there wiring the shop, and the day of gas was over in that place. M. A. Chenist.

AN ADJUSTABLE REAMER

The reamer shown in the accompanying engraving differs in construction in some respects from any that the writer has ever seen, and it is such a good tool that it seemed worth



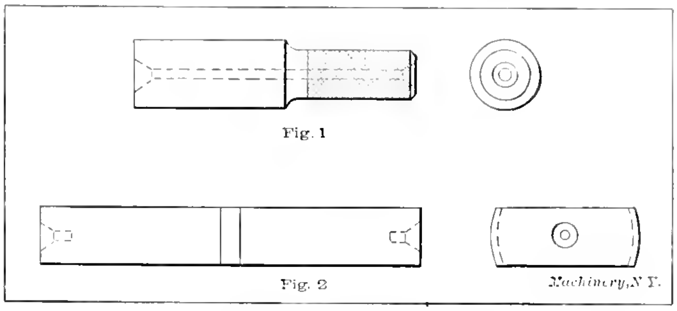
Reamer with Graduated Adjustment

while offering a description of it for publication. The means of adjustment is clearly shown in the sectioned part of the elevation. The cutters are beveled to fit the taper of the sleeve *A* at their inner ends, and are forced out by the inward movement of this sleeve, which is threaded 12 threads per inch. The taper part is turned to an angle of 16 degrees 40 minutes with the axis, and the end of the sleeve has 50 graduations, as shown in the end view, which makes each graduation equal 0.001 inch increase in diameter across the cutters. A spanner wrench is used to turn the sleeves. The cutters are brought to a snug fit in the sockets by means of tapered pins *B*, which are driven into split holes in the cutter head. The reamer chosen for this description is used for reaming 7½-inch holes. C. W. Hebert.

Nashua, N. H.

PROVISION FOR THE ESCAPE OF AIR IN PLUG GAGES

While reading an article in the September number of Machinery about plug and ring gages, I noticed that the importance of lightness was especially treated; this is indeed very important. Another important feature in connection with gage construction, which applies only to plug gages, is the provision for the escape of air when such gages are to be used in blind holes or those having closed ends. Of course, in most cases where plugs are used such provision is not necesssary, as the hole to be tested passes through the work, and therefore gives the air plenty of chance to escape; but once in awhile a hole has to be tested which is closed at one end. In this case the solid plug is rendered absolutely useless, and inside micrometers or calipers have to be used, as it is almost impossible to insert the plug before the hole is about 0.001 inch or more too large. This is because the air cannot escape, and I have been wondering why makers of plugs do not put a hole through the center, as shown in Fig. 1, so that the air could pass through it. It need not be large, but should, of course, increase in size with the size of the plug.



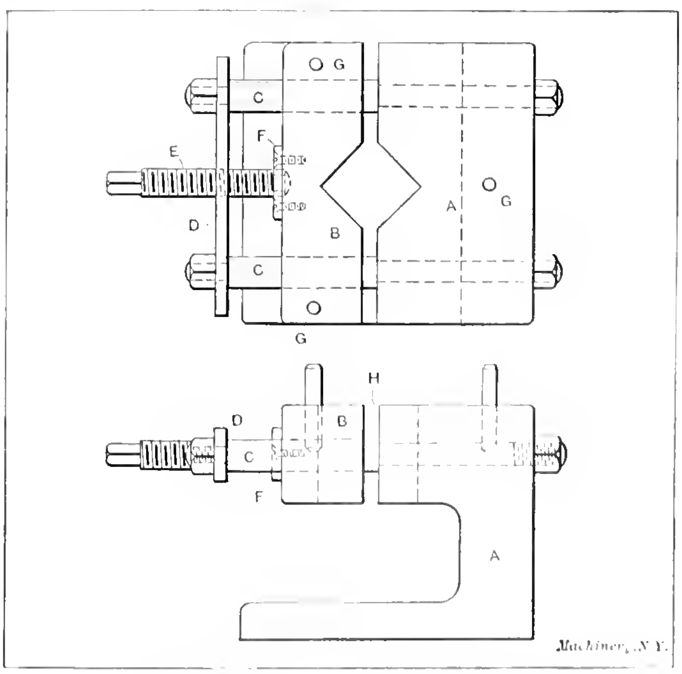
Figs 1 and 2. Plug Gage with Hole for the Escape of Air, and Form for Large Gages

Fig. 2 shows a good way of making large plug gages. They may be made in this style for sizes from one inch and up. Gages made in this way are light, which, as stated, is an important feature, and besides, it is possible to tell with this form of gage if a hole is round or not, which may be impossible with a solid one. It is good practice to make one side of the gage with about 0.005 inch taper, especially when it is used for grinding, as it gives the user a chance to tell when he is near to the gage size. After a little practice, one will know just how much to take off by observing how far the taper part goes in the hole. A. Nielsen.

Cleveland, Ohio.

DRILL PRESS CHUCK FOR ROUND OR FLAT STOCK

A simple chuck for the drill press is shown in the accompanying engraving. It is intended for holding round and square stock that is to be drilled, reamed or countersunk, and also for flat plates which are either round or irregular in shape. The round stock is held in the V's and the flat stock between the pins *G*. Bar stock may be clamped between the jaws at *H*. The cast-iron base *A* is machined on the bottom and top, as are the faces *H* and the V's. The part *B* is also



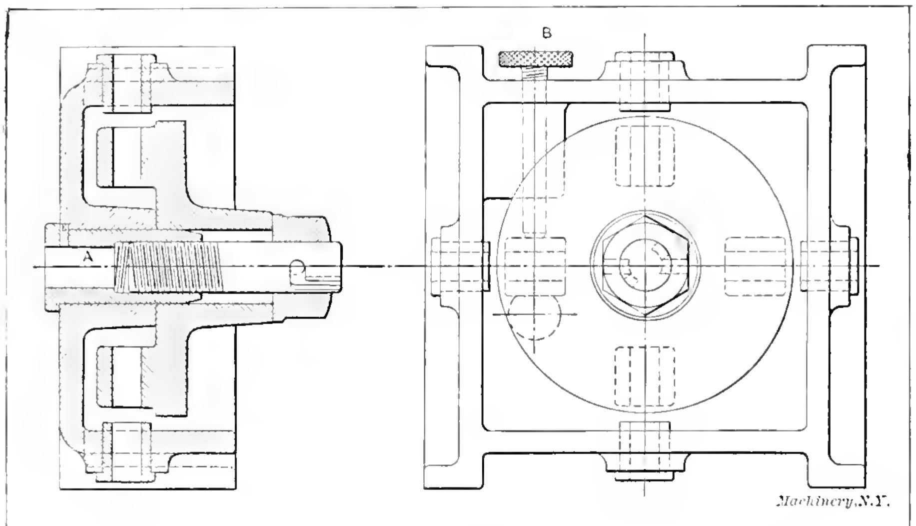
Drill Press Chuck that will hold Round or Square Stock or Flat Plates of Irregular Contour

of cast iron and it is a sliding fit on the shoulder bolts *C*. Bolted across the ends of these bolts is a machine steel piece *D*, 5/8 inch by 2¼ inches, having a 1-inch drilled and tapped hole to receive the clamping screw *E*. This screw, which is 1 inch in diameter, has its outer end squared to receive a wrench. The inner end, which is reduced to 5/8 inch, passes through a hole in plate *F* to which it is loosely riveted. Plate *F* is secured to the jaw with 7/16-inch countersunk screws. This chuck will also serve the same purpose as a vise.

MACHINIST.

QUICK-RELEASING NUT FOR JIG WORK

The application of an efficient type of quick-releasing nut to a box drill jig is shown in the engraving. By referring to the sectional view, it will be noticed that the work is centered by the nut *A* and located also by a knurled screw *B*. As there was a fairly large quantity of these pieces to drill, it was necessary to save time in every possible way. Previously a hexagon-head screw was used for clamping, but insertion and removal of the work took much longer than it should have done. The idea then occurred to me of using a bayonet lock-nut the same as is employed for cutters on facing bars. The sketch shows a hexagon nut with two pins driven in diametrically opposite to each other. These pins fit into corresponding slots in the stud, and all that needs to be done to remove the work is to turn the nut half way around, when it can then be removed from the stud. This method of clamping thus saves the time which would be required for screwing a clamping screw in and out.



Jig equipped with Quick-releasing Nut that facilitates Insertion and Removal of Work

LORIENS.

DESIGN OF TOOL CHESTS AND CASES

As one looks over the mechanical papers of to-day he cannot help but notice the neat and compact design of tool chests that are being advertised and placed upon the market by enterprising firms. No doubt this design is the outgrowth of the call from young men who travel from one end of the country to the other partly from curiosity to see this great republic and partly from a desire to gain wide experience, but who feel that the expressage on a chest the size of a small trunk is too large a drain on the pocketbook for the extra returns in wages received. When one starts to pack one of these modern tool chests, he cannot fail to be impressed with the fact that the tool manufacturing concerns are far behind the times in the designs of tool cases for such tools as micrometers, bevel protractors, height gages, and plain squares. In many instances the cases that come with such tools occupy the lion's share of the tool chest and are many times left behind on this account. The writer would suggest that the makers of such tools place upon the market cases of a flexible type made of leather or other material that would answer this purpose and advertise the same in their catalogues or mechanical papers, and he feels sure there would be a ready demand for them.

FIXTURE FOR HOLDING COUNTERSUNK SCREWS

As a number of 5/16-inch countersunk screws had to be threaded right up to the head for a certain job, and as those in stock were only threaded about two-thirds their length, I made a fixture as shown in the illustration for holding them while the die was used to cut the extra thread. As will be understood by referring to the plan view, the work was inserted or removed from the fixture by swinging the top plate to one side. To prevent the screw from turning, a plug with a tongue fitting the slot in the screw head was inserted in the hole in the bottom plate. This plug, which is held by a set-screw, was made removable so that it could be replaced in case the tongue should twist off.

Fixture for Holding Countersunk Screws while Extra Thread is being cut

SHEAVES FOR MANILA ROPE

Very little is being written on rope driving in technical papers, although this subject should be of almost universal interest to shop owners, etc., as the transmission of power by means of ropes has become an established fact.

In a general inspection of catalogues of manufacturers of power transmission material, it would appear that very little attention is given to the details of sheave construction; however, next to the ropes, the most important detail is the construction of the sheave, as the best of ropes will be quickly put out of commission if the sheaves are not perfectly smooth as to grooves, well designed, etc.

There seem to be three different angles used for grooves, 45, 50 and 60 degrees, but the 45-degree angle appears to be the most generally adopted, and it will be found that this angle will give the best results for both the English and the American systems of rope driving. It is contended by some that 45 degrees for the English and 60 degrees for the American system is the most correct, but no sound argument has yet been made why the American groove should not be the same as the English system, or 45 degrees.

The word "split," where it is used in reference to sheaves, appears in many catalogues. A split wheel, as it is generally understood, is cast whole with cored slits; wedges are then driven in the cored slits to split the wheel, and this gives fractured joints. This method is used for belt pulleys, but should not be used on sheaves. Sheaves, if not made solid, should always be cast in two pieces, the joints planed, the bolt holes drilled, reamed and fitted with finished bolts. Fig. 1 shows a sectional view of grooves as generally found in catalogues, for the English or multiple system. As generally shown, dimension *t* remains the same, whether the sheave is for one or more ropes. Section *t* is made stronger than section *f* to avoid breaking in handling; but, for instance, take a sheave that is made for ten 2-inch ropes: Section *t* will appear to be nicely proportioned, but for a sheave with two 2-inch ropes, this section will be all out of proportion with section *f* (see Fig. 2). Of course, section *t* cannot fall below a certain

thickness, but there is also no reason for making it the same for any number of ropes.

In laying out the grooves, we will find that for sheaves having six or more ropes, a certain standard for section t will be all right, but for sheaves having less than six ropes, the dimensions given in the accompanying table will be more in accord with section f for sheaves up to 60-inch pitch diameter. Sheaves larger than 60-inch pitch diameter may have

TABLE GIVING THICKNESS FOR SECTIONS t AND f FOR SHEAVES UP TO 60-INCH PITCH DIAMETER AND FIVE ROPES OR LESS

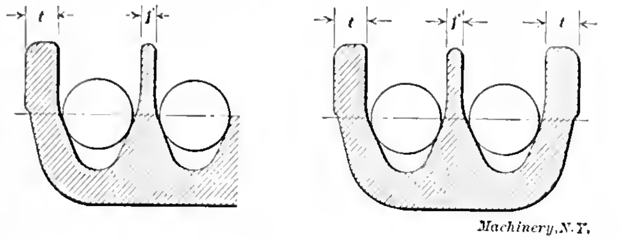

Fig. 1. Fig. 2.

Size of Rope in inches	t	f	Size of Rope in inches	t	f
1 1/8	3/8	5/16	1 1/2	9/16	3/8
1 1/4	7/16	3/8	1 3/4	5/8	3/8
1 3/8	1/2	3/8	2	11/16	3/8

the regular thickness for section t, as shown in Fig. 1, as they become too heavy if the dimensions given in the table are used.

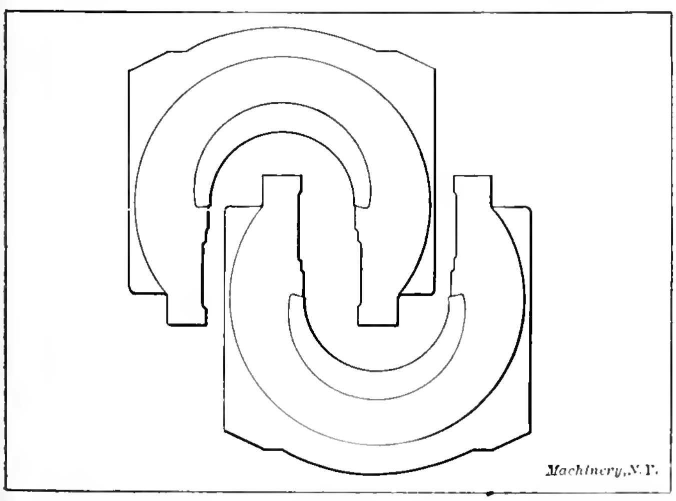
Arguments, etc., as to the advantages of rope driving, may be had from any manufacturer of Manila ropes. There is no doubt that for main drives, ropes have proved superior to belts, but for counter and machine driving, belts are still generally used.

AUGUST WACKERMANN.

Pittsburg, Pa.

CENTER REST FOR DRIVING BOXES

A machinist brought a pretty good shop kink to my notice the other day for laying out a set of driving boxes—one that saves a lot of time and trouble. In most shops when laying out a driving box the machinist fits a piece of wood in it to hold the center for his dividers. Instead of so doing, if the machinist will just slide the other box leg in between the



Simple Way of obtaining a Center Rest when Laying Out Driving Boxes

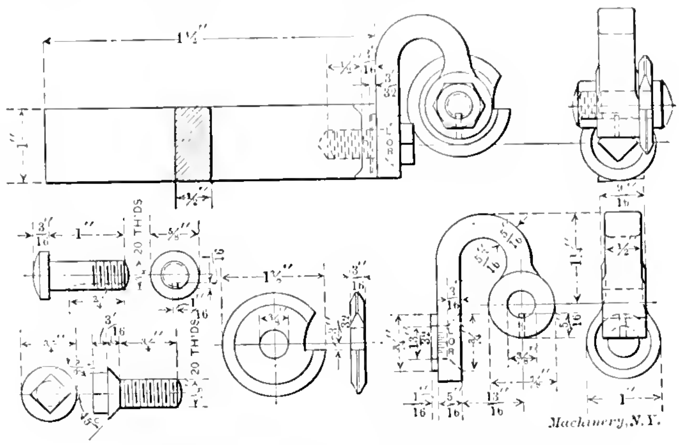
sides of the box being laid out, as shown in the illustration, he will have a good solid piece of iron, which is the same height as the box, on which to lay off the center. As the boxes are heavy, they stay in place and the two can be laid out at the same setting, using one to hold the center for the other.

A. G. JOHNSON.

Two Harbors, Minn.

A SPRING THREADING TOOL

A tool designed for use in cutting master taps, screw gages, and other parts where accuracy is desired, is shown in the engraving. It has all the advantages of a spring tool and is equipped with a removable cutter which can be sharpened and replaced without resetting. The principal advantage lies in the fact that the shape of the cutter may be ground to any desired degree of accuracy and no dependence need be placed on thread tools or gages bought in the market. The cutters are first rough turned, hardened, the hole lapped, and the faces ground parallel. They are then placed singly on a mandrel, and ground to the proper included angle and to a perfectly sharp edge. It will be noticed that the cutting edge



Circular Threading Tool with Spring Holder which may be adjusted for Right- or Left-hand Threads

is not radial, but to give clearance, is ground on a line 3/32 inch below, and parallel to the horizontal diameter. To secure the proper angle at this point, the center of the grinding spindle should be dropped 3/32 inch lower than the center of the cutter arbor, when grinding. If the cutter is to be made for U. S. S. or Acme threads, after grinding to a sharp edge, it is carefully measured on this diameter, the amount of flat calculated and subtracted therefrom, and the sharp edge reduced to this dimension. The engraving plainly shows the construction of the holder, by means of which the cutter can be tilted for right or left-hand threads. The lip of the cutter should be horizontal and the height of the lathe centers.

T. CAIN.

HEAVIER TOOL-POSTS FOR SHAPERS

Some of the so-called high-duty shapers are equipped with rather insignificant looking tool-posts, as shown in Fig. 1, having screws entirely too small for holding the tool. The tool-post screw for 18-inch shapers and over, where a single

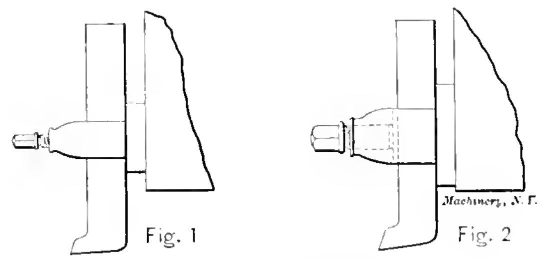


Fig. 1 Fig. 2

Figs. 1 and 2. Light Form of Tool-post found on some Shapers, and Suggested Change

screw is used, should be at least 1 inch in diameter (instead of 5/8 inch) as shown in Fig. 2. The tool-post can then be depended upon to hold the tool right where it is wanted.

PROTECTING POLISHED STEEL WORK FROM RUST

Polished steel work may easily be protected from rust by the application of the following compound:

Lard	6 parts
Rosin	1 part

The two ingredients are melted together and stirred until cold. The rosin prevents the mass from becoming rancid and also acts as an air-tight film. If rubbed upon a polished steel surface, even very thinly, it effectually preserves and protects the polish. It is easily removed by gasoline or kerosene.—*Brass World.*

HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

DEEP HOLE CALIPERS

J. W. M.—I have to determine the size of a hole at the bottom of a 4-inch bore about 12 feet long. What is the best means of accurately calipering under such conditions, using either a standard measuring device or home-made contrivances?

A.—The best means depends on the character of the work, and the degree of accuracy required. The question is referred to our readers for suggestions. Descriptions of deep-hole calipering devices will be acceptable.

OILING MACHINE PARTS WHEN ASSEMBLING

G. B. D.—Should a taper pin be oiled before driving it home?

A.—A taper pin should be oiled before driving home, and in fact almost all ordinary machine parts should be lubricated before assembling whether they are pins, bolts, screws or other members. If a taper pin is oiled before being driven into place, it can be put into place with lighter blows, and will be less likely to work loose than if put in dry.

SETTING A THREAD TOOL FOR THREADING TAPER TAPS

A. B. C.—Should a thread tool be set square with the tailstock spindle or square with the surface of the taper when cutting the thread of a taper tap, assuming the work is done in a lathe provided with a taper turning attachment?

A.—The tool should be set square with the tailstock when threading a taper tap in a lathe provided with a taper attachment. The rule is to set the tool square with the center line of the tap. If the threading is done with the tailstock set over, the tool may be set square with the surface of a straight arbor of the same length of the tap, held between the centers.

TO CALCULATE THE WEIGHT OF HEXAGON BAR STOCK

G. V.—Please give a rule for calculating the weight of hexagon bar stock.

A.—Square the thickness of the stock across the flats and multiply by 0.866, and the area thus obtained by the length, to obtain the volume. The volume, in cubic inches, multiplied by the weight of a cubic inch of the material is the weight. Example: Suppose that the weight of a steel hexagon bar 2 inches across flats and 12 inches long is required; $0.866 \times 2^2 \times 12 = 41.568$, which multiplied by 0.283 pound, the weight of one cubic inch of steel equals 11.76, the weight of the bar, in pounds.

WARPING OF PUNCHED COLD-ROLLED PLATE

F. G. S.—We make a number of 1/16 inch thick cold-rolled 10- by 14-inch sheet steel plates with about sixty 1-inch holes, punched or drilled. We have tried both drilling and punching but the plates have sprung and buckled to such an extent as to make their use impossible. We have tried rolling, peening, heating and laying between heavy cold plates, but all to no avail. Can you suggest a remedy for our trouble?

A.—The difficulty is one that you probably cannot overcome with the material used unless it is annealed before drilling or punching. Cold-rolled stock is in a state of stress due to the cold finishing process. The surface is in a state of compression and the interior in a state of tension. A cold-rolled bar or plate remains straight so long as the interior and exterior forces are balanced as they were when leaving the rolls, but if metal is removed from the surface a change of shape immediately results. This will be observed in turning cold-rolled shafting or cutting long keyways in same. When you punch or drill holes in the plate, the interior and exterior stresses readjust themselves with the resulting change in shape noted. You must carefully anneal the plate before punching or drilling, or use some other material.

PROBLEM IN METAL SPINNING

R. L. C.—I have to do the job of metal spinning, shown in Fig. 1, and am doubtful as to the best method to follow in spinning this shape. The shell is to be 20 inches diameter, 6 inches deep, and 0.060 inch thick. The metal to be used is zinc.

A.—This is an interesting metal spinning job, and not a particularly difficult one. The shell can be best spun with the aid of two spinning forms, such as are illustrated in Figs. 2 and 3. These forms should be made of kiln-dried maple if there are comparatively few shells to be spun. If there are many, the form should be made of cast iron. Fig. 2 shows the first form to be used, which conforms to the outside of the shell as far as the centers of the spherical ring. Beyond these points, the form is straight. The blank to be spun is placed as indicated by the dotted lines, and follower No. 1 is used to hold the work against the form. The chief trouble

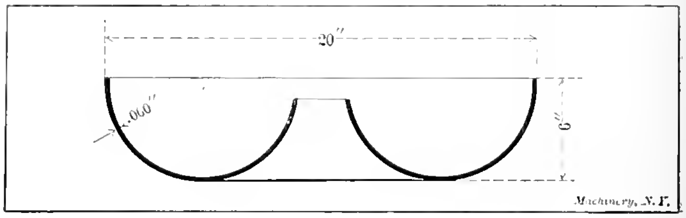

Fig. 1.

will be met in properly starting the shell, because of the small follower that must be employed. However, follower No. 2 may be substituted after working the metal back against the form a few inches, and as this gives a better grip on the shell, there will be no further danger of slipping. After spinning the zinc shell to the shape of the first form (Fig. 2) it will probably have to be annealed, but this can only be determined by trial. In annealing zinc, the flame should not be allowed to touch the metal. The half completed shell is then put on form No. 2 shown in Fig. 3. It is an easy matter to spin the metal around to complete the arc. The dotted line shows the position of the shell before starting the last part of the spinning. Of course, it will be understood that the shell must be trimmed several times during the spinning, and if the trimming is frequently done, a well-shaped shell should

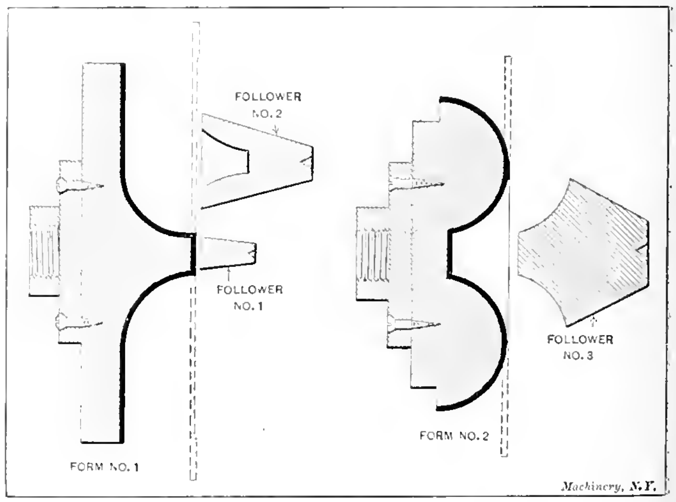

Fig. 2 Fig. 3

result. For spinning on form No. 2, follower No. 3 must be used. Either beeswax or soap should be frequently rubbed over the work while spinning. If it is necessary to cut out the center, it can be done before removing the shell from the last form by simply removing the follower and using a diamond point tool, or in large product work the swivel cutter will work well. The shell will cling to the form without the follower. The spinning speed should be from 800 to 1,000 R. P. M.

Considerable attention is given by the German technical institutions to the science of aeronautics. A bill has been introduced in the Diet of Würtemburg, asking for $2,250 yearly for a chair in aeronautics at the Stuttgart Technical University. The government also announced that a sum of $12,000 has been offered privately for the purpose of establishing a laboratory for aeronautics in connection with this chair.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

BECKER FRICTION FEED VERTICAL MILLING MACHINE

An interesting type of vertical milling machine, embodying some radically new features, has recently been brought out by the Becker Milling Machine Co., Hyde Park, Boston, Mass. This machine will be built in four sizes, known as Models

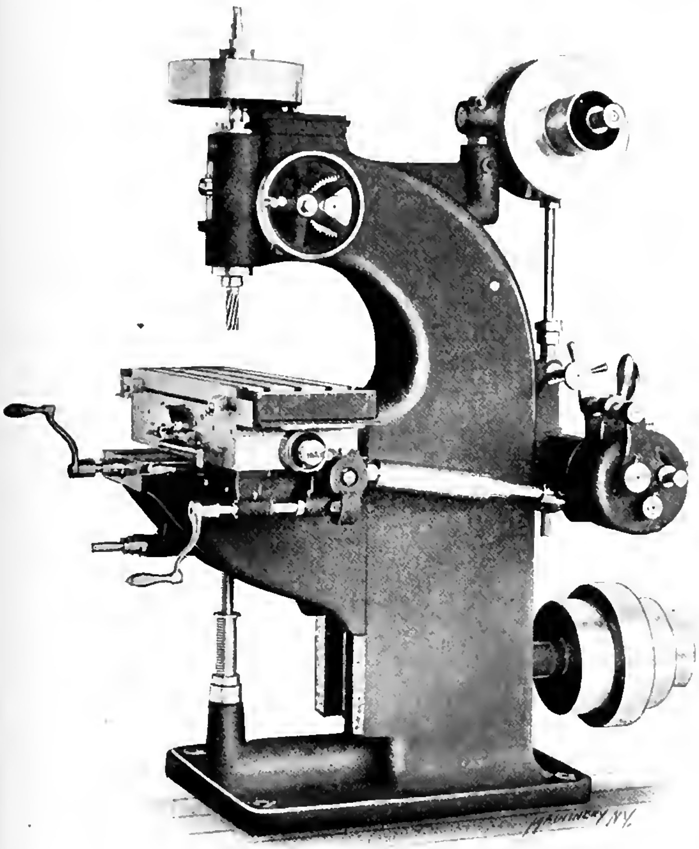

Fig. 1. Side View of Friction Feed Vertical Milling Machine, built by Becker Milling Machine Co., Hyde Park, Mass.

A, B, C and D, respectively. The accompanying half-tone illustrations show the model A machine, and the description applies in particular to this size; but all the sizes to be built embody the same features, with slight modifications in such mechanisms as the back-gearing, gear boxes, etc., which, of course, on the different sizes are made to suit the requirements for, and capacity of, each machine. Fig. 1 shows a side view of the machine and Fig. 2 a rear view, exhibiting some of the important features of the feed mechanism.

Main Spindle Drive

The main drive of the machine may be either by means of a three-step cone pulley as shown in Fig. 1, or by a constant speed single pulley drive, the power being obtained directly from an electric motor or from a pulley on the line shaft. When the single pulley drive is employed, a gear box of simple design and similar in principle to the feed gear box, which will be described later, is made use of in order to obtain the required speed variations on the driving pulley of the machine, which is belted directly to the pulley on the vertical spindle. This gear box provides for five speed changes. The machine shown is not provided with back-gearing, but if required, back-gearing arranged practically on the same principle as that of a lathe, and enclosed in a very compact gear box placed immediately beneath the pulley on the vertical spindle, is provided. The back-gearing for the model A machine is of the regular type, and for the larger sizes, of the double type, so that by means of the back-gearing and a gear box on the main driving shaft, 10 speeds on the model A machine and 15 speeds on the larger sizes may be obtained. Five of these speeds are obtained without the back-gearing, using open belt drive.

As is clear from the illustrations, Figs. 1 and 2, the 3-inch belt from the driving pulley at the bottom of the column passes over two idler pulleys. These pulleys, as is seen in Figs. 2 and 3, are mounted on the hubs of large friction disks that operate the feed mechanism which will be described later. The spindle speeds obtainable by the gear box when the constant speed pulleys run at 405 revolutions per minute—the speed recommended by the makers—are 80, 120, 180, 270 and 405 revolutions per minute. If it be desired to obtain higher speeds than these, a two-step cone pulley may be provided on the machine, and two pulleys of the required size placed on the line shafting. By this simple means another five speeds may be obtained of 150, 225, 335, 505 and 760 revolutions per minute, without resorting to back-gearing.

The column is cast in one piece, so as to insure rigidity. The vertical movement of the spindle head is obtained by means of a hand-wheel on the side of the machine, as shown. The spindle is hardened at the main bearing, and finished by grinding. The bearing boxes are made of bronze, and provided with simple means of adjustment. The head is cylindrical, which insures perfect alignment, and is provided with a micrometer stop gage, placed, as indicated in Fig. 5, in the slot at the front of the column of the machine. The graduated collar of this stop gage is of large diameter, so that each gradua-

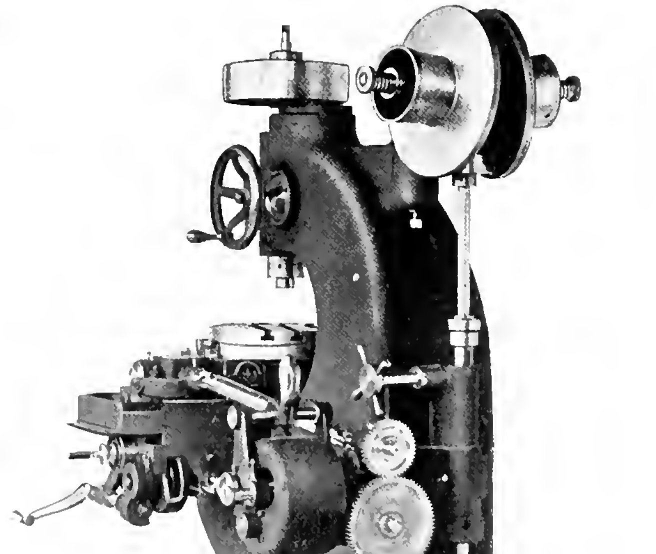

Fig. 2. Rear View of Becker Milling Machine, showing Friction Feed

tion corresponding to 0.001 inch is nearly 1/16 inch wide. This makes it possible to obtain very accurate adjustments without difficulty. At the lower end of the slot in the column a small projection or shelf is provided, on which can be placed circular gage blocks about 1½ inch in diameter, carefully made to standard thickness. By means of these gage blocks it is possible to bring the head down any definite amount; for instance, if it be required to bring the head down exactly three-quarters of an inch after one cut has been made

over the work in the machine, the micrometer stop is first brought against a $\frac{3}{4}$-inch gage block placed on the shelf or on the top of other gage blocks, and when the first milling cut has been completed on one lever, the $\frac{3}{4}$-inch gage block is removed and the head brought down until the stop rests against either the shelf or the remaining gage blocks, and the work is completed. By different combinations of gage blocks it is possible to obtain close measurements for all movements of the head. If it is required to move the head

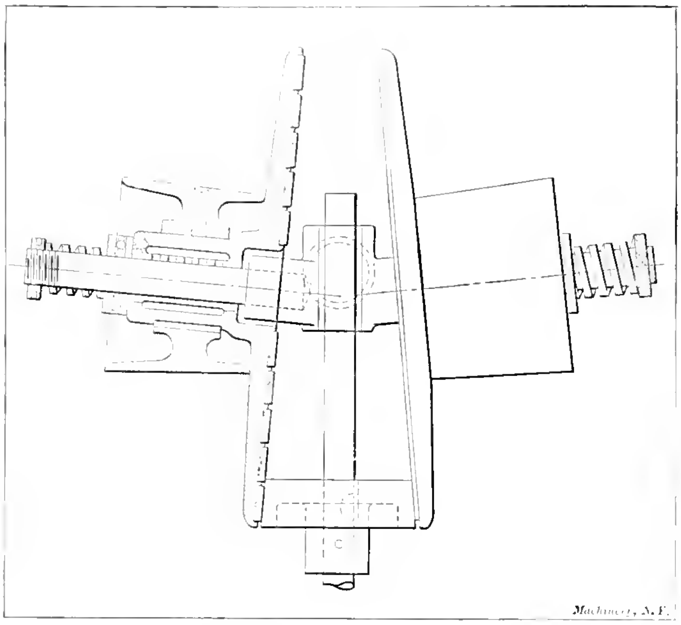

Fig. 3. Friction Feed Disks and Mounting of Idler Pulleys

only a few thousandths of an inch, the stop, of course, is brought against the gage blocks and then the graduated collar is turned the amount required, to raise or lower the head.

Friction Feed of the Machine

The distinctly novel and, without doubt, the most interesting feature of the machine is the friction feed drive. This drive may be defined as being a positive friction feed, inasmuch as the belts on the driving pulleys of the machine will slip or be thrown off their pulleys before the friction feed will cease to operate even on the heaviest cuts. This is due to the ingenious arrangement of the friction disks and the manner in which the pressure is applied to them. It will be noticed in Figs. 2 and 3 that springs are provided on the ends of the studs on which the friction disks are mounted, these springs tending to add to the pressure on the friction roller, but it has been found that by the arrangement employed these springs are unnecessary and can be removed. The pressure is furnished entirely by the driving belt passing over the idler pulleys, which are mounted on shafts placed at an angle upward and backward with the horizontal, as indicated by the position of the friction disks at the ends of the pulleys in Fig. 2. This angular arrangement produces an inward pressure of the belt on the idler pulley, which, in turn, is transmitted to the friction disks and used for obtaining the required pressure on the friction roller.

As there are two idler pulleys both placed at corresponding angles and the belt passes over both with practically the same tension, the drive is balanced, and the difficulty with friction drives usually encountered—that of providing adequate thrust bearings—is eliminated. The angle of the friction roller is 10 degrees on each side, it having been found that with the arrangement used this angle will produce the greatest pressure and the most efficient transmission of power to the feed mechanism. The idler pulleys are conical, being about one-half inch larger in diameter at the outside end than at the end abutting against the friction disks. This feature throws the belt further out on the idler pulley when running at high speed, due to the centrifugal force, and this in turn tightens the belt and increases the belt tension, at the same time increasing the pressure on the friction disks and roller. Thus, the higher the speed or the heavier the cut, the greater the belt tension, and the more powerful the friction drive mechanism.

A line drawing, illustrating in a general way the arrangement of the idler pulleys and friction disks, is shown in Fig. 3. The idler pulleys, as shown by the sectional view, are not cast in one piece with the friction disks, but are fastened to the disks by keys and set-screws, the friction disk being provided with a long hub for this purpose; the hub is provided with ample means for lubrication.

An interesting feature, and one of extreme importance in a friction drive, is the method used for fastening the leather to the cast iron friction disks; one of the chief difficulties of friction drives in the past has been the trouble met with in the loosening of the leather from the disks. A common method employed has been to first attach one disk of leather to the cast iron disk by means of small pins or rivets, turning off the rivet heads level with the surface of the leather, and then attach another thickness of leather, by means of leather cement, to the one fastened to the cast iron disk. This means of fastening gave no trouble as long as the leather was kept free from oil, but as the leather in any friction drive, in order to transmit power efficiently, must be kept soft and pliable, and, therefore, must be oiled occasionally, the oil would dissolve the cement, and the leather disk would become loose.

In the construction used in the friction feed disks on the Becker milling machine, no cement is used between the leather and the disk, and therefore the required amount of lubrication can be supplied to the leather without any danger of interfering with the durability of the drive. The cast iron disk is provided with a number of concentric grooves of a dove-tail shape, as shown in section in Fig. 3. The leather, cut into segments, is pressed into these grooves, where it is held very firmly on account of the shape of the groove. When

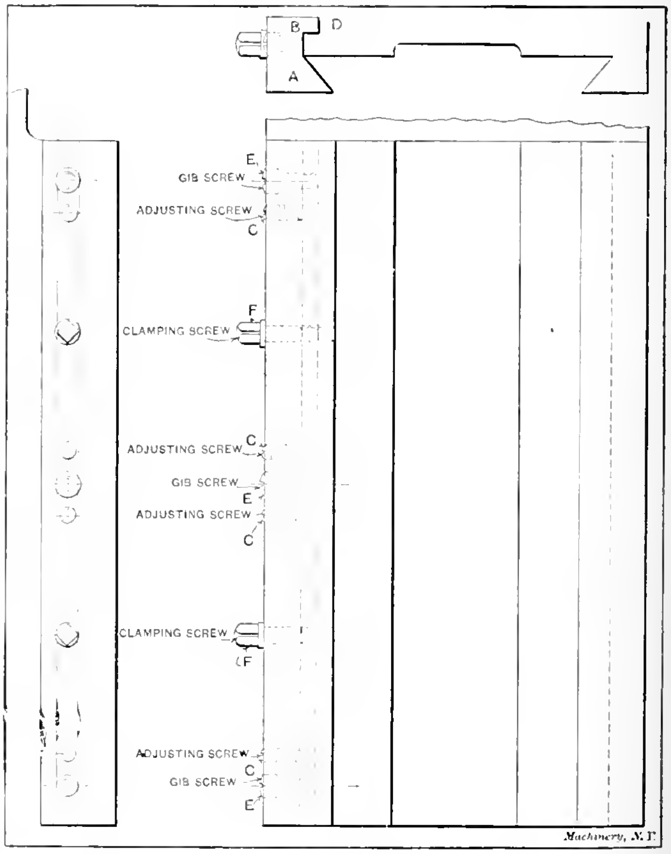

Fig. 4. Construction of Gib for Milling Machine Knee Slide

the pressure is applied to the disks against the friction roller, it is evident that the leather is still more firmly pressed into the dove-tail, so that the heavier the feed is, the firmer is the grip between the leather and the cast iron disks. The friction roller is adjusted up or down as required for different feeds by means of the small hand-wheel or spider shown in Fig. 2 at the back of the column. On the end of the shaft of this spider is a small pinion engaging with rack teeth on the sleeve of the vertical feed shaft. The power from

the vertical feed shaft is transmitted to the feed gear box shown in Figs. 1 and 2 by means of worm and worm-gear. The feed gear box is of a very simple construction. It is operated by means of the handle on the top, and by the push pin on the side of the gear box shown projecting outside of its bearing. By means of this gear box five variations in feed can be obtained without varying or changing the location of the friction roller. One of these feeds is obtained without any of the gears in the gear box proper running, but

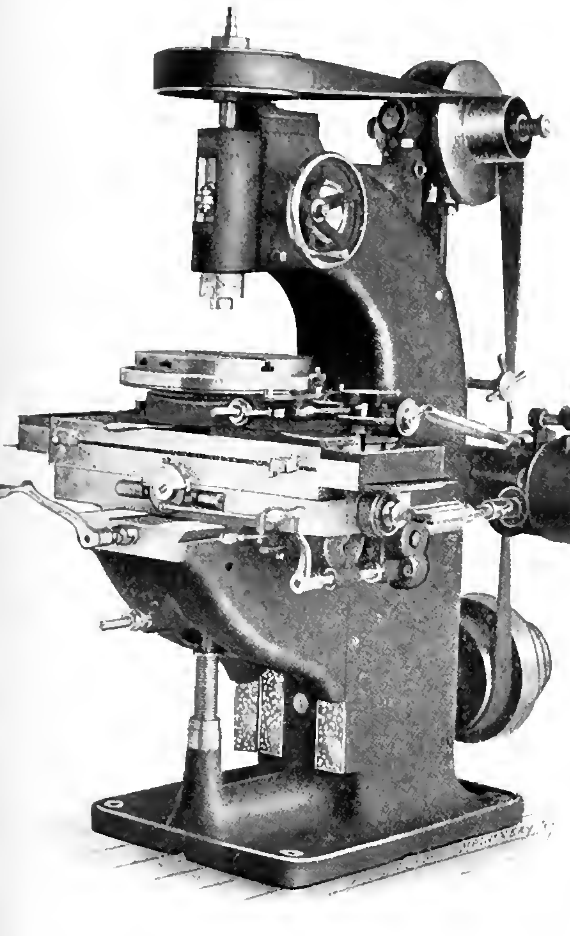

Fig. 5. Becker Milling Machine with Improved Rotary Milling Attachment

by connecting the horizontal feed shaft directly with the telescoping shaft leading to the table. In this way the loss of power incident to transmitting the motion through a great many gears is avoided, and the feed is brought to the table in as direct a manner as possible. By the combination of the friction feed disks and the gear box it is possible to obtain all feeds on the machine between 0.003 inch to 0.067 inch per revolution of the cutter. This refers to the model A machine. On the model B machine feeds can be obtained from the same minimum of 0.003 inch up to $1\frac{1}{4}$ inch per revolution of the cutter.

The design of the gear box is novel, and it differs in construction from the ordinary type in important details. Instead of using a sliding gear or tumbler moving back and forth on the tumbler shaft, the whole tumbler shaft moves by means of the push pin shown It is placed in bearings on the outside of the gear box, thus making lubrication very easy. As there are no interior bearings to oil, there is no need of a complicated lubricating arrangement with oil tubes leading to the various bearings on the inside of the gear box.

The power of the friction drive is well exhibited by the fact that the machine will take a cut in cast iron 1/16 inch deep with a feed of 1/16 inch per revolution of the spindle, with a six-inch cutter. The larger sizes, of course, will permit of proportionally heavier cuts.

Another new feature of the machine is the arrangement of the knee slide. Instead of having a knee provided with a dove-tail slide, and the dove-tail on the column of the machine, the order has been reversed, and the column of the machine is provided with a dove-tail slide, the dove-tail being on the knee. This in combination with the arrangement shown in Fig. 4 for adjusting the dove-tail slide and binding the knee when required, makes it possible to obtain a construction without any loose gibs. The piece *A*, Fig. 4, is made a very close fit in the groove in the column at *B*. In order to adjust the slide properly for the dove-tail on the knee, the adjusting screws *C* are used, which bear against the face *D* of the column, as shown. When the proper adjustment has been obtained it is permanently retained by tightening the gib screws or binding screws *E*. When it is desired to lock the knee to the column of the machine, the clamping screws *F* are tightened, which then spring the gib between the adjusting screws *C* a very small amount, enough to hold the knee rigidly in position. This method of binding insures perfect freedom from change in alignment, and is considered by the builders as a very important improvement in milling machine design. The knee is made with a double wall box construction and is thus unusually heavy and rigid.

Mechanism for Stopping and Reversing the Table

In the front of the machine in Figs. 1 and 5 is shown a new and interesting mechanism for stopping and reversing the table at the end of its travel. Stop dogs are provided as usual, operating a mechanism shown in the center of the saddle. By manipulating the two plungers on each side of the central reversing disk, it is possible to either have the machine move constantly back and forth automatically, or to have it stop at the end of its travel to the right or at the end of its travel to the left. The manipulation of the plungers can be made during any part of either the forward or the backward stroke; the machine will stop first when it comes to the end of its stroke at either the right or left, according to which one of the plungers is manipulated. The central reversing disk is provided with a spring arrangement which throws it over rapidly to either side as soon as the stop dogs have moved it over a certain amount; a pitman connects the disk with a handle which operates the clutch between the two bevel gears used for reversing the table. This makes a very simple arrangement which is exceedingly handy and useful.

The table of the machine is provided with a cover which protects the top of the saddle from chips and dirt whenever the table is moved to extreme positions either to the right or left. This cover does not telescope, but consists of a leather shield with a sheet iron hook at its end, which holds it to the end of the saddle when the end of the table passes by this point. The other end of the leather cover is rolled up in

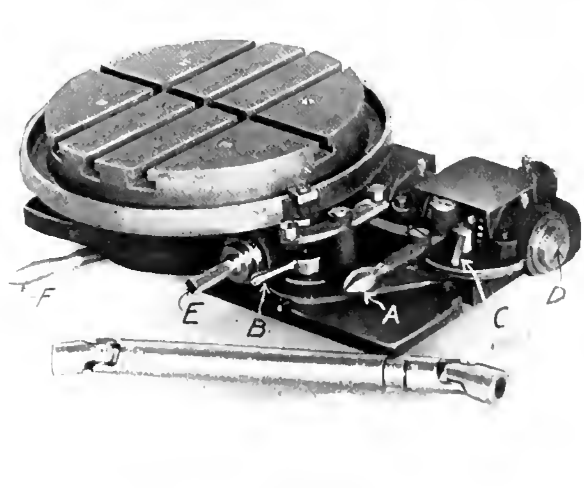

Fig. 6. Rotary Milling Attachment Removed from Table, in order to show Details

a manner similar to that of an ordinary shade. The same arrangement is used back of the table between it and the column, in order to protect the knee and the working parts contained in it from the chips when the table is moved outward.

Drive for the Rotary Milling Attachment

Another improvement which has been introduced on this milling machine relates to the drive for the rotary milling attachment shown in place on the machine in Fig. 5, and in detail in Fig. 6. In the previous types of the Becker milling machine, the rotary attachment was driven through a gear

box placed on the right-hand end of the milling machine saddle, the power being obtained through the regular telescoping shaft. In this machine, as shown very clearly in Fig. 5, the power for the rotary attachment is obtained through an independent telescoping shaft connected directly with the regular feed gear box. In Fig. 6 the attachment is shown by itself, removed from the machine; *A* is the handle which operates the clutch between the two bevel gears, by means of which the motion of the rotating table is reversed. The shaft *D* on which these two bevel gears are mounted is connected by bevel gearing with the worm-gear shaft *E*, from which the power is transmitted to the rotating table through worm and worm-gear. The motion is automatically thrown out by means of the dog shown on the rim of the rotating table, which operates the lever mechanism indicated and returns the handle *A* to a central position. The worm can be thrown out of engagement with the worm-gear by operating handle *B*, and when either thrown in or out of engagement the attachment is locked in position by the binder *C*. This arrangement has the advantage of being easily removed from the table of the machine, it being necessary only to loosen two bolts and slide it off. When required, the rotating table can be locked in position by handle *F*, and regular straight milling can be performed without removing the attachment.

General Remarks

In general, throughout the design of this machine, gears have been eliminated wherever possible. Mr. Becker, who is responsible for the design, considers that entirely too much power is lost by driving through the usual type of gear boxes, and also in obtaining feed changes through gear boxes. For this reason the drive of this machine is so arranged that even when a gear box is introduced, one set of speeds can be obtained without using the gears in the gear box; and by means of the friction feed, a wide range of feeds can also be obtained directly, without introducing the gears in the feed box. Even when the gears in the feed box are running, a maximum of two sets of gears are in engagement at a time, so that the losses due to the gearing are a minimum. The direct friction feed, when arranged as in these machines, is more positive even than a gear feed, because there is no back lash or unsteady, intermittent motion, as is likely to be the case when the gears get badly worn. As the idea of geared driving heads and speed of gear boxes has been carried rather to its extreme in some recent designs, it is all the more interesting to note the efficiency which can be obtained by returning to the older idea of using belt drives in as large a measure as possible. By means of a wide driving belt, large pulleys and high belt velocity, all the power of the regular gear-driven machine can be obtained in an open belt drive, and the present machine will do milling jobs for which the back-gears would ordinarily be used, without throwing in the back-gearing. This machine, therefore, is an interesting development in machine tool design, and will undoubtedly be received with considerable interest by the mechanical trade.

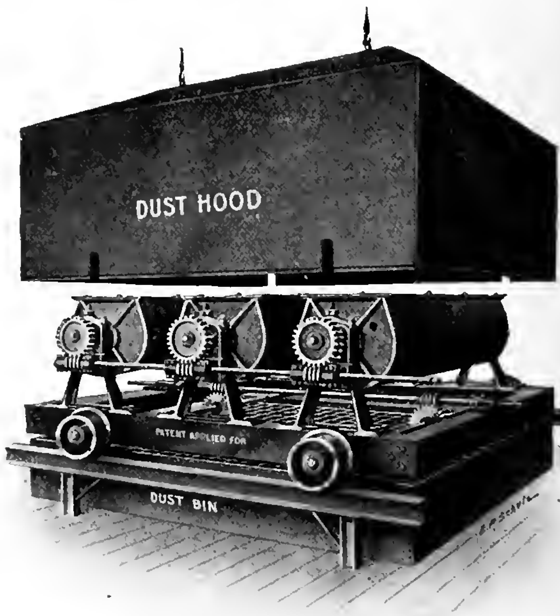
MACHINE FOR SHERARDIZING OR DRY GALVANIZING

The process of galvanizing metal products by the dry or sherardizing method has been previously described in MACHINERY (see article on the subject in the August, 1908, number). It consists, in brief, in packing the articles of iron or steel to be galvanized in air-tight drums with the impalpable powder swept from the flues of zinc smelters. This powder (known to commerce as zinc dust) consists of particles of metallic zinc, about 0.00002 inch in diameter, coated with a layer of zinc oxide. When the work thus packed is heated for the proper length of time to a temperature of 800 or 900 degrees, it is given a lustrous gray coating of zinc. Apparently the zinc dust remains as it was before, the action being somewhat of a mystery. In reality, however, the dust has parted with metallic zinc and it gradually deteriorates, though it may be used over and over again for months.

The apparatus for sherardizing shown herewith is the invention of Albert F. Schroeder, and is built by the Globe Machine & Stamping Co., of Cleveland, O. This firm established the first commercial sherardizing plant in the country, designing practically all its equipment for the purpose. Its experience in this work has been applied to the machine here shown, with the result of great improvement in efficiency and economy over the methods originally followed.

The most important improvement is in the provision made for rotating the drums in which the work is subject to action of the dust. Three of these drums, as shown, are mounted on a car, which can be pushed bodily into the heater. The constant agitation of the work and the dust together brings them into contact at every point of their surfaces, packing the zinc down into the interstices of chains or into the finest threads of bolts and screws. Where this rotating or tumbling is not resorted to, there are parts of the work which are liable to escape galvanizing on account of being in contact with each other, to the exclusion of the zinc.

The rotating of the drums also expedites the process by bringing new dust into contact with the work. It also assists in bringing the interior up to the same degree of heat as the



Schroeder Machine for Dry Galvanizing

oven, by continually bringing new hot dust from the walls to the cooler interior. This shortens the time required, as zinc dust is naturally a poor conductor of heat. For the same reason, the interior temperature tends to keep the same throughout the whole area, enabling the operator to control the process better than under the old conditions.

As may be seen the drums are rotated by worm gearing. The contents are shoveled into them through the opening made by removing a flat plate on top. To empty the drums, they are revolved half way round. The emptying takes place over a bin provided with a screen top, which allows the dust to fall through, leaving the work clear on top. The dust-hood shown is dropped over the machine during this emptying process, preventing its escape into the room. The dust-hood and bin are, of course, located outside the oven, from which the car is removed previous to tumbling.

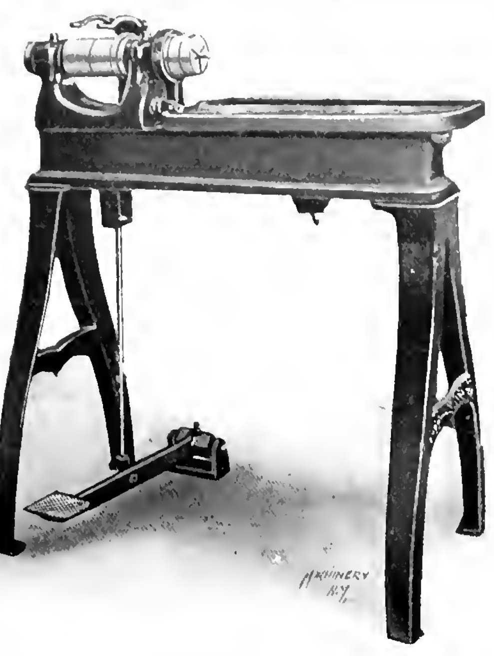
The sherardizing process has been adopted by some of the largest electrical and other concerns of the country, and has been in successful use for several years in foreign countries.

WELLS POLISHING AND FINISHING LATHE

The polishing and finishing lathe shown in the accompanying half-tone illustration is built by the F. E. Wells & Son Co., Greenfield, Mass., and is designed for all kinds of light work, such as polishing, burring, etc., on pieces which can be held in a spring or collet chuck. As indicated in the illustration, the chuck is opened by a foot lever, which at the same time shifts the belt to the loose pulley and applies a friction brake for stopping the machine immediately. When the pressure on the foot lever is released, a spring shifts the

belt back again to its driving position on the tight pulley, and the chuck, at the same time, is closed. This arrangement makes it possible for the operator to have both hands free for handling the work.

The general dimensions of this machine are as follows: The length of the bed is 42 inches; the swing over the bed,



Polishing and Finishing Lathe, built by the F. E. Wells & Son Co., Greenfield, Mass

11 inches; and the capacity of the chuck from ⅛ to 2 inches. The width of the driving belt is 2 inches, and the weight of the machine complete is 325 pounds.

NO. 1 TILTED TURRET SCREW MACHINE

In the department of New Machinery and Tools in the July, 1909, number of MACHINERY, we described in some detail the design and construction of the "tilted turret" screw machine made by the Wood Turret Machine Co., of Brazil, Ind. The

Fig. 1. No. 1 Size Tilted Turret Screw Machine

turret slide of the machine then illustrated was operated by a pilot-wheel. The accompanying illustrations show a smaller size of this machine of the same general design, but provided with a lever feed.

Fig. 2 shows this lever feed to best advantage, and illustrates as well the novel points of its construction. A rack and sector movement is used. The lever and sector form one piece, and the latter meshes with a rack secured to the turret-slide. With the usual construction on small size screw machines, the lever is pivoted to the slide, and is connected to the slide bed by a link or swiveling post. Under these conditions a changing leverage results, which requires the operator to exert more power at the start and finish of the stroke than in the middle. The arrangement shown in Fig. 2, however, permits the operator to exert the same pressure against the work at all parts of the stroke, allowing a much greater effective length of motion, so that longer cuts can be taken than on other machines of the same capacity.

The general construction of this machine is the same as with the designs previously illustrated. The tilting turret, from which the machine takes its name, will be readily recognized. It allows the stock to pass into or directly through the turret head, the center bolt being bored to permit this. When projecting through, the stock passes out through one of the auxiliary holes in the lower half of the turret in the rear, without interfering with tools clamped in the rear position. The construction has other incidental advantages as well. The strain on the center bolt is minimized, since the angular setting of the turret applies a part of the thrust directly onto the slide, doing away with the tipping occurring with the old style high turret. Furthermore, the construction permits the use of die heads or box tools of larger diameter than on other machines of the same capacity and the same swing.

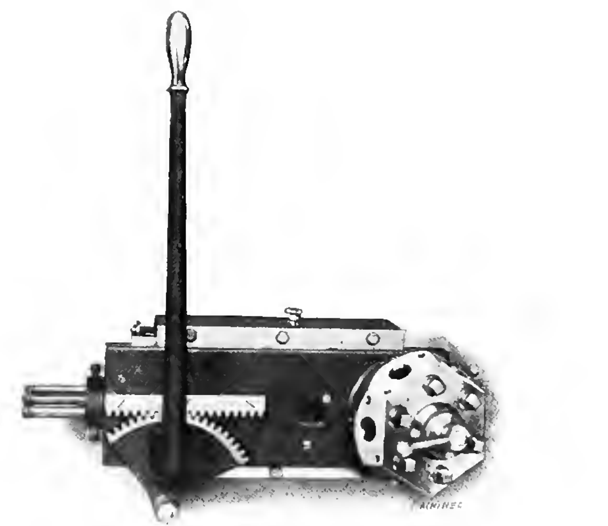


Fig. 2. Lever Feed of No. 1 Tilted Turret Screw Machine

Other features of this design that should be noted are the provision for lining the turret holes horizontally and vertically with the spindle, the provision of independent stops for each hole in the turret, and the arrangement for throwing out the indexing mechanism when only one hole in the turret is to be used. The lock pin holes are bushed so that any wear that may occur can be taken care of by rebushing the holes.

The machine here shown is the No. 1 size, having an automatic bar chuck capacity of ¾ inch. It is provided with an automatic stop feed. This tool may be seen in operation at the demonstration shops of Hill, Clarke & Co., in Boston or Chicago, or at their branch offices in New York, Philadelphia and Cleveland.

BAKER BROS. NO. 0 CYLINDER BORING MACHINE

The illustrations herewith presented show the well-known drilling machine made by Baker Bros., of Toledo, O., in a design especially adapted to automobile cylinder boring. This machine is the smallest member of a line which includes five sizes and types of single, double and four-spindle machines. This particular one is designed for boring small cylinders, being rated for diameters up to 3¾ inch and depths up to 8 inches. This is its range with maximum production, but it will easily bore much larger diameters, as it is provided with an unusually powerful spindle driving mechanism.

A distinctive feature of the machine is the provision made for employing boring bars of nearly the full diameter of the cylinder being bored. It is this feature which accounts for

the large output of which the machine is capable. The bar is driven from the spindle by a tongue and groove joint as shown. It has a bearing in a housing bracket, which is secured to the front of the machine, and carries a bronze bushing fitted to a taper seat. This provides adjustment for the bearing of the hardened boring bar, which is thus held so closely that there is no danger of its following the cored hole.

It is customary to set these machines up in gangs of three or four units. Where the cylinders are reamed, they are roughed under the first spindle, straightened under the second and reamed under the third. When two cuts only are taken before grinding, the cylinders are roughed in the first and third spindles and straightened in the second and fourth. The method of handling the work is such that the cylinders may progress from one spindle to the next without interruption for rough boring, straightened boring and reaming. The design is such as to adapt the machine to the boring of single cylinders, twin cylinders, or four cylinders "cast in block." The engravings show the machine with a fixture for holding an unusual type of open end cylinder.

In regard to the general design of the machine, it may be said that it is adapted to high speeds and feeds. All shafts are ground, and all bearings are bronze bushed. Most of the gears are of steel, hardened where necessary, and run in a bath of oil. The machine swings 12 inches from the center of the spindle to the frame. It has 8 quick change geared spindle speeds, and 12 changes of geared feeds. A single belt-drive is provided, the design of the machine being such that it may be belted directly to the line-shaft, allowing a number of them to be placed side by side to form gangs of any required number of units. The weight of the machine is 3,500 pounds and the floor space occupied is 3 feet, 6 inches square.

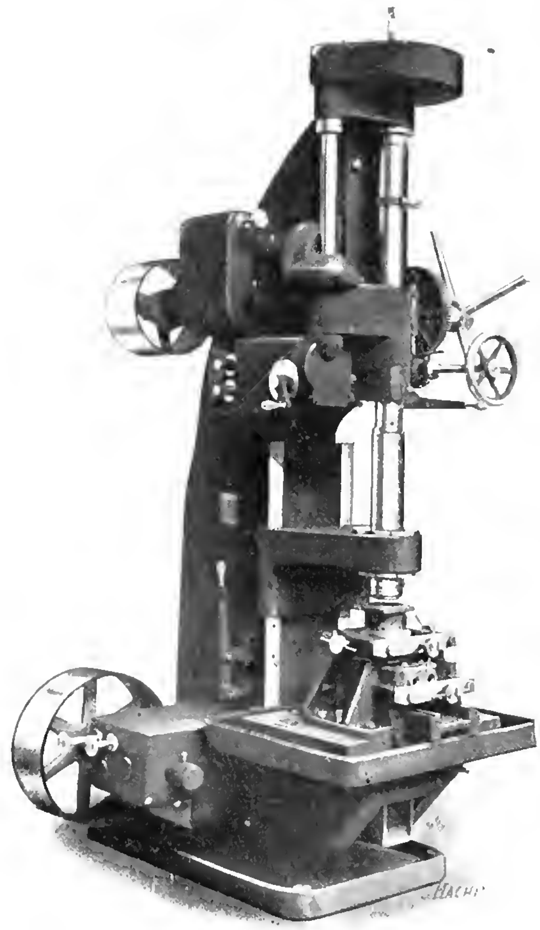

Fig. 1 Baker Automobile Cylinder Boring Machine

The makers of this tool have kept in close touch with automobile work from the beginning, and are prepared both to design and build tools and fixtures for use in machines of this type, or, if preferred, they will give their customers the benefit of their experience in this line in the way of suggestions. When required, special attachments for boring, facing and tapping the seats of automobile cylinders will be furnished. With these attachments, either two or four tools can

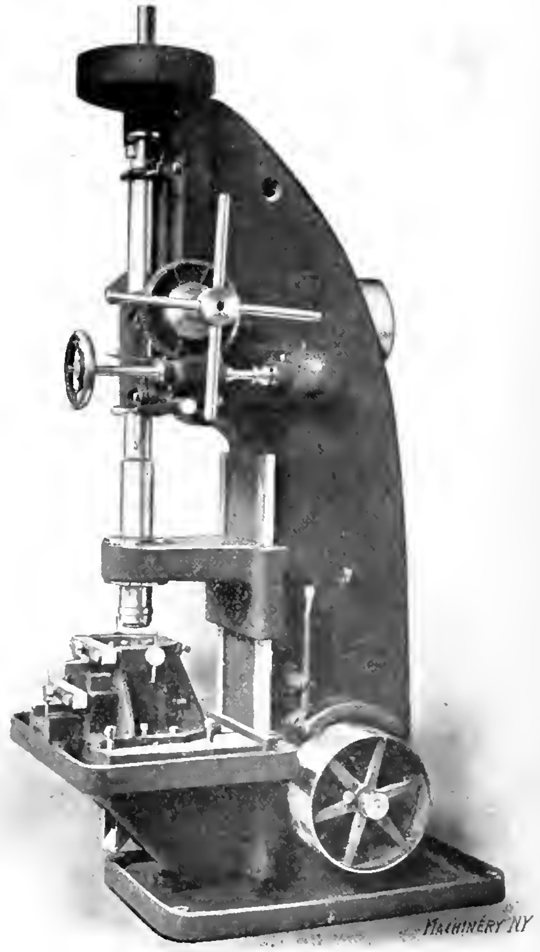

Fig. 2. Side View, showing Single Pulley Drive, Boring Bar Support, etc.

be carried by each spindle, thus materially increasing the capacity of the machine.

P. S. ANROS CO.'S BEAM COMPASS

Every draftsman has experienced the need of a light, convenient beam compass that can be quickly and accurately adjusted and still be rigid enough to insure good work. The P. S. Anros Co. of North Tonawanda, N. Y., have met this demand by putting on the market a very neat and convenient instrument of this kind. It is the acme of simplicity, inex-

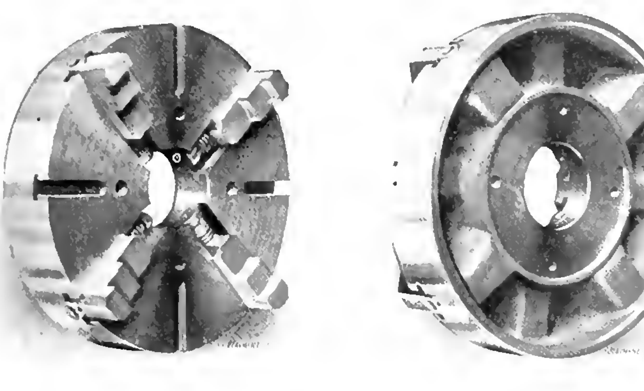
An Inexpensive but Practical Beam Compass

pensive, and at the same time a tool that is thoroughly practical. The construction is such that use is made of the opposite ends of the pen and pencil for the needle points, so that either pen or pencil is instantly available by turning the instrument over. The adjustment of the sliders, which carry the pen and pencil along the beam, is particularly smooth, making it possible to set the compass as accurately as with some of the more expensive instruments. These sliders are simply spring steel bands that fit the wooden beam closely and retain their position by friction. Both pen and pencil are easily adjusted vertically, and they, like the sliders, are held in place by friction. Undoubtedly, draftsmen in need of a beam compass will find this a very handy addition to their set of instruments. The price of the tool is one dollar.

S. E. HORTON FOUR-JAW INDEPENDENT CHUCKS

The S. E. Horton Machine Co., of Windsor Locks, Conn., has entered the chuck field with the line of four-jaw independent chucks herewith illustrated and described. This type of chuck possesses certain advantages for general work. The jaws are reversible by simply running them out and turning them end for end; the independent control of the jaws makes it possible to handle a large variety of rough forgings, castings and pieces of irregular outline; and it permits as well, the truing up of finished work to run with any desired degree of accuracy.

In addition to these general qualifications, this design has special advantages of its own, which fit it to meet the three prime requirements of a good independent chuck—namely, the requirements of strength and gripping power, durability, and workmanship. These advantages are derived largely from the improved proportions given the jaws and screws, as shown in detail in Figs. 5 and 6.



Figs. 1 and 2. Front and Rear Views of the S. E. Horton Four-Jaw Independent Chuck, 18-inch size

The strength and stiffness of the mounting provided for the jaw are shown clearly at the right of Fig. 6. A plain T-slot is cut in the face of the chuck in place of the usual tongued groove construction shown at the left of the engraving. A glance will explain the advantage of this arrangement in the matter of the resistance of the jaw to the lateral thrust (shown by the arrow) imposed on it by the driving of the work. The broad base and liberal bearing surface give, also, unusual strength and long life to the jaws and slides.

A further advantage of this form of jaw is that it permits the use of a screw of unusually large diameter (1¼ inch for the 10-inch chuck and 1½ inch for the 15-inch size). This screw, as shown, has a complete half bearing in the jaw, bringing the tightening strain more nearly in line with the work than the usual construction allows. There is thus less tendency for the jaws to spring away from the work. In addition it should be noted that three bearings are provided for the screw, all of them on turned diameters, no reliance being placed on the threaded surface as a journal. This greatly increases the durability at a point where durability is very necessary. The thrust is so taken up on these bearings as to distribute the strain properly through the chuck body. The shell cannot break out at the end of the screw.

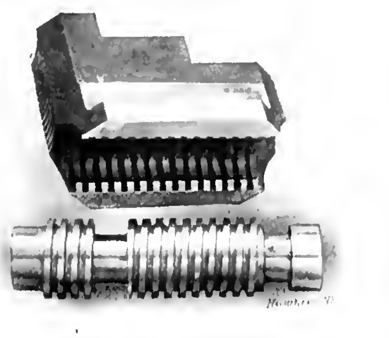


Fig. 5. The Broad Based Jaw and Large Screw

It will be seen that the socket for the wrench is formed in stock of the full root diameter of the thread, thus giving the maximum size and strength at this important point.

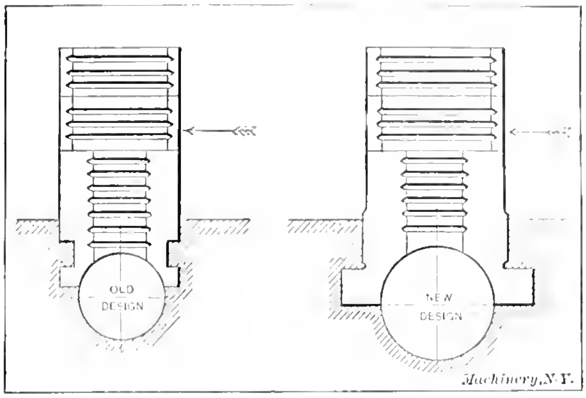

Fig. 6. Comparison of Jaws and Screws in Old and New Designs

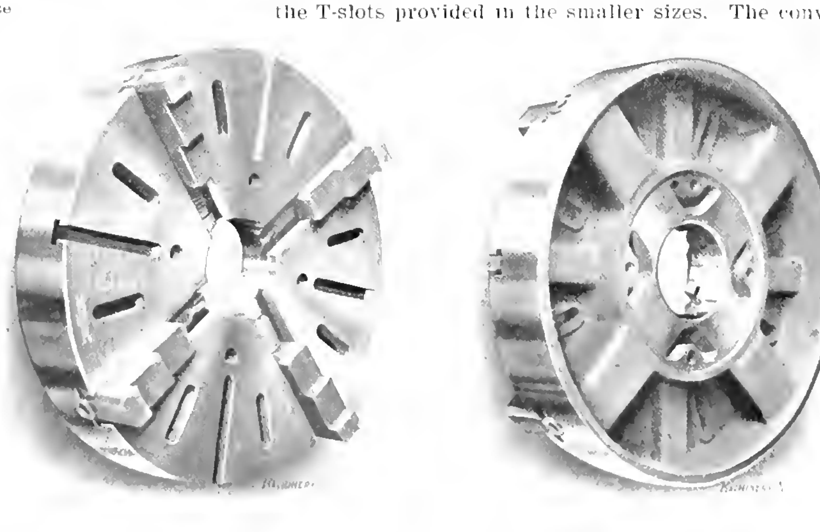
As a result of this increase in the stiffness and durability of the jaw and screw, a much heavier clamping strain can be exerted without danger of breakage or excessive wear. For this reason, wrenches of much greater leverage than usual can be, and are, provided. The construction also permits the extension of the jaws for one-third of their length outside of the body, giving an increased capacity. This extended diameter is 11 inches for the 10-inch size, and 16½ inches for the 15-inch.

Figs. 1 and 2 illustrate front and rear views, respectively, of the 18-inch chuck. The body, it will be seen, is of standard design, but of very heavy and rigid proportions. Chucks from 20 inches up are made in the styles shown in Figs. 3 and 4, being provided with through slots for face-plate clamping, in addition to the T-slots provided in the smaller sizes. The convenience of this on large chucks is well recognized by mechanics. The hole through the body is unusually large. This feature, which is permitted by the improved design, is an advantage in holding work having a large hub; or it may be utilized, if desired, in fastening on the spindle face-plate with the hub projecting inward instead of outward as usual. This method of mounting greatly reduces the over-hang, and gives a corresponding advantage in the matter of stiffness, but the central hole of the chuck is not usually large enough to permit it. The hole through the body of the 10-inch chuck is 2¾ inches in diameter; on the 15-inch size, the diameter of the hole is 4 inches.



Figs. 3 and 4 A Larger Size of the Horton Chuck, with Provision for Using Clamp Bolts

In relation to the matter of workmanship, a study of the illustrations will show that the construction is such that accuracy is easily secured. This line also has the advantage of being designed and made by men who have been in the business for many years, and have become specialists in this work. The regular list covers sizes from 8 to 26 inches inclusive.

HAMMOND WIRE BELT LACING TOOL

A tool of simple construction for making wire hinged joints for leather belts, is shown herewith. It is intended to take the place of the more costly machine for this work. Besides having the advantage of cheapness, it has that of portability. These tools may be kept in the various tool-rooms of an establishment and checked out for bench work the same as drills, clamps, etc., it being convenient to hold them in an ordinary vise as shown in Fig. 1.

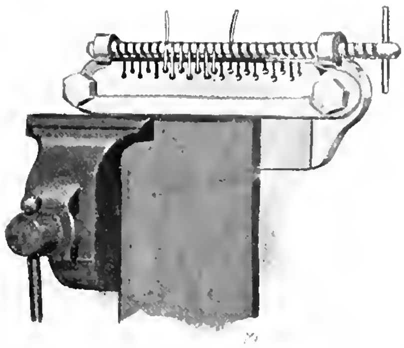


Fig. 1 An Inexpensive and Efficient Wire Belt Lacing Tool

The process of lacing the belt should be obvious from an inspection of the engravings. The threaded guide-rod is inserted in place and the belt (whose end has been squared) is pushed into place between the clamps, being fastened there with its edge resting against the guide-screw. Holes are then punched through the belt with an ordinary awl, the slots cut in the clamping bar serving as a guide. Wires are then threaded through these holes and around the guide-screw, using ordinary pliers for the operation. When the belt has thus been laced, the guide-screw is threaded out of the lacing. After the other end of the belt has been treated in the same manner, the lacings for the two ends are pressed flat in the vise, and then interlocked with each other. A rawhide pivot pressed in between the two, forms the hinge and completes the joint.

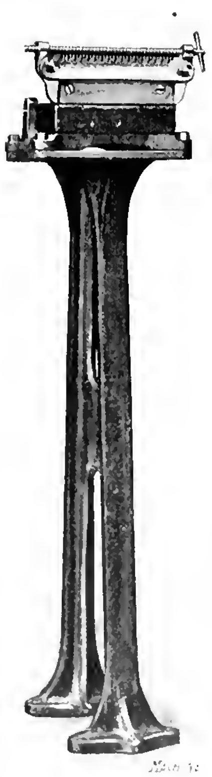

Fig. 2. Tool Mounted on Stand

A belt thus laced is provided with a joint which has a maximum of strength, and a thickness no greater than that of the belt. At the same time, it is flexible enough to run over a very small pulley at high speed. The staggering of the holes greatly increases the efficiency of the joint. There is oftentimes great advantage in lacing a belt away from the machine, in places where such an operation in place would be dangerous or even impossible. A simple insertion of the rawhide pin completes the joint, when the belt is again put in motion.

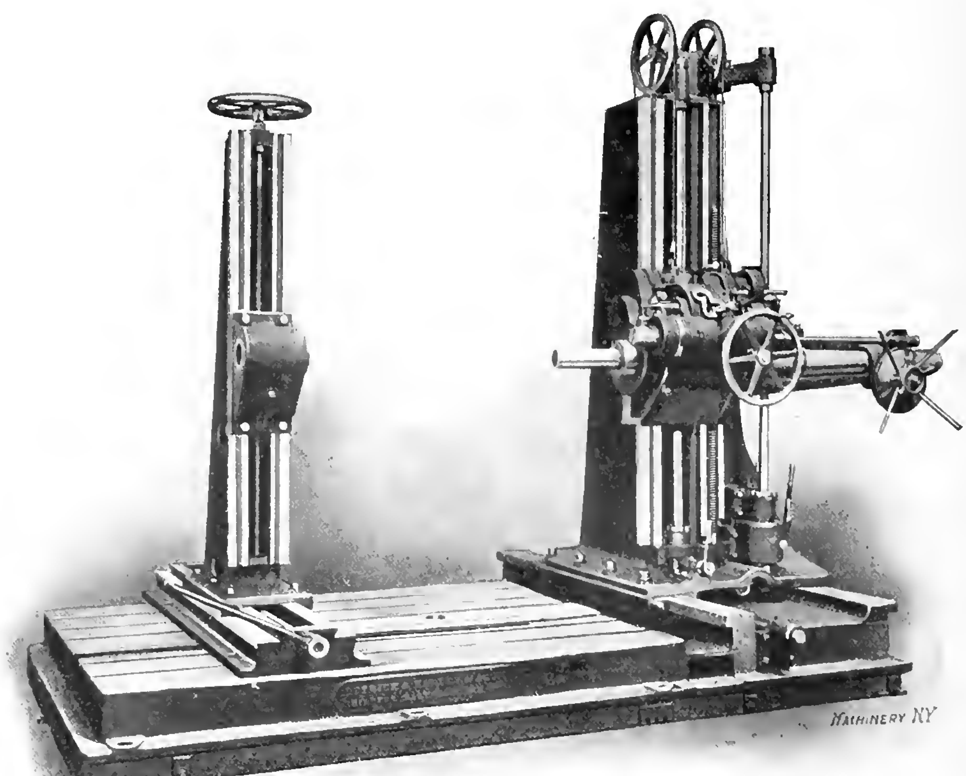
This tool is made by Geo. W. Southwick Co., 35 Warren St., New York. It weighs only three pounds and is sold at a very low price. This tool may be used in a vise, as shown in Fig. 1, or it will be furnished with a stand, as shown in Fig. 2, for use in shops where vises are not employed.

DETRICK & HARVEY NO. 1 HORIZONTAL DRILLING, BORING AND MILLING MACHINE

The accompanying illustration shows a recent design of the horizontal drilling, boring and milling machine made by the Detrick & Harvey Machine Co., of Baltimore, Md. The machine shown is the No. 1 or 50-inch size, so proportioned as to drill and bore anywhere on a surface 50 inches square.

The column is a box section tapered to a broad base, which is gibbed with a sliding fit to the bearing on the runway. This bearing is carefully scraped and guides the column between long narrow surfaces which preserve the alignment with great accuracy. The saddle or head has a vertical movement on the column by hand or by power; the same is true of the column in its movement on the runway. Six changes of power feed are provided in both these movements, of suitable range for milling operations. The bed-plate and length of runway are made in sizes to suit the requirements of the purchaser. Suitable T-slots for clamping the work-table and the outboard boring bar support, are provided.

The steel spindle carried by the saddle is back-geared at the front end, giving a direct drive for heavy face milling operations; the end of the spindle will be threaded if required, for carrying these heavy cutters. A No. 6 Morse taper hole is provided for driving end mills, drills and boring bars. The twelve rates of spindle speed range from 5½ to 125 revolutions per minute. These are controlled by levers on the saddle within convenient reach of the operator. The spindle reverse for tapping is governed by a lever at the bottom of the driving shaft on the column.



New Design of the Detrick & Harvey Horizontal Boring, Drilling and Milling Machine

The following dimensions will give an idea of the capacity of the machine. The spindle has a maximum vertical adjustment on the column of 50 inches, and a standard traverse of the column on the runway of the same amount. The spindle is 4 inches in diameter with a feed of 30 inches. The standard work bed has 50 by 84 inches of surface. With this size

of work bed, the maximum distance from the end of the spindle to the outer support is 61 inches, and the floor space occupied is 12 by 17 feet.

This machine will be furnished if desired with a universal tilting and rotating table by means of which the operator can drill and bore at any angle anywhere on five sides of a cube. This table can be firmly clamped in any position and moved in a direction parallel with the spindle, toward and away from the column. It is provided with T-slots and a central hole. A rotating table without the tilting feature can be furnished when desired.

Other extras which the manufacturers are prepared to furnish are graduated scales for the various adjustments, rotary pump for providing lubricant when drilling on steel, motor drives, etc. The machine will also be furnished without the bed-plate if desired, or for use as a portable machine. It is made in four other sizes to cover the range from 40 to 96 inches maximum capacity of vertical and horizontal movements.

STROMBERG ELECTRIC CHRONOGRAPH

An electric chronograph or time recorder for registering the exact time of the entrance or departure of employes from manufacturing or mercantile establishments, is shown in the illustrations presented herewith. Another model of the chronograph, intended for general office purposes, was illustrated and described in the New Machinery and Tools department of the February, 1909, number. Those who read that description will probably recall that this instrument is a radical departure from the usual time-recording device in that it, together with any number of instruments both for general office and in-and-out recording, can be connected in the same circuit and operated by one master clock, thereby insuring absolute uniformity and agreement. It will thus be seen that all of the clock mechanism is removed from the recorder itself, so that the jar when registering does not in any way affect the delicate mechanism of the controlling timepiece.

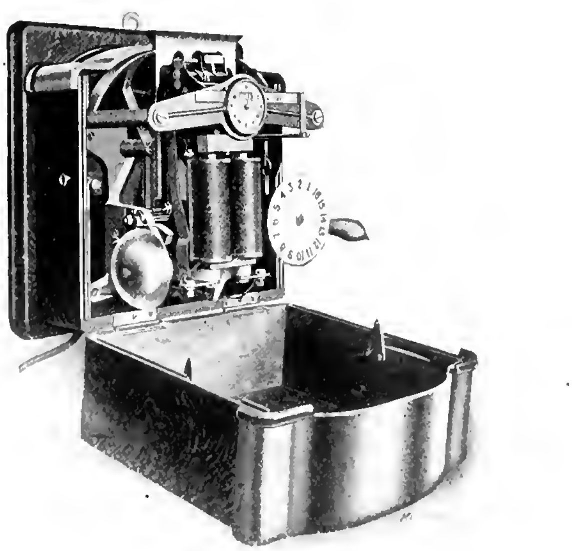


Fig. 1. Stromberg Electric In-and-out Time Recorder Opened to expose Mechanism

Another salient feature of the chronograph is that it prints on the front of the card instead of on the reverse side, as is the case with other makes of in-and-out recorders. It is not necessary to provide a special master clock, as any factory clock equipped with a second hand can be used. The illustration, Fig. 1, shows the interior mechanism of the instrument. The printing wheels and the hand of the dial on the side of the chronograph are moved by a simple magnetic action controlled by a make-and-break device attached to the master clock. Either direct or alternating 110-volt current storage battery or primary batteries may be used to operate the instruments. For alternating current, however, a rectifier, which will be furnished by the company, is necessary to convert the alternating to direct current. The illustration, Fig. 2, shows the chronograph with the time-card cases on either side. The instrument is so made that there are no bolts, screws or other parts exposed, which can be tampered with by a malicious employe. The model for in-and-out recording is fitted with an adjustable gage which insures the recording of time in the proper place on the card, without any manipulation on the part of the operator beyond inserting the card into the chute and depressing the printing arm in the usual manner. When this is done, an exact and indelible record of the time of arrival or departure is accurately recorded. The chronograph is manufactured by the Stromberg Electric Mfg. Co., 108-128 North Jefferson St., Chicago, Ill.

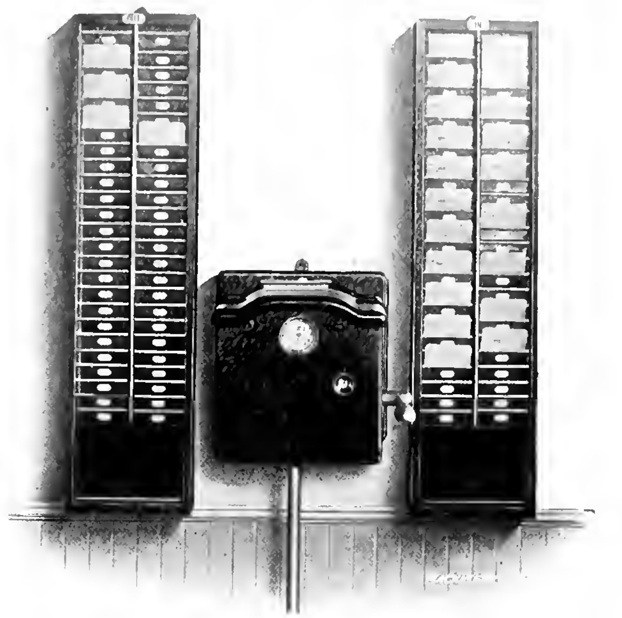

Fig. 2. The Chronograph and the Time-card Filing Cases

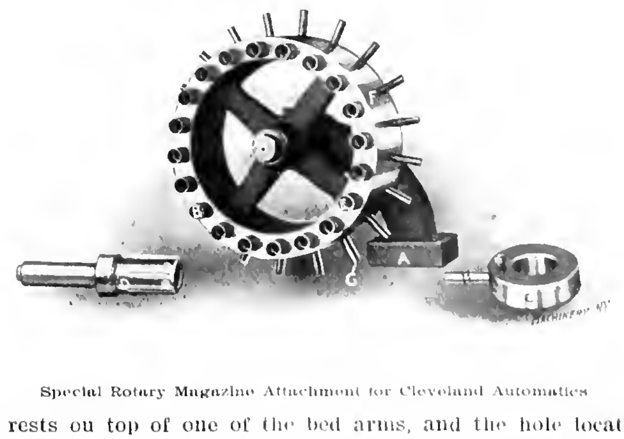
CLEVELAND ROTARY MAGAZINE ATTACHMENT

A special rotary magazine attachment has just been brought out by the Cleveland Automatic Machine Co., Cleveland, Ohio, that is exceedingly simple in its construction and yet, undoubtedly, a most effective piece of mechanism. This is not a regular attachment, but simply a new fixture which has been devised to handle some of the second-operation work which, because of peculiar snapes, cannot be easily handled in a standard tilting magazine. This new drum magazine can be applied to any "Cleveland" automatic, and it is recommended by the company to those having thousands of one-piece to make which are exceptionally large at one end, small in diameter, but long and light.

A view of this magazine is shown in the accompanying illustration. When it is attached to the machine, the bracket *A* rests on top of one of the bed arms, and the hole located in position *B*, is in line with one of the turret holes. The collar *C* fits on the cam-shaft, and a conveyor *D* is held in the turret of the machine. Directly back of the hole in position *E*, there is a spring plunger which enters the rear of the hole at this point and serves to hold the drum rigidly with



Special Rotary Magazine Attachment for Cleveland Automatics

the supporting bracket *A*. This plunger, however, allows drum *F* to be indexed to the next hole when pressure is applied to one of the pins projecting from the periphery of the drum.

In operation, the pieces of work are placed in the bushings which are inserted in the face of the drum *F*. When the conveyor is carried forward by the turret, it removes the piece from bushing *B*, and when the turret recedes, the pin *H* in the collar *C* engages pin *G*, thus indexing the drum to the next position. When this magazine is attached to an automatic it is simply necessary to keep it filled with work, and one man or boy can easily attend to six machines. As is evident, the mechanism is exceedingly simple, and this is always a reliable guarantee against trouble of any kind.

PRYIBIL SELF-BALANCING ELLIPTICAL CHUCK

The elliptical chuck is an old piece of apparatus, made in a number of different designs by different manufacturers. It finds a limited application in machine work, and a more extensive one in wood-working and metal spinning. In woodworking it is used for such operations as the turning of oval picture and mirror frames, ornamentations, etc.; the large variety of elliptical and oval shapes in sheet metal requires its use for metal spinning. These more common uses of the device require high speeds. In this respect the elliptical chuck has hitherto been defective, owing to the fact that the

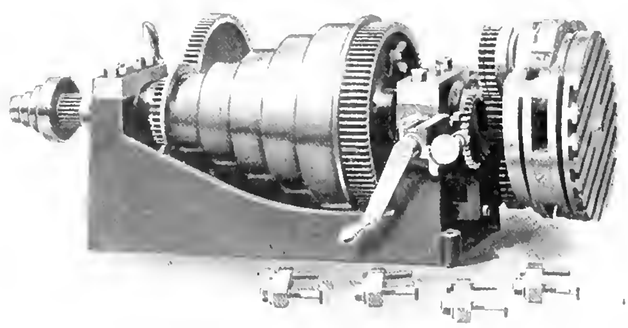


Fig. 1. Pryibil Self-balancing Chuck, adapted to Heavy Work

reciprocating parts are unbalanced, causing excessive and dangerous vibration if it were attempted to run at a rate of speed such as would be used for circular work of a corresponding character. In the chuck herewith illustrated and described, made by P. Pryibil, 512-524 West 41st St., New York City, the reciprocating parts have been balanced so that the

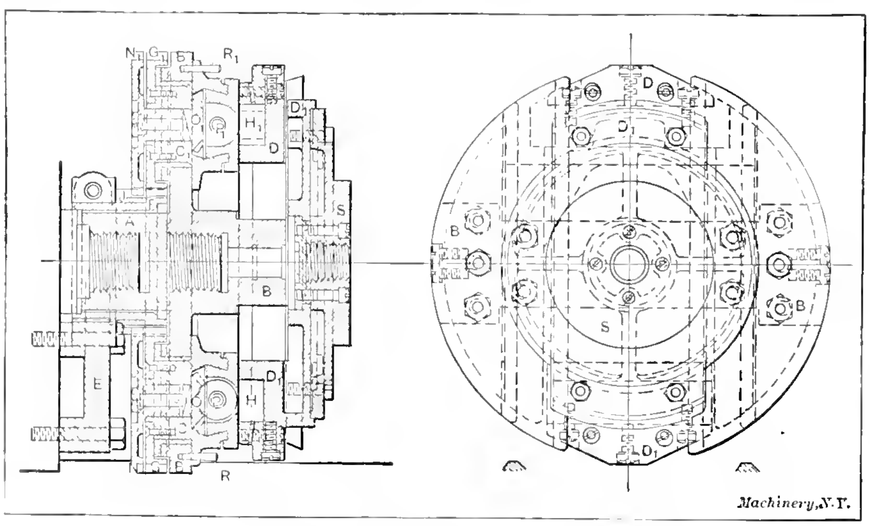

Fig. 2. Section and Face View of Chuck, showing Construction

chuck can run smoothly at high speeds. This greatly increases its capacity, giving a large return in product per hour of work, for the extra mechanism employed.

Fig. 1 shows the heavier form of chuck used for metal turning, attached to an engine lathe head-stock; Figs. 2 and 3 show details of the construction. A false nose *A* is screwed onto the lathe spindle to extend the latter sufficiently to bring the chuck clear of the head-stock. Screwed onto this false nose, and therefore revolving with the spindle, is the main frame *B* of the chuck. This main frame is in the form of a cross

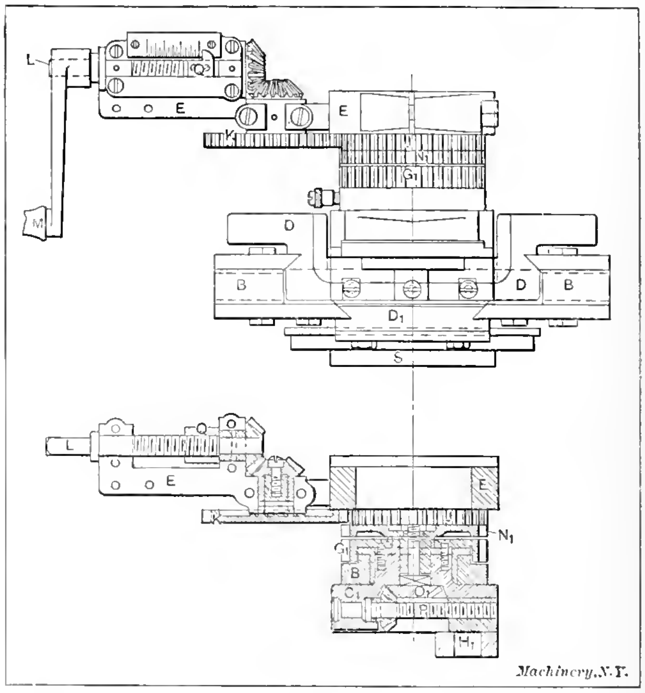

Fig. 3. Top View and Section through Adjusting Mechanism

arm (this construction is not very clearly shown in the engravings) whose vertical arms carry bearings for revolving cranks at *C* and C_1, while the horizontal arms, seen in Fig. 3, are provided with gibs for the two reciprocating slides, one in back at *D* and the other in front at D_1.

The bracket *E*, bolted to the face of the head-stock, has keyed to it a spur gear *F*, concentric with the spindle. Cranks *C* and C_1 have screwed and doweled to them gears *G* and G_1, meshing with this gear *F*. Crank pins at *H* and H_1 (so mounted in cranks *C* and C_1 as to give an adjustable stroke as will be described) are pivoted in square blocks fitted to slots in slides *D* and D_1. It will thus be seen that, as the spindle of the lathe, false nose *A*, and body *B* revolve together, gears *G* and G_1 will roll around on stationary gear *F*, revolving cranks *C* and C_1, and thus causing, through crank pins *H* and H_1, the reciprocating of slides *D* and D_1. Slide D_1 travels back and forth across the face of the chuck, carrying the work, which thus receives a proper movement for elliptical turning. Slide *D*, on the other hand, on the backside of the chuck, moves always in opposite directions to slide D_1. Owing to the fact that these two slides are practically equal in weight, they balance each other in their movement, and permit the rotating of the chuck at a high rate of speed. This is the important innovation in the design.

Adjustments are provided for all the important sliding bearings, such as those for slides *D* and D_1 in body *B*, and for the squared blocks *H* and H_1 in slide *C*. The face-plate *S*, which is mounted on slide D_1 can be rotated and clamped in any position to bring the major axis of the ellipse in any required relation with the work being operated on.

There is another feature which adds greatly to the usefulness of this tool—the provision made for adjusting the eccentricity of the movement while the chuck is revolving. By this means, the difference between the major and minor axes of the ellipse being turned, can be adjusted as required, without stopping the work and without measurement. On the hub of stationary gear *F* is mounted a gear *J* (see Fig. 3), mesh-

ing with a gear K, having a bearing in bracket E. Bevel gears connect this with a shaft and crank L and M, by means of which gear J may be revolved. Gears N and N_1, which also mesh with J, are keyed to bevel gears O and O_1, which in turn operate adjusting screws P and P_1, which are threaded into the adjustable crank pins H and H_1.

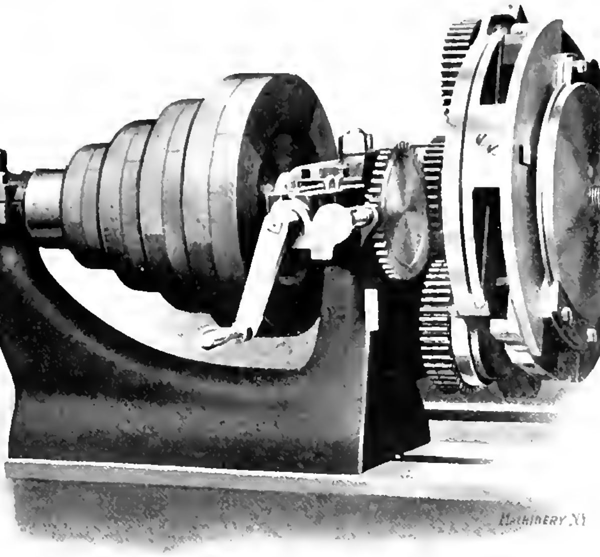

Fig. 4. Lighter Design of Chuck, used for Wood Working and Metal Spinning

It will be seen that with J and F both fixed in position, gears N and G, and N_1 and G_1, will rotate together without any movement relative to each other, so that the adjusting screws P and P_1 will be stationary and the adjustment of crank pins H and H_1 will remain unchanged. When, however, gear J is revolved by crank M, N is moved with reference to G, and N_1 with reference to G_1, so that adjusting screws P and P_1 are rotated and the throw of crank pins H and H_1 is increased or diminished. By this means the difference between the major and minor axes of the ellipse being turned is increased or diminished at will. As may be plainly seen, it makes no difference whether or not the machine is running, for while gears N and G are running around gears J and F, the adjustment can be made either way.

Adjusting shaft L is threaded and is provided with a nut Q, having an index finger reading the amount of eccentricity on a fixed scale. This is a great convenience in setting up the

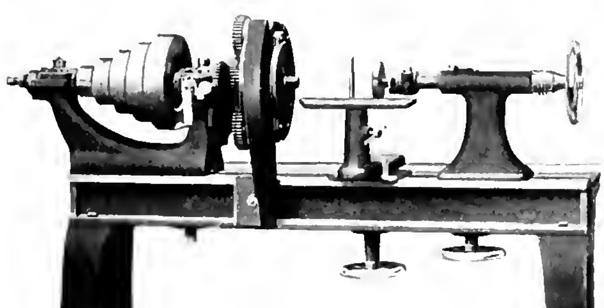

Fig. 5. Elliptical Chuck mounted on Spinning Lathe

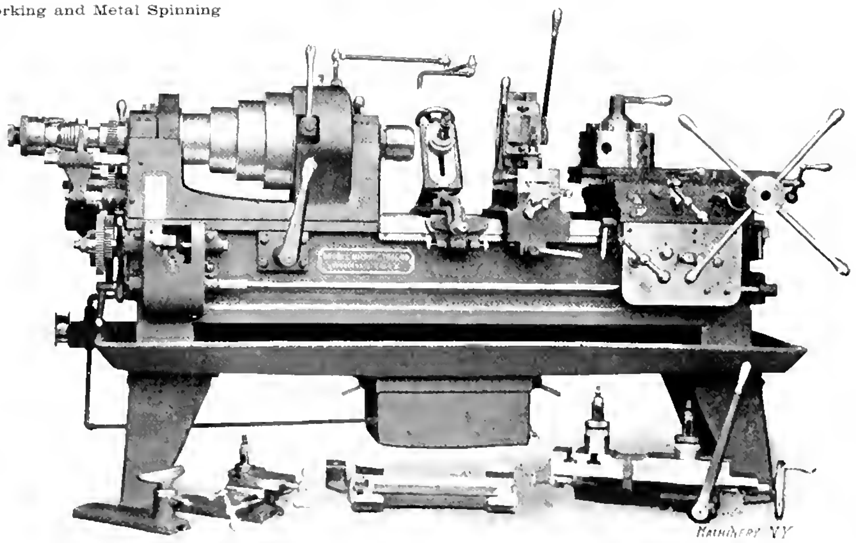
device. To insure the proper relation of all the parts when the chuck is removed from the work, taper pins R and R_1 (see Fig. 2) are inserted to lock the cranks in position. This insures the proper action of the chuck when it is again mounted in place on the machine.

Fig. 4 shows a larger and lighter form of this fixture, operating on the same principle used for wood work and metal spinning. It will be noticed in both Figs. 1 and 4 that a positive means of locking is provided, by a bolt entering the spaces between the teeth of gear K, so that no accidental change of adjustment is possible. In Fig. 5, this interesting device is shown attached to a metal spinning lathe, provided with a proper guard for protecting the workman from the mechanism.

DRESES 20-INCH FULL UNIVERSAL "MONITOR" LATHE

The "Monitor" lathe herewith illustrated and described is built by the Dreses Machine Tool Co., Cincinnati, O. It is designed for general brass and similar work of a heavy character, made from castings, forgings and stock. It is provided with such adjustments as make it possible to manufacture, without special tools, many pieces for which it would not pay to equip the ordinary machine of this type.

The turret carriage feed mechanism is similar in design to that of the standard engine lathe. A positive geared feed is provided, with a quick gear change box, giving eight variations.



A Monitor Lathe with Universal Adjustments for a Wide Range of Work

These changes cover the ordinary standard pipe threads, as well as giving suitable turning and boring feeds. Provision is made for obtaining other feeds and pitches by the use of change gears.

The turret slide is in two parts, with a taper dove-tail plate interposed, on the lower side of which is carried a shoe swivel sliding on the bar of the taper attachment. The latter is shown dismounted from the machine, lying on the floor under the center of the bed. This, when in use, slides on the inside of the bed and is held in place by a suitable clamping bolt. It can be readily removed and no special provisions are necessary in the design of the bed for holding it. By its use, inside or outside, taper or straight threads, can be chased by a tool in the turret without the use of a tap or die.

The upper section of the intermediate dove-tail plate has a screw with a ball crank for cross feeding by hand. Positive stops are provided for setting the turret holes in alignment with the spindle. The turret slide is provided with a pilot wheel for rapid movement, and with a screw for finer adjustments. The pilot wheel may be removed from its stem so as to be out of the way when the screw feed is in constant use. The turret is adjustable for wear on its seat. The locking bolt withdraws at the return movement of the top slide, making the rotation of the turret semi-automatic.

The head-stock is provided with carefully enclosed friction

back gears, with clutches of the toggle joint type, so designed that the whole operating mechanism can be put in place or removed without taking out the spindle. The automatic chuck is operated with the handle shown below the cone pulley.

Various forms of cross-slides, rests, etc., are provided, as shown in the illustration, fitting the machine for a wide range of work. The chasing bar has a yielding follower holder, which maintains contact with the leader when chasing taper work. The taper attachment for the chasing bar is provided with knurled screws for minute adjustment. A vertical forming rest is also shown in place on the bed. The cutting-off rest is shown on the floor at the right, and hand and slide rests at the left. The taper attachment has already been mentioned.

This lathe is furnished with a pan, oil reservoir, pump and piping, adapting it for iron and steel as well as brass. It swings $20\frac{1}{2}$ inches over the V's, has a bed 6 feet 6 inches long, and weighs about 3,600 pounds.

CUTTER GRINDING HEAD FOR B. & S. UNIVERSAL GRINDING MACHINES

The cutter holding head and its attachments, shown herewith, is made by the Brown & Sharpe Mfg. Co., of Providence, R. I. It is similar in design to the corresponding parts pro-

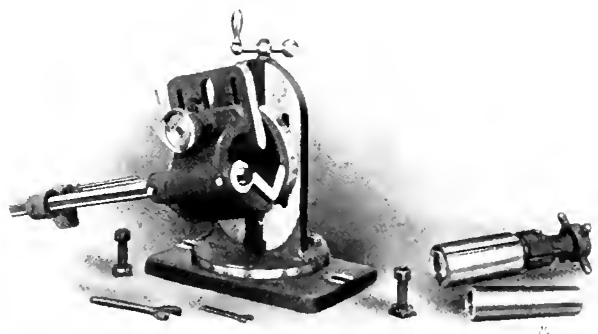


Fig. 1. Universal Cutter Sharpening Head and Equipment

vided for their No. 13 universal and tool grinding machine, but is arranged to be used on any of the universal grinding machines made by the builders. The device should, therefore, prove a great convenience in shops whose requirements are so small as to make the purchase of a special cutter and reamer grinding machine inadvisable, but whose management still desires to obtain the benefit of the economical production only possible with milling cutters kept in proper cutting condition.

The attachment consists principally of a swivel vertical column, upon the slide of which a swivel head for supporting

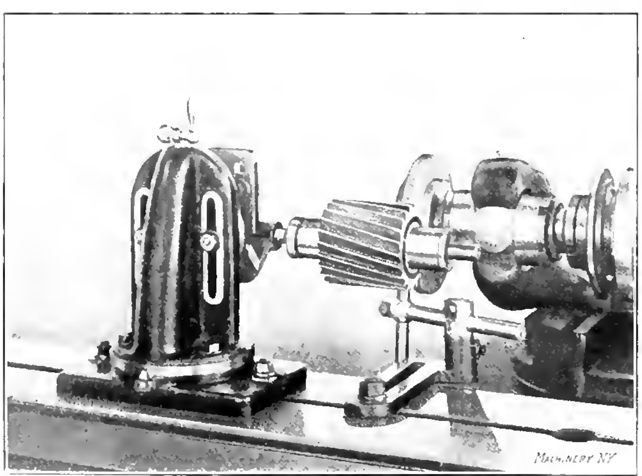

Fig. 2. Spiral Milling Cutter being sharpened on Cutter Bar

the work is fastened. The vertical column is mounted on the base-plate which, in turn, is securely fastened to the table by means of a clamping bolt at each end, passing through slots in the base casting.

The base plate is of solid construction and has a large bearing surface upon the table, thus insuring a rigid support for the vertical column. It is made in two styles, one of which has a tongue on the under side to fit the T-slot in the table of universal machines; the other has a longitudinal V-way that fits over a way of like design on the table of the No. 13

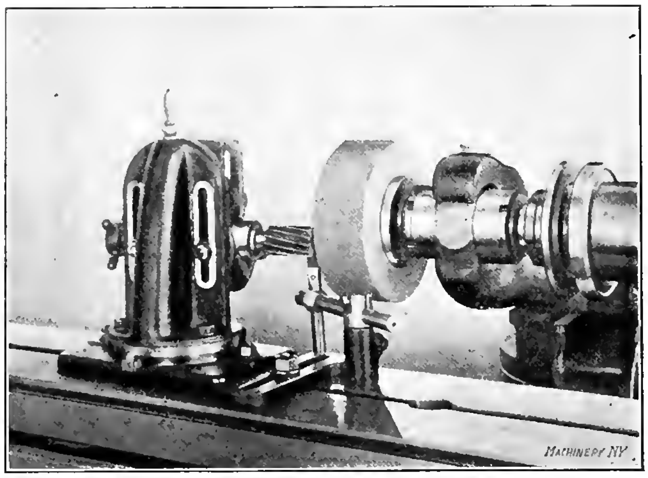

Fig. 3. The Taper Shank Mill Sleeve in Use

universal and tool grinding machine. In either case the alignment of the head, with relation to that of the table, is correctly and simply maintained. The column swivels in a horizontal plane and may be set at any angle with the table. A dial graduated to degrees, encircling the entire circumference of the base, facilitates quick adjustment to any desired angle. Two bolts, which pass through the base and slide in circular slots in the base plate, serve to securely clamp the column.

In the convenience and adaptability of the work head are found the features of the attachment. It is simply and compactly constructed and has a large bearing surface on the vertical column, thus making it fully capable of resisting vibrations due to the action of the wheel on any work within

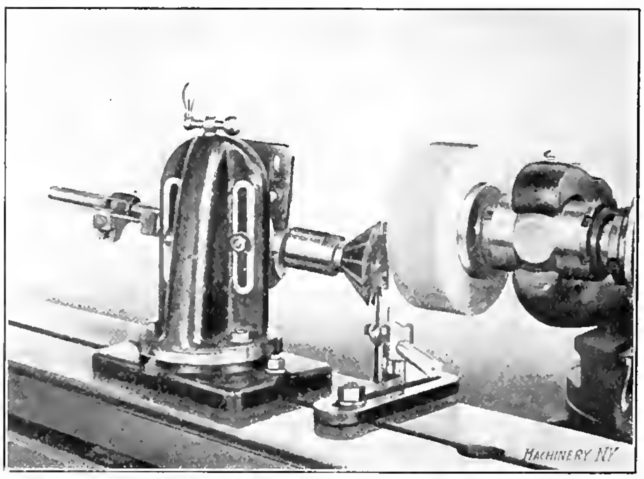

Fig. 4 Grinding the End Teeth of an Angular Cutter, supported in the Vise

the range of the attachment. The head swivels in a vertical plane and may be clamped at any angle up to 90 degrees either side of zero, its position being indicated by a dial graduated to degrees on the circumference of the base. The clamping bolts pass through circular slots in the head casting and vertical slots in that of the column. Provision is made for a vertical adjustment of 4 inches, by means of a ball crank at the top of the elevating screw. With the head at its extreme height, work up to 16 inches in diameter will swing over the table; by turning the head at right angles, light work up to 24 inches in diameter can be accommodated.

Two methods of holding work are provided; milling cutters being clamped directly by their shanks or arbors in a V-shaped vise, while work requiring sliding shells is supported on a rod known as the cutter bar. The vise is rigid and readily adaptable to many varieties of work. The lower jaw consists of a heavy V-shaped trough in which the shank or arbor of the work is placed. The upper jaw pivots, and is adjusted by

means of a hand clamp screw. A long drop-back rest is carried by the upper jaw. To fasten work, this rest is lowered until it touches the piece and is clamped in this position. Then, by simply adjusting the hand clamp wheel the drop back rest is securely fastened upon the piece. An adjustable center rod is provided for supporting and taking the end thrust of work having a tapered shank; it may also be used for taking the end thrust of centered pieces that are not clamped solidly in the vise while grinding.

The cutter bar is made of steel, ¾ inch in diameter, and has a flat side for clamping screws to seat upon without injuring the working surface. It is supported in bearings in the work head casting and, in addition to holding work to be ground, serves as an arbor for the upper portion of the vise to pivot upon. It can be adjusted to any length and clamped by means of set screws. An additional cutter bar ⅝ inch in diameter can be furnished when so desired.

A device known as a taper shank mill sleeve is furnished with the universal head and is particularly useful in grinding work having taper shanks, such as end mills, etc. It consists of an outer sleeve that can be rigidly clamped in the vise, and a taper bushing in which the work is held. The bushing is free to turn in the sleeve, but is held positively against the end of the sleeve by a spring. A handle fastened to the outer end of the bushing serves to hold the work against the tooth rest as well as for indexing. Two taper bushings are furnished with the attachment; one No. 7 and the other No. 9.

By the employment of this device, it will be seen, reamers, milling cutters, counterbores, countersinks and a large variety of other cutting tools can be quickly and accurately sharpened. The attachment is simple in design, convenient in operation, and is easily removed and placed in position.

COLBURN FLOATING REAMER HOLDER

The tool herewith illustrated and described is intended for holding reamers in turret machines, particularly vertical boring and turning machines with turret heads, when it is necessary to so support the reamer that it will find its own center in the work. In other words, the tool is a floating holder. It is impossible to depend on having the turret near enough in line or the reamer straight enough to permit holding it rigidly for a power operation. Floating reamer holders

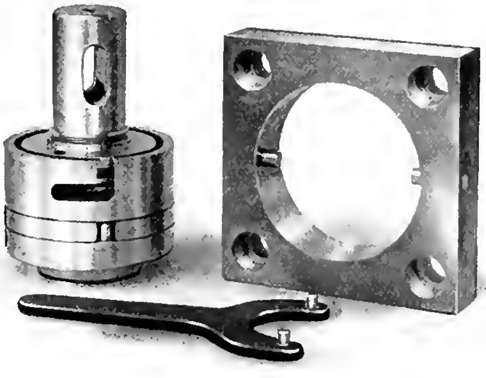

Fig. 1. Colburn Floating Reamer Holder

have been made for many years in individual shops for home use. The design here described is intended to make a commercial product of the device, the object being to provide a construction which would be thoroughly practical and satisfactory in every particular, and which could at the same time be readily adapted to machines of any make.

In Fig. 1 the tool is shown assembled; Fig. 2 shows it separated into its component parts; Fig. 3 shows it in use in the machine, and Fig. 4 is a detailed drawing. The construction of the tool will perhaps be best understood by referring to Figs. 2 and 4.

The reamer, which may be of the solid or shell, adjustable or non-adjustable styles, is mounted by its taper shank in socket E. The latter is driven from sleeve C by a universal coupling arrangement. This consists of a collar F, interposed between C and E, and provided with slots closely engaging pins G which are fast in E, and pins G_1 which are fast in C. E and the reamer which it contains are thus allowed to find their own centers with relation to the work, there being no cylindrical fit between socket E and sleeve C. At the same time a strong and direct drive is provided. This coupling will be seen to be an interesting use of a well-known mechanical principle. To keep the faces of C, F and E tightly pressed

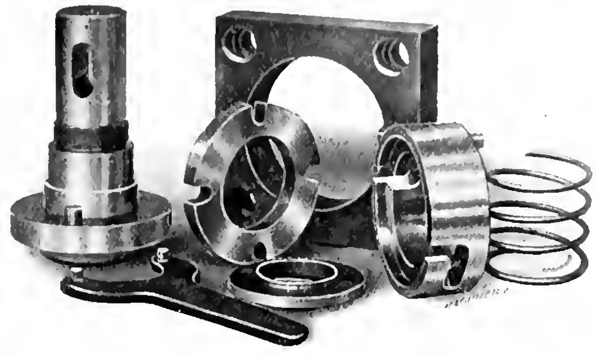

Fig. 2. Reamer Holder separated into its Component Parts

together, nut I is threaded onto the socket, compressing spring H against its seat in C. The spring may be adjusted to be strong enough to overcome the weight of the reamer and its shank, and to keep the parts of the holder tightly pressed together.

The socket and sleeve are held in a base A by a bayonet lock arrangement, which permits their instantaneous insertion or removal, as may be required. The bayonet grooves

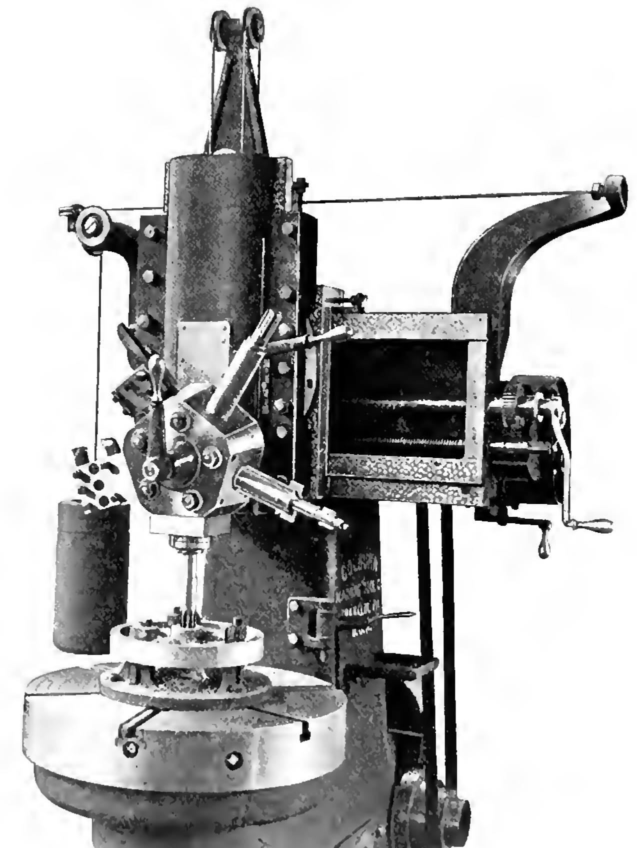

Fig. 3. Reamer Holder in Use in Vertical Boring Mill

are formed in sleeve C, and they are engaged by pins B driven into A as clearly shown in the engraving. Base A is the only member which has to be fitted to the turret; this will be provided by the makers, the Colburn Machine Tool Co., Franklin, Pa., for any dimensions to agree with the machine on which it is to be used.

The advantage of this device may be summed up as follows. It is a commercial product made on a manufacturing basis after a carefully thought out design, instead of being a home-

made and make-shift contrivance. It will fit any make or style of reamer, it only being necessary to provide a shank having the usual Morse taper. It can be used on any make or style of boring mill having a turret with flat sides. It will hold the reamer parallel with the axis of rotation at the same time that it permits it to center itself.

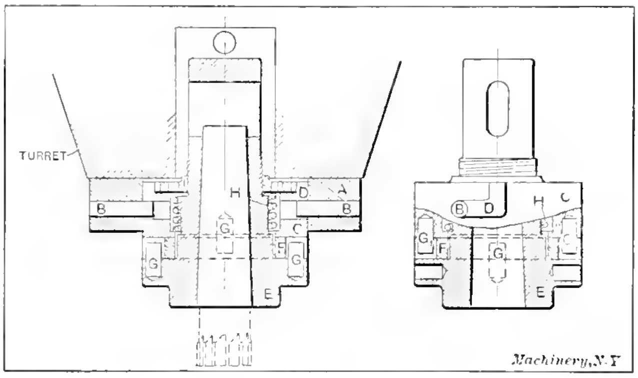

Fig. 4. Details of the Construction

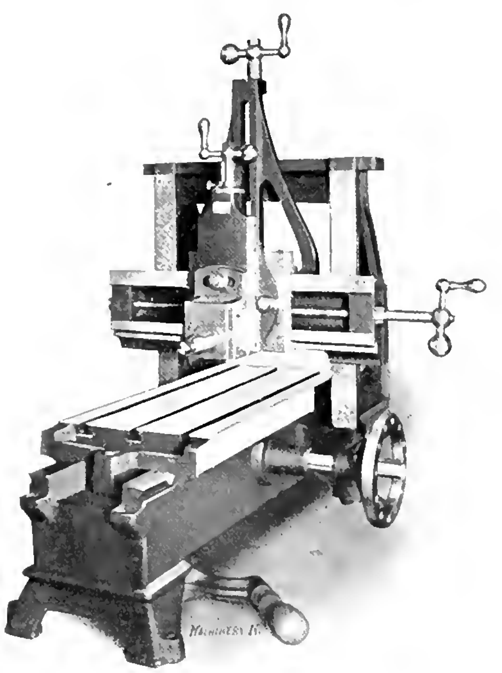
These holders are made in two sizes. The No. 1 has a No. 4 Morse taper socket capable of holding reamers up to 3 inches in diameter; the No. 2 size has a No. 5 Morse taper socket, and will carry reamers up to 4 inches in diameter.

SCHNEIDER HAND-OPERATED METAL PLANER

The illustration shows a metal planer of small size, built by the Schneider Machine Tool Co., 20 East 9th St., Cincinnati, O. This planer is built for hand-operation only, so is especially fitted for model, experimental and tool work.

The illustration shows that the machine is built on the general lines of the heavier power-driven planers. It is provided with a modification of the cross-rail elevating mechanism, however, which is more appropriate to a machine of this size. A slide or frame attached to the back side of the cross-rail extends upward above the top of the housings, where it forms a bearing for a single elevating screw. A slot cut in this frame is guided by a bearing block attached to the housing tie-piece. By this means the rail is kept accurately in alignment with the surface of the table even though but one screw is used instead of two as usual.



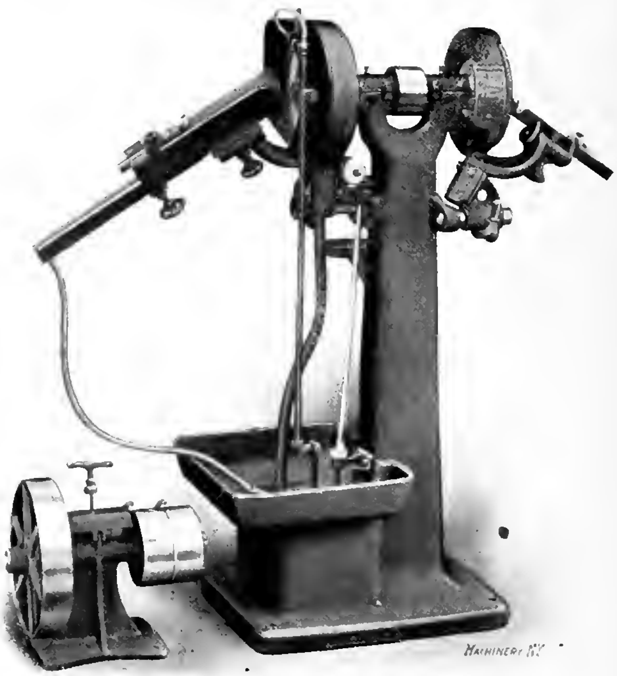
Hand-operated Planer for Tool, Model and Experimental Work

A rack and gear are used as in larger planers for reciprocating the table; the gear is mounted directly on the shaft to which the hand-crank is attached. The hand-wheel on this shaft, as shown, is provided with a series of holes into any one of which a locating pin on the crank may be inserted, thus permitting the latter to be set in any position that is convenient for the cut on the table. It also permits rapid change in position whenever required by the work.

The machine is substantially built to secure the stiffness required for accurate work. The bed has flat ways and is provided with oil channels and pockets to prevent the lubricant from running down outside or inside of the bed. The table takes in 10 inches between the housings, and 8½ inches under the cross-rail. The rack is 24 inches long. An automatic cross-feed will be furnished if desired.

IMPROVEMENTS IN THE "YANKEE" DRILL GRINDER

An improved "Yankee" drill grinder has lately been placed on the market by the Wilmarth & Morman Co., 580 Canal St., Grand Rapids, Mich. Some difficulty has been experienced in previous constructions in regard to the handling of small drills in a holder of sufficient capacity to take care of the large sizes of drills which are in more common use. In the machine now placed on the market this difficulty has been eliminated, and the machine combines a capacity for handling



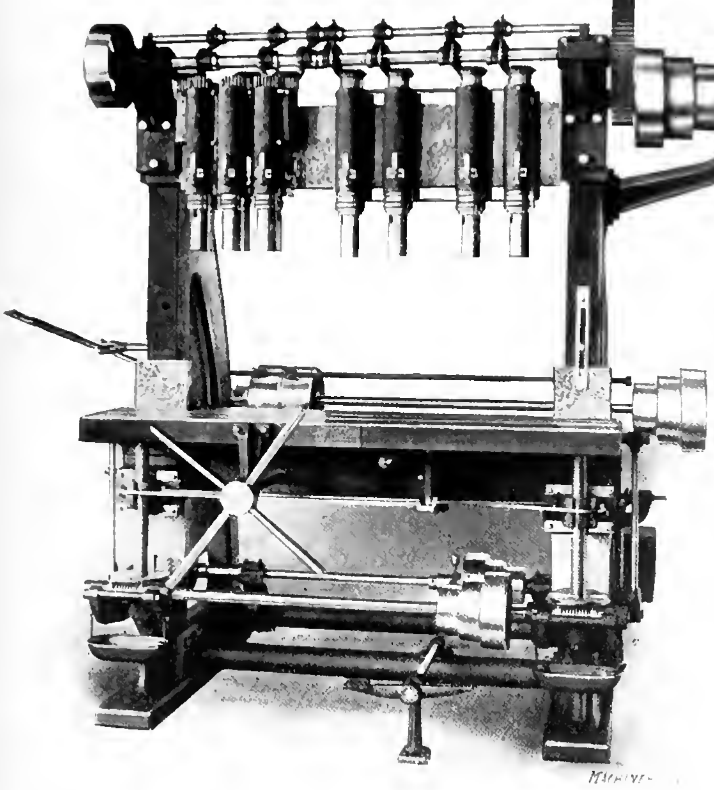
"New Yankee" Drill Grinder with Improved Drill Holder for Smaller Sizes; built by the Wilmarth & Morman Co., Grand Rapids, Mich.

large sized drills with the greatest convenience in grinding small drills. A large holder is furnished for wet grinding of large drills, having a maximum normal capacity for 2¼-inch diameter drills with a minimum capacity for ⅛-inch drills. A smaller holder, however, is also provided in which, with greatly increased convenience, drills from a maximum of ⅝-inch diameter down to a minimum of No. 60 drill gage size can be ground. A finer grade of emery wheel is provided for the smaller drills, and, as seen in the accompanying illustration, two operators can be working, one on each of the two holders, without interfering with each other. Both holders embody the regular "New Yankee" construction, by which the time-consuming preliminary adjustments are avoided by means of the angle of the V-shaped groove or trough which automatically locates each different size of drill in the right position for grinding.

The clearance can be adjusted when required, so as to provide for either the small amount of clearance desirable for working in hard steel, or the much greater clearance necessary for drilling softer metals. The normal clearance, however, is maintained for drills of different sizes for ordinary service, without any adjustment being required on the part of the operator. The machine shown in the accompanying engraving is designated by the makers as the style "WPL." Its general design, outside of the features referred to, is entirely along the same lines as that of the well-known regular type of the "New Yankee" drill grinders.

ANDREW AUTOMATIC CYLINDER BORING MACHINE

M. L. Andrew & Co., of Cincinnati, O., make a multiple drill of the double housing and cross-rail type, which we have before illustrated in a variety of designs for a variety of applications. (See, for instance, the department of New Machinery



Andrew Multiple Spindle Drill Modified for Cylinder Boring

and Tools in the November, 1907, and the April and November, 1908, numbers of MACHINERY.) Still another modification of this machine is herewith illustrated.

This particular design is intended for the boring operations on automobile cylinders. The multiple spindles are divided into two groups. The three shown at the left are permanently gibbed and bolted to the cross-rail, in such a position that they can bore the four valve seat chambers and the two spark plug holes, in the time required to finish one hole on the single-spindle machine. The four spindles at the right of the cross-rail are gibbed to the rail, but are adjustable on their mounting. In the arrangement shown, they are tied together by gages at the top and bottom to preserve definite center distance. These may be used for boring the cylinders themselves, or for boring angle holes for cylinder plugs.
